A sectional view of this magnet is shown in Fig. 3. Its principle of operation is the taking advantage of the end pull on a polyphase induction motor when the rotor is axially shifted out of line with the stator. This characteristic everyone is familiar with, and it is also generally known that the synchronous rotating magnetic field of such a motor is always constant.

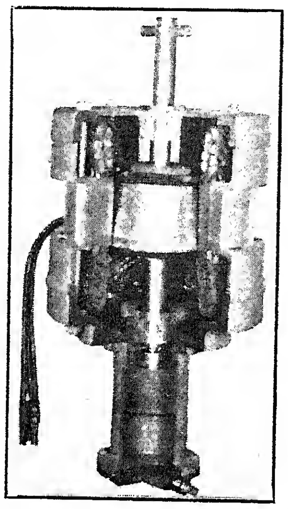

Fig. 3—Non-Sealing A-C. Brake Magnet

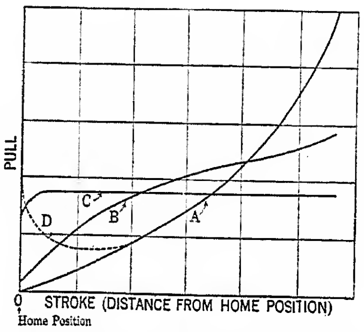

Fig. 4—Characteristic Curves of A-C. Magnets

Curves A, B, and C are for the rotating-field type of magnet. Curve A is for a cylindrical coil. Curves B and C are for tapered cores, Curve C being the most desirable design. Curve D is a characteristic of the ordinary a-c. magnet.

Now if only the rotor iron is used with no closed winding on the rotor, there will be little rotative action but the end pull action remains the same, and its value will be absolutely steady and entirely free from a cyclic vibration.

With a laminated core having a surface parallel to the axis, the end pull curve characteristic is as shown by curve A in Fig. 4. The abscissa of this curve is shown as inches of stroke or movement from the home position, shown at zero, with the extreme right hand end showing the position at which the core is about to leave the stator. The ordinates are shown as the end pull in pounds necessary to maintain any particular position or stroke.

It was found that the core surface can be tapered slightly and produce curve B and by a different tapering to produce a curve similar to C which was the desired characteristic curve for this particular application.

It should be remembered that other types of a-c. reciprocating magnets have a characteristic pull curve similar to curve A except that the lower or home position will follow curve D. With this it is seen that the magnet could not be required to operate and hold more than the lowest point of curve D and with the maximum as shown by curve A it inherently produces the violent action of a-c. magnets so familiar to electrical engineers.

Test Records

The following test records were taken at random from files and it is hoped they will prove of interest.

Figs. 5, 6, and 7 were traced from tests made by one of the largest power companies and are of an elevator rated for 1500-lb. capacity at 425 ft. per min. The

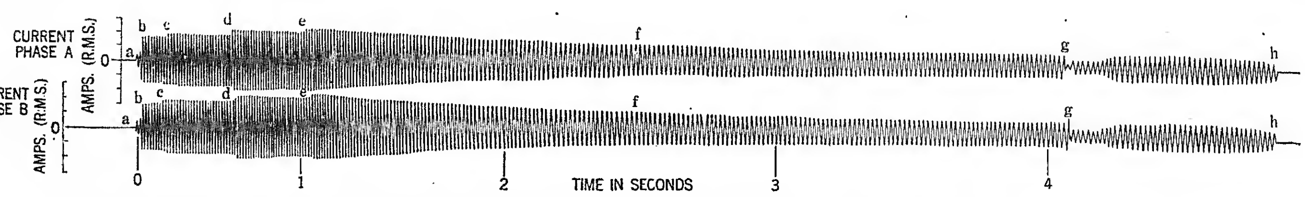

Fig. 5—Oscillogram Showing Current in A-C. Elevator Motor, Starting, Running, and Stopping

Taken on an elevator rated 1500 lb. at 425 ft. per min, with a two-phase, 220-volt motor having 3:1 speed ratio. The elevator was run from the third to the fifth floor with 1000 lb. in the car. At a the motor was started on its low-speed connection. At b it was transferred to the high-speed connection. Positions c, d, and e show respectively the closing of the first, second, and third accelerating switches. At f the elevator is in full speed. Position g shows the transfer to low-speed connection and h shows the disconnection for stopping.

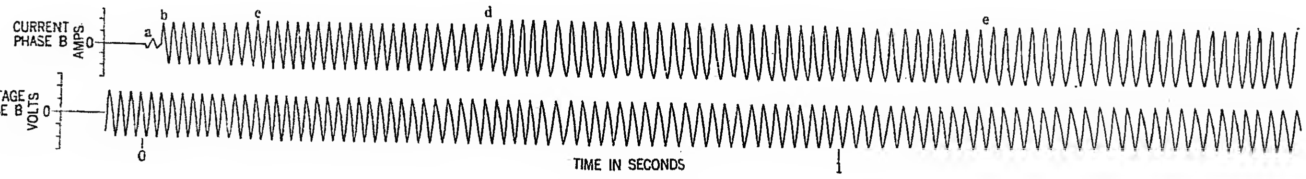

Fig. 6—Oscillograms Showing Elevator Operation with Overload

The conditions are the same as those in Fig. 5 except that the car carried 2000 lb., an overload of 33 per cent.

motor is a 3:1 speed ratio, 220 volts, two-phase. Fig. 5 is an oscillogram showing the amperes in each phase with time in seconds as abscissa. In this particular operation the elevator was run from the third to the fifth floor with 1000 lb. in the car. Starting from the left at zero time, position *a*, the motor was connected

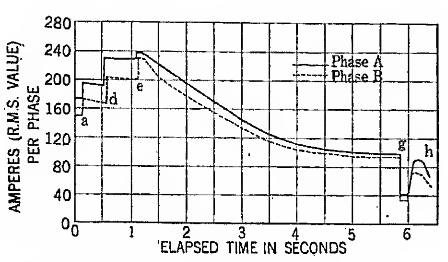

FIG. 7—CURRENT CURVES OF ELEVATOR LIFTING OVERLOAD
The load is 2000 lb. The points *c*, *d*, *e*, *g*, and *h* correspond to similar points in Figs. 5 and 6.

for its low speed. Position *b* shows the current on transferring to the high-speed connection. Position *c* shows the closing of the first accelerating switch. Positions *d* and *e* show the closing of the second and third accelerating switches. Position *f* shows that the elevator has attained approximately full running speed and that this has taken place in 2½ sec. Position *g* shows the transfer to low speed for slowing down or stopping and position *h* shows the point where motor was disconnected for stopping, thus completing a two-floor travel in less than five sec.

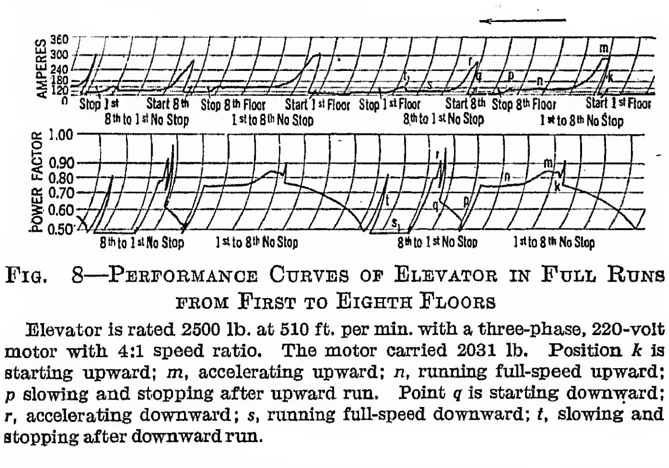

FIG. 8—PERFORMANCE CURVES OF ELEVATOR IN FULL RUNS FROM FIRST TO EIGHTH FLOORS
Elevator is rated 2500 lb. at 510 ft. per min. with a three-phase, 220-volt motor with 4:1 speed ratio. The motor carried 2031 lb. Position *k* is starting upward; *m*, accelerating upward; *n*, running full-speed upward; *p* slowing and stopping after upward run. Point *q* is starting downward; *r*, accelerating downward; *s*, running full-speed downward; *t*, slowing and stopping after downward run.

Fig. 6 shows oscillograms of the voltage and current in one phase with *a*, *b*, *c*, *d*, and *e*, representing the same positions as shown in Fig. 5, but with a more rapid time scale and lifting a load of 2000 lb. in the car. It should be noted this is an overload of 33 per cent.

Fig. 7 is a curve plotted by the power company from an oscillogram of the amperes in each phase while the elevator is operating from the third to the fifth floor with a load of 2000 lb.

Figs. 8, 9, and 10 were taken by another large power company and are curve-drawing instrument records; they are to be read from right to left. This elevator has a rated capacity of 2500 lb. at 510 ft. per min., the motor being a 220-volt, three-phase and having a 4:1 speed ratio. The same letter on each curve represents the same operation in all three figures. Position *k* is the point of starting in the up direction, *m* is accelerating in the up direction, *n* the full speed running in the up direction, *p* the slowing down and stopping in the up direction, *q* the point of starting in the down direction, *r* is accelerating in the down direction, *s* the full speed running in the down direction, and *t* the slowing down and stopping in the down direction.

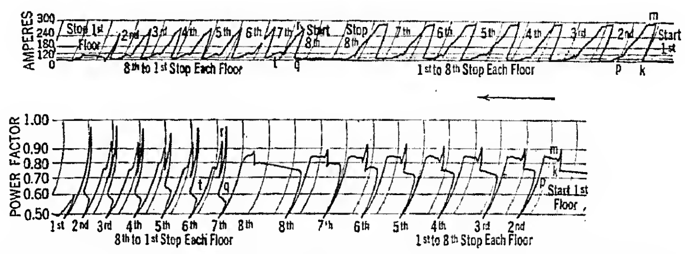

FIG. 9—ELEVATOR PERFORMANCE STOPPING AT ALL FLOORS
Elevator, load, and notations are the same as in Fig. 8

It should also be noted all these tests were with a load of 2031 lb.

Fig. 8 shows full runs between first and eighth floors, the upper curve being for amperes and the lower one for power factor.

Fig. 9 shows full runs between first and eighth floors but stopping at all intermediate floors.

It is understood that this installation in actual service is showing an average power factor in excess of 80 per cent.

Fig. 10 is of particular interest because it shows the effect on the current when the elevator is traveling at full speed in each direction and an instantaneous full reverse movement of the car control switch is made.

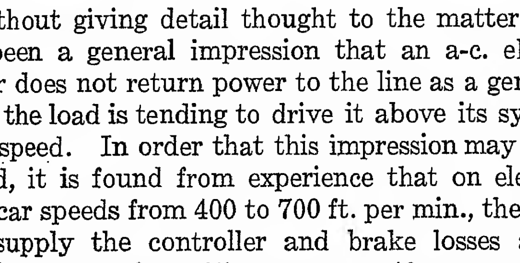

FIG. 10—EFFECT OF REVERSING ELEVATOR WHEN RUNNING AT FULL SPEED
Elevator, load, and notations are the same as in Fig. 8

Without giving detail thought to the matter, there has been a general impression that an a-c. elevator motor does not return power to the line as a generator when the load is tending to drive it above its synchronous speed. In order that this impression may be corrected, it is found from experience that on elevators with car speeds from 400 to 700 ft. per min., the motor will supply the controller and brake losses and in addition return from 25 per cent to 40 per cent of its rated hp. back to the power line as a generator.

Discussion

P. A. Lindemann: Unfortunately Mr. Thurston's paper does not give speed-time curves of the high-speed geared a-c. elevator. I should like to know the details of the stopping period of a fully loaded elevator having a car speed of 700 ft. per min. and the brake applied without appreciable slow down by the motor.

I rather expect an unevenly divided period of deceleration with too abrupt an ending due to the absence of dynamic braking, and too great a pressure on the shoes at low rotor speeds. I wonder if this assumption is correct?

It would also be interesting to know as to the thrust performance on a-c. elevators operating at car speeds of over 500 ft. per min.

To me it seems that the electrical efficiency would be higher, and cost of maintenance lower, were the compensator principle of control used, instead of the series resistance type which is liable to unbalance the phases due to loose and broken grids.

J. Lebovici: We would appreciate some description of the construction of the motor mentioned in this paper and would like to know in what respect it differs from a high-resistance Rotor squirrel-cage motor. We would appreciate having some speed-torque characteristics of the motor; also the slow-down characteristic.

We also would like to know if the motor is of two-speed, two-winding type.

We notice the statement that an elevator motor must allow torque characteristic changes at the installation. I would like to know how these changes could be made at the installation outside of varying, of course, the resistance in series with the motor stator.

We also notice that the number of switches or the number of magnets should be kept to a minimum. While we agree with this statement, we believe that the number of steps of acceleration should be as high as possible.

We would like to call attention to the development of a controller using an induction regulator for the purpose of applying a varying voltage in an infinite number of steps to the elevator motor. Such a control approaches the variable-voltage control of the d-c. motor.

E. B. Thurston: The question by Mr. Lindemann in regard to the stopping characteristics of a 700 ft. per min. a-c. elevator, if understood correctly, is a very important one. While he mentions the absence of dynamic braking, it is believed the information desired is the stopping characteristics, when the controller is moved quickly to the off position.

The apparatus covered by this paper is such that there is always automatic dynamic braking in slowing down, stopping, or reversing from high speed independent of what the operator does.

The accompanying curve gives a typical test taken by an oscillograph. Curve *A* shows where the operator is slowing down the elevator by the motor only and running a short distance *C* on the slowest speed point and finally stopping at point *D* by the action of the brake.

Curve *B* is one showing the action when the operator quickly moves the car control switch to the off position.

It is, of course, to be appreciated that by adjustment any rate of retardation desired can be obtained.

It is felt this feature of combined braking action is part of the development that made the a-c. elevator possible for higher speed service.

As to his next question in regard to the thrust performance on a-c. elevators, experience has indicated that there is no difference in in the use of a-c. from that with d-c. power. If the question is in regard to the geared-type machine for the higher car speeds, we would cite as an illustration, a machine designed for either duty of 10,000-lb. capacity at 150 ft. per min. or for 2500-lb. capacity at 600 ft. per min. It is only necessary to change the gear ratio, to change from one to the other rating, and it surely is self-evident that the thrust loads, the tooth load and machine stresses are less on the 600 ft. per min. than on the 150 ft. per min. service.

Experience has proven that the wearing qualities of the gear in the higher speed service is much better.

The thrust load may be calculated by different methods and it will be found that for full load lifting the 10,000-lb. service will have a thrust load of four times that of the 2500-lb. service, and for all allowable acceleration and retardation rates, the thrust loads of the 10,000-lb. service will be more than twice that of the 2500-lb. service.

Incidentally, it will be of interest to know that the 10,000-lb. service requires from 20 to 25 per cent greater motor horse power than that of the 2500-lb. service, even though the actual work done is the same. This is due to the much higher efficiency of the higher speed gear ratio, and is a fact well known in the gear art.

The question of compensator principle of control or resistance was raised and experience has indicated as yet that the resistance has worked out the best. It does not increase materially the power consumption but does increase considerably the starting power factor, which is a very vital point in connection with power companies, especially where the lights and power are supplied from the same transformers.

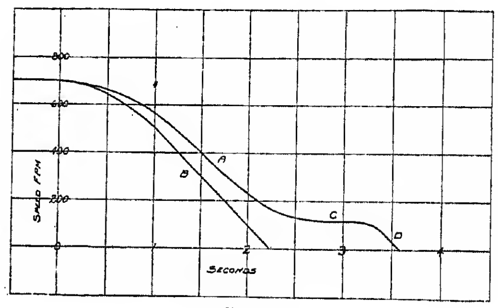

FIG. 1

The first question by J. Lebovici in regard to the motor characteristics is a very logical one, but it would be too long to go into the discussion of that at this time. It is hoped that in the next year or two a complete paper on motor development can be given.

His next question is in regard to the winding of the motor. The one to which this paper refers has a single stator, with two windings in the primary and with the high-resistance squirrel-cage rotor. However, as far as safe operation is concerned it is immaterial whether it is a single winding reconnected, or a double-type motor, providing it can be made to produce the other desirable characteristics mentioned in the paper.

His next question is in regard to a minimum number of magnets. This is one of the desirable features of the rotating type of magnet allowing the reduction to a minimum. Referring to Fig. 1 of the paper, it will be noted there are four magnets, and that each magnet can operate four or eight accelerating switches and results in a very reliable controller.

He next refers to a controller that uses an induction regulator for giving a varying voltage. This is a comparatively new development, and it is hoped in the near future we may have a paper by those who are building this type of controller.

Since this brings up the question of smoothness or the elimination of the sensation of accelerating or retarding steps, it is desired to state that it has not been found difficult entirely to eliminate these sensations with the equipment covered in this paper.

Stroboscopic Method of Testing Watthour Meters

BY H. P. SPARKES[1]

Member, A. I. E. E.

Synopsis.—*This paper deals with an optical method applied to watthour meter testing. The method as presented overcomes, to a great extent, personal error, and lessens the time required through the use of measured light impulses. It gives instantaneous comparison between watt-seconds on two measuring devices.*

The objects of this method are:

First: To reduce the time of laboratory tests, acceptance tests, and re-calibration.

Second: To reduce personal error, and to increase the accuracy of the test.

Third: To provide a device that gives precision instrument accuracy.

Fourth: To make time devices in precision tests unnecessary.

Introduction

THE present-day ideal of calibrating and checking watthour meters requires maximum accuracy with minimum loss of time. This paper deals with a device that reduces the time required per meter and increases the accuracy of the test by eliminating the human error factor and giving large indications of small increments of speed. In reality, this device is a wattmeter with a light vernier scale for measuring watt-seconds and giving instantaneous indications of meter speed.

This device measures watts with a high degree of precision, then transfers the measurement into a corresponding number of light impulses per second. The meter disk is calibrated in watt-seconds by means of marks placed on the circumferential edge of the disk.

In operation, a load is placed on the meter and the light impulses are then synchronized with the lines on the disk. When thus synchronized the markings appear to be stationary. The error of the watthour meter is then read on a balance indicator. By this method the accuracy of the meter is checked.

For calibrating the watthour meter the frequency of the light impulses is kept proportional to the meter load. Then if the meter is running at an incorrect speed, the markings on the disk will appear to move. For high speed they will progress and for low speed they will retrogress. To calibrate the meter it is adjusted until the markings appear stationary.

This apparent standing still and moving of the disk markings is the stroboscopic effect, which is more or less familiar to most engineers.

Principles of the Device

To illustrate the principles, it may be well first to refer to Fig. 1 which shows a portable outfit with hand adjustment only for controlling the frequency of the light impulses. This outfit consists of two principal parts. The first is the light-impulsing machine consisting of a driving motor on whose shaft are mounted a commutator which makes and breaks the light circuit and a magneto whose voltage varies as its speed. A hand rheostat is used to adjust the motor speed. The second part is the balance indicator. This is similar to a polyphase wattmeter except that one element is replaced by a standard d'Arsonval d-c. voltmeter element. In operation the two elements mechanically oppose or buck each other. To the a-c. element is connected the same load that passes through the watthour meter under test. The d-c. element is connected in series with the magneto and its torque is proportional to the speed of the motor or the frequency of the light impulses.

When a meter is to be checked it is connected to a load as shown in Fig. 1. The speed of the motor is then adjusted by the hand adjuster until the markings on the meter disk appear stationary when viewed by the impulsed light. The error in meter speed is then read from the balance indicator.

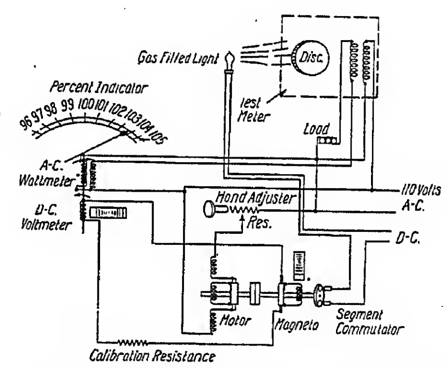

Fig. 1—Connection Diagram for Portable Stroboscopic Watthour Meter Checker

May be used with calibrator by means of transfer switches not shown.

The functioning of the parts may be explained as follows: At the given load the meter revolves at a certain speed. This load also causes a certain torque on the a-c. element of the balance indicator. The speed of the motor is adjusted to synchronize with the disk markings. This causes the magneto to generate a certain voltage and this acts on the d-c. element of the balance indicator. If these two elements exactly balance, then the meter is running at the correct speed for the given load. If the meter is running too fast, the frequency of the light impulses must be increased to bring them in synchronism with the meter disk. On

1. Westinghouse Electric & Mfg. Co.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

increasing the light frequency the speed of the magneto is increased which increases its voltage and this increases the torque on the d-c. element of the balance indicator causing it to read high.

Conversely if the watthour meter is running too slow, the balance indicator will read below normal.

The foregoing illustrates the method of checking the accuracy of a meter. For calibrating, the method is varied as follows: The speed of the motor is adjusted so that the balance indicator reads 100 per cent speed or no error. Then if the watthour meter is running

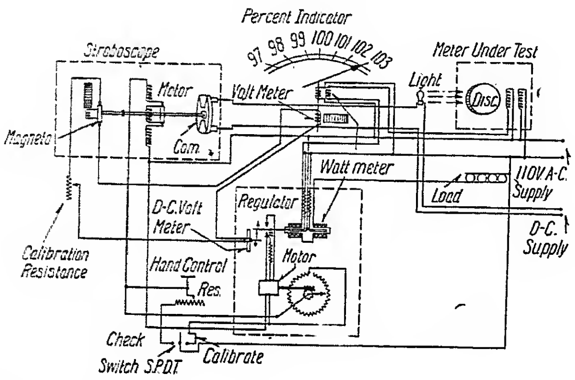

Fig. 2—Connection Diagram of Stroboscopic Watthour Meter Calibrator and Checker

at an incorrect speed the markings on the disk will appear to rotate. There will be progression for a fast meter and retrogression for a slow meter. Adjustments may then be made on the meter until the marks appear stationary which will mean that the speed is correct.

Laboratory Form of the Device

The job of holding the balance indicator at the point of 100 per cent speed is performed by hand in the portable device but in the laboratory form of the device this is performed by an automatic regulator. Such a regulator is necessary where a high degree of accuracy is desired as it eliminates the necessity of maintaining a balance by hand. This regulator is shown in Fig. 2 which is a design of the laboratory device and connections. The regulator consists of three main parts. The first part is a wattmeter of the Kelvin-balance type which takes the same load as does the tested watthour meter. The second part is a standard d-c. voltmeter of the d'Arsonval type. This d-c. meter is actuated by the magneto already mentioned and its torque is proportional to the speed of the stroboscope motor. These two elements are mechanically connected in opposition and by means of contacts and a reversing control motor (the third part), they control the series resistor of the stroboscope motor. By this arrangement the speed of the stroboscope motor and the frequency of the light impulses are maintained proportional to the watthour meter load.

The foregoing is a general description of this device and in the following paragraphs further descriptions will be given of the four main parts, (1) the watthour meter to be tested, (2) the regulator balance, (3) the light impulsing machine, and (4) the balance indicator.

The Watthour Meter to be Tested

The watthour meter to be tested must have its disk marked with a number of equally spaced lines, usually 300. Fig. 3 is an illustration of a commercial five-ampere, 115-volt watthour meter with marks on the edge of the disk. These marks are carefully graduated so that there are 300 equidistant marks filled with black. However, the black may be omitted, as the lines are visible and are much sharper without the black.

Disks for new meters and old meters may be marked with precision at a very low cost. The major expense will be in changing the disks. Standard disks may be used; but the graduations must be perfect and of the proper number to match the range of speed of the calibrator.

The Light-Impulsing Machine

The light-impulsing machine is composed of a high-speed series motor (a-c.), a commutator and brush ring, and a speed indicating magneto, all of which are mounted on a heavy bed plate. The shafts are coupled with a high-speed pin coupling of large diameter, the flexible portion being mounted on the motor shaft.

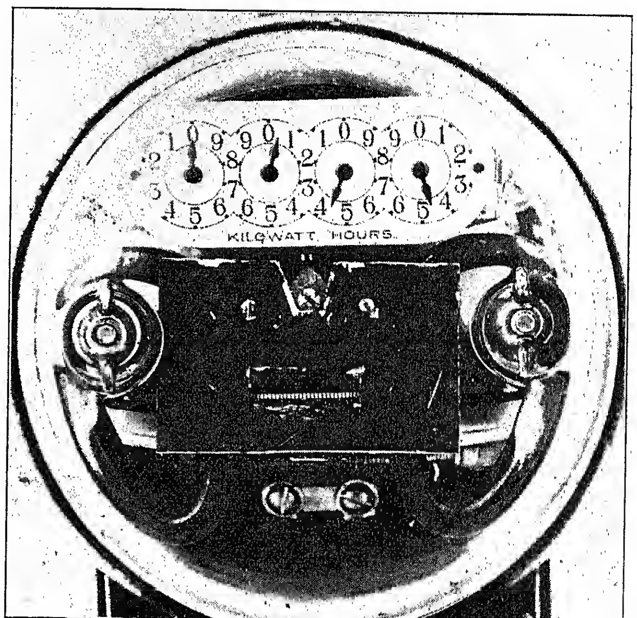

Fig. 3—Watthour Meter With Stroboscopic Lines on Disk

The motor is of the high-speed, high-torque type so that it will follow the regulator quickly. This feature would cause the regulator to hunt if it were not properly damped. A magneto with a straight line speed—voltage curve is used and direct connected to the motor by means of a special coupling. This magneto must have annular ball bearings and a very well made commutator.

The light-impulse commutator mounted on the non-

flexible end of the coupling has eight sections equally spaced consisting of four metal bars and four insulated sections. The metal bars are held in place by shrink rings which short-circuit them, forming a simple flashing commutator. The brush support is a ring section with one permanent and one adjustable brush. The adjustable brush may be adjusted to the proper "cut-off" or "light-on" position to produce a clear vision of the lines. At slow speed this adjustment is proportional to the ratio of width of space to the width of line on the disk. At high speed such adjustment is not required. It may, therefore, be set for the low-speed point and fixed, namely at 5 per cent of full load as this is about the lowest point at which the stroboscopic effect has been found satisfactory.

A special lamp is connected with a battery or rectifier unit in series with the commutator, so that for each revolution of the magneto, the light is on and off four times. This means that the lamp will have to flicker at a maximum frequency of $300 \times 25 = 7500$ cycles per minute. This is too fast for standard lamps, and a high-speed lamp such as used in aero signaling was developed in miniature for this work. It is necessary to have a cooling medium and hydrogen gas is used. It was found that 15,000 light periods per minute could be recognized by means of the stroboscope when using this lamp. The possibility of air leaking into the lamp makes it necessary to enclose the lamp completely and to vent the housing to provide for explosion. The explosions are very powerful and danger exists unless properly guarded lamps are used. The current consumed by the lamp is above normal, because the gas absorbs a large portion of the heat at a high rate.

A flood-light may be used for gang or group testing, either for one bench or for several. In fact, the overhead lighting in the laboratory may be changed to operate with this system. Where the room has exceptionally good daylight, it may be best to use a small hand lamp with a focus beam; or the operator may use dark glasses. Dark glasses seem to protect the eyes, preventing eye fatigue.

Balance Indicator

The balance indicator acts as a check on the regulator when calibrating, and as an error indicator when checking. In the laboratory it should be mounted directly above the tester's position at the test bench. It is similar to an indicating polyphase wattmeter except that one element is a d-c. voltmeter of the d'Arsonval type and is connected to buck the watt element mechanically. Both elements have a uniform scale and, as a result, the pointer indicates the difference which may be calibrated in watts or in per cent at one load. The author is devising an instrument which will read per cent for all loads. The connections for the balance indicator are shown in Figs. 1 and 2.

The Automatic Regulator

In making tests, no means is provided for keeping the watthour meter load absolutely constant. Therefore, in calibrating, the speed of the stroboscope motor must be varied as the watt load changes and for great accuracy this must be done by an automatic regulator. This regulator keeps the speed proportional to the load. As already mentioned the a-c. measuring element of the regulator is connected to measure the same load as that which the watthour meter measures, and the d-c. voltmeter element is connected to the magneto. These two elements are mechanically connected in opposition. The measuring elements, by means of contacts and the reversing motor, control the series resistor of the commutator motor. The contacts are of the standard three-point type such as are used in graphic meters.

As the wattmeter element is of the Kelvin-balance type, it has a straight-line scale of watt values. This means that there must be a buck-balance with a similar straight-line scale. The standard d-c. voltmeter of the d'Arsonval type may therefore be used for a buck balance. With these two elements mechanically connected in opposition, they will find a point of balance over their entire range. This means that the speed must be proportional to the watts; otherwise the balance will close its contacts, causing the control motor to adjust the series resistor until a balancing speed is obtained through the voltmeter element. This part of the scheme is the heart of the device. Taps for voltage, a range for various current capacities, and a changeover switch on the voltmeter element for various makes of meters should be provided.

When a precision wattmeter is used, the torsion head should be left intact, so that it may be checked with a potentiometer, the calibration of the device being thus established from this point. The torsion spring will have practically no effect, as the balance operates at zero torque, and with practically no movement. On the other hand the torsion head may be set to balance part of the meter torque and thus eliminate the necessity for some of the switches and taps.

The voltmeter element should be of the finest workmanship; also it should be connected to the wattmeter through suitable mechanical linkage and the entire balance must be properly damped.

This part of the device should be built so that it may be located near a standardizing bench, thereby facilitating a check test on the outfit.

Operation

The general diagram of connections, as shown in Fig. 2 gives an idea of the electrical connections used for the laboratory set. A source of alternating current is required for loading the watthour meter, the Kelvin balance, and the wattmeter element of the per cent indicator. A small source of direct-current is required

for the light. This may be a battery or rectified alternating current with a wave filter in the circuit.

Several load switches are required to cover the testing range. The major switches cover full load, light load and 50 per cent power factor.

To make a check or "as found" test throw the regulator switch to the check position which cuts out the regulator and cuts in the hand control. Then adjust the set until the lines stop moving and read the per cent indicator.

In calibrating, the power is supplied to the load deflecting the watthour meter, Kelvin balance, and per cent meter. This upsets the balance, starts the watthour meter, and gives an indication on the per cent indicator. The Kelvin balance then closes its contacts which control the motor on the rheostat. This decreases the resistance in the commutator-motor circuit until this motor reaches a speed at which the voltage generated by the magneto produces a torque on the voltmeter element that bucks the Kelvin balance and equals the torque developed by the watts in the meter circuit. The contacts then open and regulate the speed of the commutator motor by increasing or decreasing the series resistor.

The speed of the commutator is the same as that of the motor, so that the light is impulsed at a proportional speed. This speed depends upon the number of segments on the commutator. When the frequency of the light impulses is the same as that of the movement of the lines on the watthour meter disk, or the disk line movement is synchronized with the light, the lines will appear to stand stationary, which is the well-known stroboscopic effect. If they are not synchronized, there will be progression for high speed on the meter or retrogression for low speed on the meter, indicating that the meter is out of step or calibration. In some of the standard meters, moving the adjustment screw in the direction of the line motion will correct the error.

While this action has been taking place, the balance meter has been indicating the difference in calibration, as it functions the same as does the regulator. The two elements are bucking and as a result, when speed is proportional to watts, this instrument should read zero or 100 per cent. When the regulator is in use for calibrating, the balance indicator is simply a check on the regulator; but when the hand control is used for checking, this indication reads watts error plus or minus, slow or fast.

At this point it may be well to bring out the fact that the disk markings may appear stationary at harmonic values of speed, but the image is very poor at such values. At the calibration values the image is very sharp and clear. Also, noting the action of the per cent indicator and the range of calibration of the watthour meter will prevent mistakes.

After the above mentioned operations have been taken care of, note the per cent indicator to see if the regulator is functioning properly. Then observe the line movement and adjust the tested meter until the lines stop. Then test for the other load and power factor by simply throwing the proper switch, as the regulator will take care of the change.

The meter under test may be connected after the set is started if quick-connection test blocks are used, as the regulator will take care of the system when the test meter is out of the circuit by stopping the commutator motor, exactly as it would for a no-load condition. This means that no time is lost while changing meters. Because of a possible short circuit at the lead ends, this procedure is not advisable if leads are used to connect the test meter.

Accuracy of Test

As personal errors of switching are eliminated in this laboratory set the accuracy will be materially improved. A second point is that a precision wattmeter may be used, if desired, giving maximum accuracy while calibrating. Observation of the motion of the lines is made through a cylinder type of lens which apparently

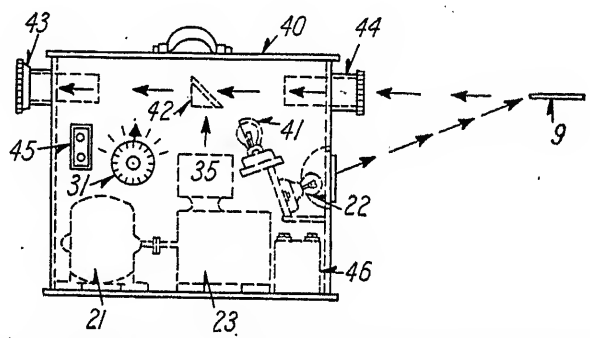

Fig. 4—Schematic Drawing of Portable Stroboscopic Watthour Meter Checker

speeds up the motion in case of slow speed. The author has tried several types, and this cylinder lens gives the best results, although a telescope with cross hairs will give minute measurements.

It has been found by test that progression of one line one division in 30 sec. is quite perceptible with the unaided eye. Therefore the error which may be discerned equals a movement of 1/30 division in one second.

Full load on the meter used is 500 watts and the disk constant is ⅓. Therefore at 500 watts the disk will revolve at the following speed:

$$n = \frac{500}{3600} \div \tfrac{1}{3} = 0.4167 \text{ rev. per sec.}$$

As there were 300 equal divisions on the disk the number of divisions per second is $0.4167 \times 300 = 125$ divisions per sec. But the error which can be read equals 1/30 division per second. Expressed in per cent this is $1/30 \div 125 \times 100 = 0.026$ per cent. Translated into watthours at full load this equals:

$$500 \times 0.026 \div 100 = 0.13 \text{ watt-hr.}$$

Discussion

W. B. Kouwenhoven: The method described by Mr. Sparkes is very ingenious. The arrangement that he has provided, for changing the speed of his flashing lamp so as to bring it into synchronism with the marks on the meter disk, makes it possible to use the device to check over a wide range of speed.

The method should give accurate results, as the torque of the wattmeter measuring the a-c. load, is balanced by the torque of a d-c. voltmeter element supplied with current from a magneto driven from the flasher shaft. Care must be taken to see that the armature reaction of the magneto is negligible, otherwise errors may be introduced.

I regret to note that the author has found it necessary to put 300 marks on the meter disk. This requires a high-speed lamp of special construction, and special apparatus in the laboratory always means trouble. If, however, he had used fewer marks and a standard lamp, which would operate at a low speed, he could not have obtained such a high degree of accuracy for his device.

I think that his statement, that his method is excellent for gang meter testing is open to question.

As I see it, the advantages of Mr. Sparkes' method, depend upon the fact that it is easier to detect a departure from zero than it is to read a meter accurately. Mr. Sparkes' method also does away with the necessity of calculation and meter reading, as the scale provided in his device reads per cent error directly. It should give good results in the hands of the unskilled meter tester.

B. J. Brown: I am very much interested in some points made by Dr. Kouwenhoven, particularly to anything that would give trouble in the future in the apparatus, especially such that develops after service.

In regard to the number of marks on the disk, can they be reduced? And the lamp, could it be changed?

And also its use in gang testing? There are other devices on the market. I would like to hear somebody's opinion regarding them.

H. J. Blakeslee: Mr. Sparkes has made a distinct advance that doubtless will eventually be of benefit, to meter manufacturers and electric light and power companies alike.

For many years efforts have been made to reduce the time required for testing watthour meters. Mr. Brown has just spoken of the group methods of testing. There are a number of such methods in use, and also a number of methods for making at least a part of the test automatic and so eliminating the personal error.

Group methods reduce the time required not only for determining the accuracy of the meters, but also for making the necessary records and for removing the covers, hanging the meters in position, connecting them in circuit, and reversing those operations. It has been found that the actual time required for testing a meter is small in comparison with the total time required for the entire procedure.

However, every advance of this kind in reducing the time required for the test is an incentive to reduce the time for the balance of the operation, and for that reason I do not wish at all to disparage Mr. Sparkes' contribution. I think that efforts will follow to catch up on the other end of the process.

I do not understand just what Mr. Sparkes means by his statement that he is able to make tests to an accuracy of 0.0026 per cent. As I understand it, in the apparatus which Mr. Sparkes has described, the accuracy is dependent upon the precision of the per cent indicator and the accuracy to which it can be read. Possibly I am mistaken about that.

One of the most desirable features of Mr. Sparkes' method is the fact that the meter is tested at speed so that any possible errors of start and stop do not enter into the result.

One other point which Mr. Sparkes has not brought out, but which should be borne in mind, is that his method is a distinct contribution to human welfare. Anyone who has intimate knowledge of the tediousness involved in counting meter revolutions day after day, will appreciate how relief from that monotony may add to the desirability of the meter tester's work.

G. A. Sawin: Referring to Mr. Sparkes' paper, the item that will most interest the operating man is his statement that this testing device will reduce personal errors and save time. Just how is this to be accomplished?

To illustrate, supposing we paint a picture of the meter man of the present and a possible meter man of the future. Today the meter man goes into the premises with a rotating standard and his load-box, connects up, and then counts the revolutions of the disk through his test meter. In order to avoid stopping and starting errors, and possible personal errors, he has to take a reading of three-quarters of a minute to a minute long and usually checks himself three times. I think that is the rule of most operating companies. He does the same thing at full load and at light load. Then if the meter is incorrect, he adjusts it a little bit and counts revolutions all over again, and he continues this same process until he gets the meter correct. Now the meter man of the future comes in. He has a box in his hand, which is probably about the same size as his present rotating standard, maybe smaller, and his load-box. He connects up, puts the testing device in front of the meter, adjusts the hand rheostat until the lines of the disk stand still, and reads his indicator. He has obtained his meter accuracy. He will probably check himself once, to make sure that he is right. He does the same thing at full load and at light load. You can see how much quicker that is, than the present method.

Now take your meter room where you have the laboratory device; in this case the flickering of the light is held constant by the standard meter. The tester knows that if the lines are going one way the meter is fast; the opposite way it is slow. He puts a screw-driver into the full-load adjustment, turns that adjustment gradually; watches the lines slow down and finally stand still. The meter is calibrated. Of course, he will check himself to make sure he is correct, but there are no counting revolutions of the disk, no long waits, no stopping and starting errors.

As Mr. Sparkes says, the device is still in the experimental stage, but I think it marks a step forward. If we could only get away from that old bugbear of counting revolutions, it would be a blessing. I think Mr. Sparkes has earned a great deal of credit for showing us a possible way toward that end.

A. E. Knowlton: I should like to ask Mr. Sparkes to give an answer to this question: Does the logarithmic manipulation of the torque of the per cent indicator assure getting the same degree of accuracy of the percentage indication on a 50 per cent power-factor test as on a 100 per cent power-factor test?

The other question I would like to ask is: Does the limitation of the use of harmonic values of speed prevent accurate testing of the meter at 200 per cent or even 300 per cent of load, for which the claim is made, that a large number of meters now available are quite reliably accurate?

P. van Santen Kolff: Mr. Sparkes evidently needs in the tachometer a magneto that for a certain range of speed will give a perfectly straight curve. The particular magneto used by Mr. Sparkes has that characteristic. A much higher speed could be got, and still give a straight line curve, but, naturally slow speed tends to give more permanent and better commutation than high speed.

Mr. Sparkes might have added that the speed of his motor is by no means limited. If I understood his paper, all that Mr. Sparkes desires to do is to create a certain number of impulses, which may run to a maximum of maybe 8000 per min. for the flashing of his light; and by mounting more contact points or cams on his commutator, he naturally can reduce the maximum running speed of his motor and subsequently the speed of his magneto to any speed he likes. If a magneto at 600 rev. per min.

would not serve his purpose, he could reduce that speed to 300 rev. per. min.

Mr. Sparkes wanted a lamp which would flicker very rapidly. Filling the lamp with hydrogen gas is ideal for accomplishing this. Nevertheless, if the bulb becomes cracked or for some reason oxygen and hydrogen become mixed in just the right proportion, a very dangerous explosion may result.

In Mr. Sparkes' work, danger from explosions must be absolutely eliminated. So his lamps, made up for him by our lamp laboratories, have very small bulbs, in fact, the bulb is about the size of an olive, and in these bulbs is less than atmospheric pressure of hydrogen gas. The danger of explosion is still there, but in Mr. Sparkes' apparatus he has the lamp enclosed in a fixture with a piece of plate-glass about ten times as thick as is needed, so the danger is so small as to be negligible. Furthermore, if his later experiments show it is necessary, we may fill these lamps with helium gas, which is almost as good for the lamp, and with it there is no danger from explosion.

H. P. Sparkes: Dr. Kouwenhoven's first question concerns the characteristics of the magneto. In developing this machine as far as it is developed, care was used in choosing the proper speed range. We selected from the curve of the magneto that portion which we may term "straight." The machine has been operated from 4 per cent load on the watthour meter to approximately 200 per cent. In the range of the magneto we are using that section of the curve which is straight for such operating conditions. The straight-line range runs from approximately zero to 1200 rev. per. min.

The next point brought out under Dr. Kouwenhoven's discussion was the question as to whether the number of lines could be reduced or not. All electrical men are familiar with the fact that after passing approximately 30 cycles, the vision of light interruption ceases; in other words, the eye is not sensitive enough to record over 30 cycles. Keep in mind that when operating this machine at light load, we must have a large number of lines passing the focal center of the eye within a given period, otherwise we cannot get the stroboscopic effect, we see the actual motion. It is therefore necessary to keep the stroboscopic lines on the disk in the vicinity of 300 or better. Experimental tests were made at 200, and at present we are working at 300. Some tests were made at 360, but care will have to be used in selecting the number of lines to match the watthour constant of the meters now being used. I make that remark because in calibrating with this device it will be necessary to supply a switch to take care of the various constant values as applied to various makes of meters.

I believe the point about the mechanism running at high speed is covered in the past remark concerning the lines.

For a reply to the question on special lamps see Mr. Beggs' remarks.

Another point which I wish to emphasize is the fact that the machine entirely eliminates personal error other than bad vision.

As to the point of gang testing, the term is applied in several different ways. You may make a gang test where the meters all stop and start at the same time. You start them all, time them, stop them, go over and adjust those that are out of calibration. With the stroboscopic machine you turn on the machine with the gang test running and in place of checking, you go along and calibrate while the load is on the meters. It eliminates the cut-and-try method.

As to Mr. Blakeslee's remarks, I would like to bring out one point in his statement. The meters, when placed on acceptance test, may be checked and passed, if they are within limits of required accuracy, without breaking the seals or removing the covers. The lines are placed on the circumferential edge and have a greater visibility than the present calibrating mark on the disk. This means that there will be considerable saving in time in the actual set-up for the test. That is, it will not be necessary to remove the metal covering, because the light beam can be projected through the glass opening on to the disk and a check made without touching the original manufacturers' seals.

The accuracy figures given in the paper, 0.0026, are based on calculations of the ultimate accuracy, and I believe in the paper I remark that the accuracy is based entirely upon the regulator, and as the regulator is composed of a precision wattmeter, you may see quickly that the accuracy of the entire machine or the overall accuracy depends entirely upon the linkage in the machine, 0.0026 being the ultimate accuracy according to visibility. Those figures are taken on what you may see through a 16-power cylindrical lens; in other words, that is the maximum.

Mr. Knowlton asks the question as to 50 per cent power factor. At 50 per cent power factor, we have the same change in the stroboscopic machine as you have in the watthour meter, so there will be no effect to introduce an error at this point, the stroboscope will follow the load with the meter and will act as though the meter had simply had the 50 per cent power-factor load placed on it, and the stroboscope will follow right through with it. I have made a number of tests at this point with the machine and no errors were found.

The last point brought out by Mr. Knowlton is an important one, concerning the harmonic adjustment. In developing this machine, I found that the eye is subject to a number of tricks. For instance, we are running the machine at twice the speed of the meter. The result is that the number of lines will apparently be double the actual number because you are taking a picture with your eye, of the line in two positions in place of one. Reverse the condition, with the meter running at 200 per cent and the stroboscope at 100, and you will be taking the opposite condition, every other line. In fact, you can check harmonic values from zero up to about 200 per cent. But realize what happens when you strike those harmonic values you are possibly working at one-half of 0.0026, which makes the point unstable so that it is impossible to hold it; you have reduced your vision by the multiplier of your harmonic, and as a result your vision is exceedingly poor. At some harmonic values you have to reduce the light in the room or the external source of light to practically total darkness to observe some of the harmonic values. I have used colored glasses to determine some of these harmonic values.

Now, a point that hasn't been discussed is the question of using a lens multiplier at light load. Remember at light load you are getting an impulse-light. The light condition actually goes off and on to the human eye, meaning that the retina of the eye and the iris will get a flicker of light. Now the eye will automatically adjust itself to an intermediate position. You cannot follow the stroboscopic action at exceedingly light load by simply glancing at it. You have to give the eye several seconds, possibly, to see the extreme light-load conditions. By using a cylindrical lens in front of that moving object, it apparently speeds up the action to the eye and you get away from the eye delay.

In the criticism of the paper, the point was brought out: Does the stroboscopic machine have any effect upon the eye, such as injury to sight or fatigue to the eye? I would like to bring out one point here, and that is this: The optician today, with his methods of correcting eye trouble, often places an image on the edge of a wheel and asks you to watch that. The effect is that your eye rotates, exercising the muscles. In the case of the stroboscope operating at slow speed, you exercise the muscles in the eye. I have been operating this machine over a period of a year and I have had no eye trouble from it.

Theory of Action of the Induction Watthour Meter and Analysis of its Temperature Errors

BY D. T. CANFIELD[1]

Associate, A. I. E. E.

Synopsis.—*The question of changes in the registration of watthour meters due to variations in temperature is receiving considerable attention at the present time from manufacturers and public utilities alike. This paper discusses the development of a temperature-compensated watthour meter. The effect of certain changes in the fundamental constants of the meter circuits and the materials of certain vital parts are shown to point out the necessity of two independent compensating devices.*

The compensating devices found most effective consist, first, of a permanent magnet flux diverter mounted on bimetal strips in such a way that it shunts more or less of the permanent magnet flux around the disk, on a decrease or an increase in temperature, respectively, and second, a moving lag plate controlled by bimetal strips arranged in such a way as to cause the plate to move up or down with an increase or a decrease of temperature, respectively.

In Appendix I is given the construction of a theoretical vector diagram of an induction type watthour meter showing the relative phase positions of the various fluxes, voltages, and currents that are present.

In Appendix II is given a discussion of the sources of temperature errors in watthour-meters as derived from an analytical study of this diagram.

An attempt is also made in this paper to summarize these sources, the reason for their existence, and their effect upon the registration of the meter, in convenient tabular form.

* * * * *

INTRODUCTION

THE interchange of large blocks of power between utilities, the need for accurately determining water rates of turbines, and the increasing number of consumers who use large amounts of energy, are making various refinements in watthour meter practise desirable. In loads of this character, any real increase in precision is more than desirable.

As a natural consequence, it follows that the task of developing a temperature compensated watthour meter is typical of the problems to which American meter manufacturers are devoting their attention. Moreover, the study of temperature errors in watthour meters is in line with the suggestions made by the subcommittee on Instruments and Measurements of the American Institute of Electrical Engineers.

The writer was engaged to investigate the effectiveness of temperature compensation by thermostatic control of the lag adjustment and drag element of a watthour meter.[2]

At the time the solution of this problem was undertaken, very little of a definite nature was available in the literature of the art concerning the real sources of the change in registration of watthour meters, due to changes in ambient temperature. Subsequently, however, there appeared a very excellent discussion and classification of these sources by Messrs. I. F. Kinnard and H. T. Faus.[3]

Since a complete understanding of the action of the compensating devices later to be described is contingent upon an equally complete understanding of the sources of the errors they compensate for, it will not be out of place to repeat a similar classification and discussion in this paper.

Table I gives a summary of such a classification and discussion. This table was derived from a theoretical analysis of the vector diagram of Appendix I, the discussion given in Appendix II, and a study of the registration curves of meters at different temperatures.

DETERMINATION OF THE RESULTANT EFFECT OF GROUP I ERRORS

Since in Group I there are some effects producing an increase in speed and others producing a decrease in

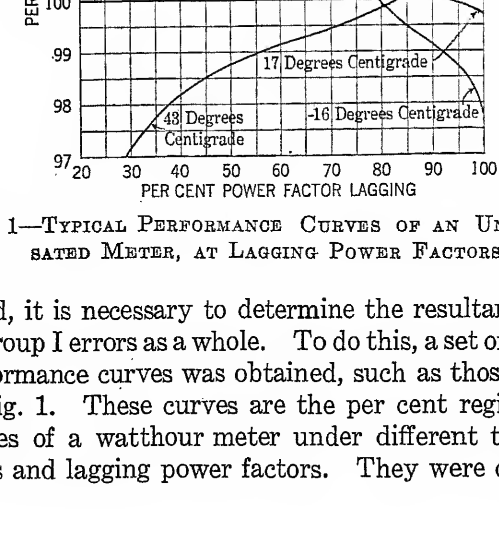

FIG. 1—TYPICAL PERFORMANCE CURVES OF AN UNCOMPENSATED METER, AT LAGGING POWER FACTORS

speed, it is necessary to determine the resultant effect of Group I errors as a whole. To do this, a set of typical performance curves was obtained, such as those shown in Fig. 1. These curves are the per cent registration curves of a watthour meter under different temperatures and lagging power factors. They were obtained

1. Assistant Professor of Electrical Engineering, Purdue University, Lafayette, Indiana, and Consulting Engineer for Duncan Electric Mfg. Co.

2. Developed by Mr. Jesse Harris, Chief Development Engineer of the Duncan Electric Manufacturing Company.

3. TRANS. A. I. E. E., 1925, p. 275.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

TABLE I

A SUMMATION OF THE SOURCES OF ERRORS IN WATTHOUR METERS DUE TO VARIATIONS IN TEMPERATURE AND THEIR EFFECT UPON REGISTRATION

Combination I—Assumes an increase in ambient temperature with lagging power factor

Group	Error	Description of error	Effect on meter speed	Effect of decreasing power factor	Reasons for the changes in speed
	1	Changes in the magnetic properties of the permanent magnet.	Increases	Independent	Decrease in permeability, reluctance increases, dragging flux decreases, meter speeds up.
	2	Changes in the magnetic properties of the magnetic circuits of the potential and current elements.	Decreases	Independent	Decrease in permeability, reluctance increases, driving fluxes decrease, meter slows down.
I	3	Changes in length of the air-gap of the permanent magnet.	Decreases	Independent	Magnet gap widens, causing the flux passing between the gap to decrease. Meters using this flux for dragging will speed up, while meters using a shunted portion of this flux will slow down.
	4	A shift in the phase position of the exciting current.	Increases	Independent	The exciting current shifts down due to decreased iron losses, causing a shift in $I_p\ R_1$ This in turn increases E^1 which must be accompanied by an increase in Φ. (See Fig. 12.)
	5	An increase in the magnitude of the exciting current.	Decreases	Independent	Increase in reluctance of iron cuts down Φ, exciting current then increases but not enough to increase Φ to its original value. This means a decrease in E^1 and therefore in the speed of the motor.
I	6	Changes in the choking effect of the lag and light-load plates.	Increases	Independent	The choking effect of these plates upon the main flux decreases. More of the main flux acts as a driving flux. Meter speeds up.
	7	Changes in the resistance of the potential windings.	Decreases	Independent	Shift of $I_p\ R_1$ due to shift in exciting current causes E^1 to decrease and consequently Φ. Speed decreases.
II	8	Changes in the resistance of the potential windings.	Decreases	Increasingly	Reacts to decrease the 90 deg. relation between the driving fluxes. Speed decreases.
II	9	Changes in the phase position and magnitude of the exciting current.	Decreases	Increasingly	Both effects shift the voltage V^1 (See Fig. 12) so as to decrease the 90-deg. relation between the driving fluxes. Speed decreases.
	10	Changes in the resistance of the lag and light-load plates.	Decreases	Increasingly	Increase in resistance of these plates decreases the 90-deg. relation between the driving fluxes. Speed decreases.
	11	Changes in the resistance of the disk.	Decreases	Increasingly	Reacts to decrease the 90-deg. relation between the driving fluxes. Speed decreases.

by comparison to another watthour meter kept at a constant temperature. In all these curves the potential coils were left excited continually and the current coils warmed up for a reasonable time prior to checking. As a result, the errors caused by self heating are negligible so that the change in registration is due solely to a change in ambient temperature.

As seen by the 100 per cent power-factor points of the curves of Fig. 1, the resultant effect of Group I errors is to speed the meter up on an increase in temperature. This means that errors No. 2, 3, 5, and 7 are small in the aggregate compared to the combination of No. 1, 4, and 6. Fig. 1 also shows that as the lagging power factor decreases, the meter slows down at high temperatures and speeds up at low temperatures. This substantiates the reasoning with respect to Group II errors.

Since, as just shown, the resultant effect of Group I and Group II errors is opposite, it is obvious that at some lagging power factor the meter will be independent of changes in temperature. In the meter of Fig. 1, this lagging power factor is approximately 80 per cent as the curves meet here in a common point. This point will vary up and down the power-factor scale, depending on the relative magnitude of the resultant effects of Group I and II errors.

If, however, leading power factors are used in place of lagging power factors, the resultant effect of Group II errors will be reversed and, therefore, Group I and Group II errors will not oppose each other. As a result, there is no leading power factor at which the meter is independent of temperature.

This is illustrated by the curves of Fig. 2 where the broken lines are the corresponding leading power-factor curves to the solid or lagging power-factor curves.

It should be noticed that the leading power-factor curves, although similar in form, are opposite in direction to the lagging power-factor curves and therefore do not meet in a common point.

The effect of leading power factors, as far as single-phase meters are concerned, is of little importance, since single-phase meters are rarely subject to leading

power factors, but with two-element polyphase meters this is not necessarily true. In the first place, polyphase meters are more apt to be used where leading power factors exist, and in the second place, a polyphase meter at lagging load power factors above 86.67 per cent has one element operating on a leading power factor. The two elements would tend, therefore, to compensate each other as far as temperature errors are concerned.

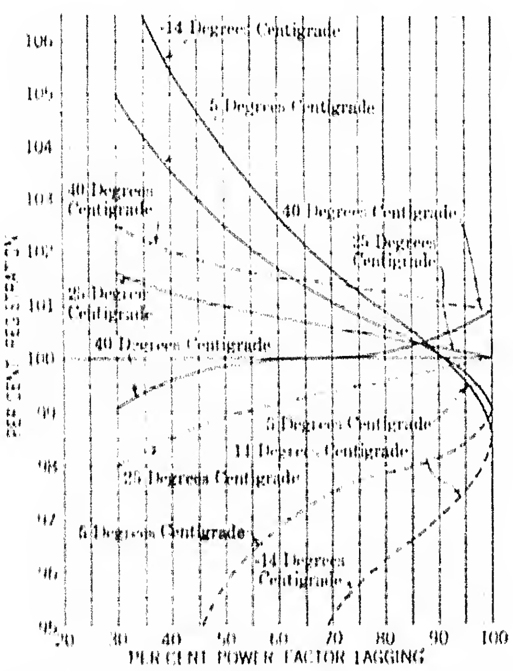

FIG. 2 EFFECT UPON THE TYPICAL PERFORMANCE CURVES OF LEADING POWER FACTORS

This probably accounts for the fact that polyphase meters in general have less over-all temperature error at low power factors than do single-phase meters of the same make.[4]

EFFECT OF CHANGES IN THE CONSTANTS AND MATERIALS OF THE METER

Any change in the constants of the meter circuits, in the materials of which they are made, or in the design of the meter will change the relative magnitude of the several errors and thereby change the typical performance curves. The effect of some of these changes will now be illustrated.

Fig. 3 shows the effect of a brass phasing plate in the meter of Fig. 1. Since brass has a lower temperature coefficient than copper, its resistance will change less with a given change in temperature than the copper plate, and, therefore, the error due to this change will be less pronounced. Comparing Fig. 3 with Fig. 1, it is seen that the spread of the curves in Fig. 3 is less and the neutralizing or crossing point has been lowered. This means that the resultant effect of Group II errors has been reduced so that they do not overcome the resultant effect of Group I errors as quickly as in Fig. 1. Furthermore, the spread of the curves at the lower power factors has been greatly reduced. This indicates that error No. 10 is the predominant one of the Group II errors. This figure also illustrates that it is possible by proper calibration to get virtually perfect performance at some one temperature, 20 deg. cent. in this case.

The substitution of a lag plate which has nearly zero temperature coefficient has been suggested, but, unfortunately, all the metals which have low temperature coefficients also have high specific resistance. Even with brass, it is necessary to use a plate nearly four times as thick as the copper plate it replaces, in order to obtain the proper lagging. The design of the average present-day meter has a relatively small space available for the lagging device with the result that the limit to which this idea can be carried without materially changing the dimensions of the meter, is quickly reached.

In order to determine the effect of error No. 8, two otherwise similar meters were made up, one with its potential coil resistance increase above normal and the other with its potential coil resistance decreased below normal.

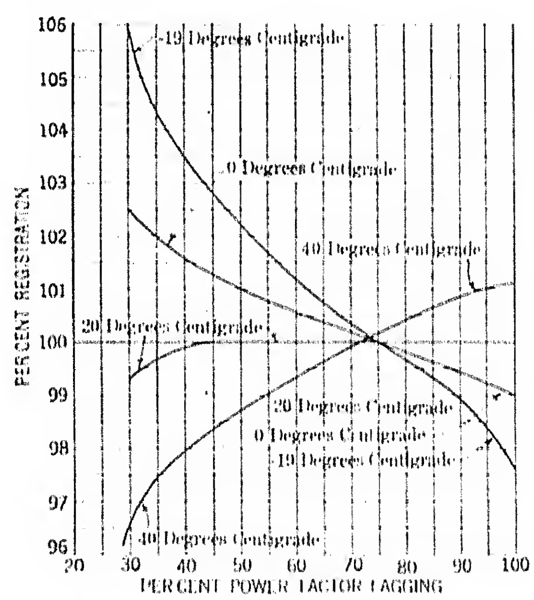

FIG. 3—EFFECT UPON THE TYPICAL PERFORMANCE CURVES OF SUBSTITUTING A BRASS PHASING PLATE FOR THE CUSTOMARY COPPER PLATE

The first of these meters was obtained by winding the potential coil with the same number of turns of No. 33 wire instead of the customary No. 30. Neglecting a small change in the mean length of turn, the resistance of these coils would be approximately twice the normal resistance.

Since increased potential losses mean a decrease in the angle between the applied voltage and the flux

4. See the author's paper, "Watthour Meter Accuracy as Affected by Temperature Changes," *Experiment Station Bulletin* No. 22, Purdue University.

set up thereby (see Fig. 12), it follows that greater lagging must be applied to this meter. It was found that to obtain the proper lagging, a larger or thicker lag plate was required than that normally used.

Turning now to Table I, it is evident that both errors

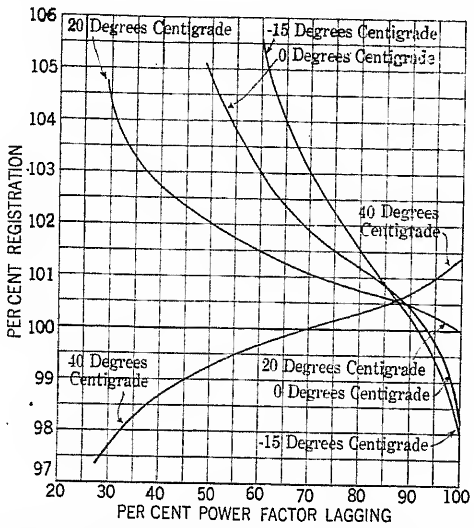

FIG. 4—EFFECT UPON THE TYPICAL PERFORMANCE CURVES OF INCREASING THE RESISTANCE OF THE POTENTIAL WINDING ABOVE NORMAL

No. 8 and 10 will be affected and moreover in the same direction. The result is an increase in the resultant effect of Group II errors. This means that Group II errors are now better able to overpower Group I errors,

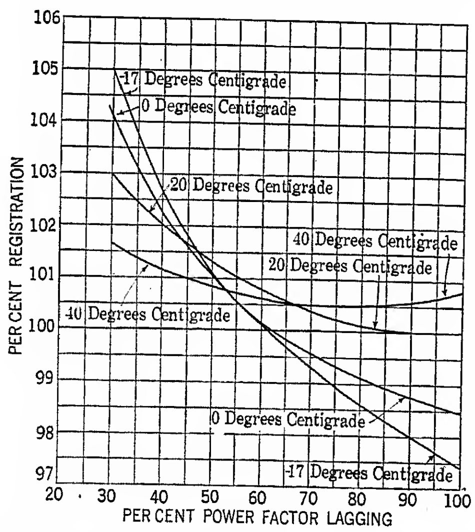

FIG. 5—EFFECT UPON THE TYPICAL PERFORMANCE CURVES OF DECREASING THE RESISTANCE OF THE POTENTIAL WINDING BELOW NORMAL

thereby raising the crossing or neutral point on the power factor scale.

The result of the test is plotted in Fig. 4. Comparing these curves with those of Fig. 1, it is seen, as had been predicted, that the crossing point has moved from approximately 80 per cent power factor to nearly 90 per cent. This is a desirable change as far as high power-factor operation is concerned, but it should be noticed that at the lower power factors, the spread of the curves has been greatly increased.

Although this meter is compensated to some extent at high power factors, it is accomplished at the expense of accuracy at low power factors, and, furthermore, any compensation which depends upon an increase in the losses is fundamentallly wrong.

The second meter referred to above was obtained by winding the potential coils with two strands of No. 30 wire instead of the customary single strand. As before, neglecting the change in the mean length of turn, the resistance of these coils would be approximately half the normal resistance.

Also as before, a change in the lag plate is necessary, but in this case in the opposite direction. A No. 16 brass phasing plate was substituted for the customary

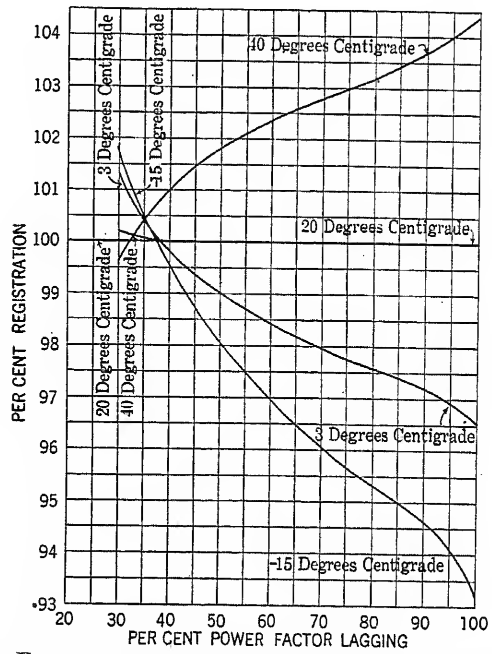

FIG. 6—EFFECT UPON THE TYPICAL PERFORMANCE CURVES OF LAGGING BOTH THE POTENTIAL AND CURRENT FLUXES

copper plate. The result of these changes is just the opposite to that obtained with an increase of resistance.

The effect upon the performance curves is shown in Fig. 5. Comparing these curves to those of Fig. 1, it is evident that the crossing occurs at lower power factors and with less variation at very low power factors.

This is obviously a step in the right direction as far as Group II errors are concerned, but it is equally obvious that it is not a complete solution as it would be impossible to have zero resistance in the potential circuit, so doing away with the lag plate entirely.

In Fig. 5, the curves show the meter running fast at all temperatures on low power factors. This is due to over lagging of the meter when it was adjusted and calibrated. Had it been properly lagged at the customary 50 per cent power factor, the curves as a whole would have been more nearly coincident with the 100

per cent registration line, but the spread of the curves at either end would not have been changed appreciably.

As previously mentioned, changes in design will also affect the typical performance curves. As an example, consider the simultaneous lagging of both the potential and current fluxes. This is done by over-lagging the potential flux and then lagging the current flux sufficiently to produce the required 90 deg. relation between them at unity power factor.

As the temperature increases in a meter so modified, it will tend to lessen the lagging of both the potential and current fluxes. By proper proportioning of these

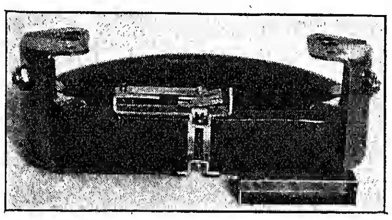

FIG. 7—THE COMPENSATING DEVICE USED FOR GROUP I ERRORS—COVER REMOVED

two lag plates, it might be possible to shift these two fluxes by approximately the same amount for a given change in temperature so that the angle between them would remain at 90 deg.

Fig. 6 shows the result of an attempt to apply this principle. Comparing these curves with those of Fig. 1, a slight improvement is found in the slope of the curves.

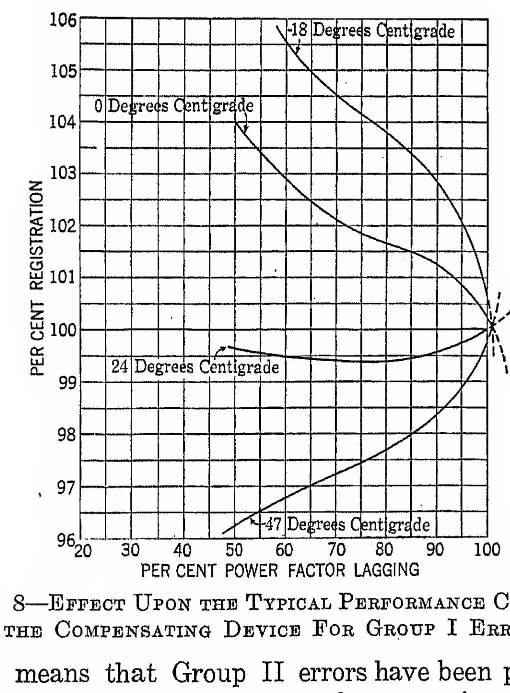

FIG. 8—EFFECT UPON THE TYPICAL PERFORMANCE CURVES OF THE COMPENSATING DEVICE FOR GROUP I ERRORS

This means that Group II errors have been partially compensated for. The effect, however, is not very pronounced.

TYPE OF COMPENSATING DEVICES FOUND TO BE MOST EFFECTIVE

The compensating device found to be most effective for Group I errors in the meters investigated consisted of a flux diverter for the permanent magnet. This diverter was mounted across the gap of the magnet on a bimetal strip, so that it moved out or in as the temperature went up or down. See Fig. 7.

The law which this diverter obeys depends on the relative magnitude of the magnetic pull upon it and the spring and thermal action of the bimetal strip. These, in turn, depend on the position, size, and shape of the iron diverter and bimetal strip.

The effect of this device on the meter of Fig. 1 is shown in Fig. 8. This figure shows that by this means it is possible to over-compensate for Group I errors, as the crossing point has moved beyond the 100 per cent power-factor point. By moving the diverter away from the gap, the crossing point may be made to occur at 100 per cent power factor exactly. It should be noticed that the removal of Group I errors leaves Group II errors unrestrained, as shown by the excessive spread of the curves at low power factors.

From what has just been said, it is evident that two independent compensating devices are needed, one for

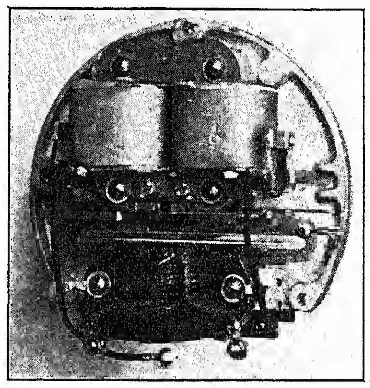

FIG. 9—THE COMPENSATING DEVICE USED FOR GROUP II ERRORS

Group I errors and another for Group II errors, to completely compensate a meter for changes in temperature.

The compensating method found most effective for Group II errors consisted in mounting the phasing plate on bimetal strips in such a way as to cause it to move up and down with a rise and fall of temperature. See Fig. 9.

The effect of this device alone on the meter of Fig. 1 is shown in Fig. 10.

The effect of both of these devices combined in the same meter resulted in the performance shown in Fig. 11, which, when compared to Fig. 1, shows a marked improvement.

The solid curves are the average curves of ten separate tests made on this meter at frequent intervals over a period of four weeks. Between tests the meter received average handling and transportation and was not found to be appreciably affected by this treatment.

This would indicate that although movable com-

pensating devices are used, they are rigid enough to withstand ordinary handling.

The dash lines represent the maximum deviation from 100 per cent registration of any one of six compensated meters, each tested three times between −18 deg. cent. and 40 deg. cent. and 100 per cent power factor and 30 per cent power factor.

In other words, the solid curves of Fig. 11 illustrate the best performance obtained thus far in any one meter as a whole by careful adjustment. The dash lines on the other hand represent the poorest performance of any of six different meters taken severally.

This would indicate that compensated meters of this type might be produced and calibrated by the customary methods of production and testing and have none of its temperature power factor registration curves outside the range bounded by the dash lines of Fig. 11, and will on the average be better.

Conclusions

To completely compensate a meter for changes in temperature two independent compensating devices are needed, one to compensate the meter at unity power factor or Group I errors and another to compensate the meter at any power factor other than unity, or Group II errors.

The compensating device found most effective for Group I errors is a permanent magnetic flux diverter mounted on a bimetal strip across the gap of the magnet

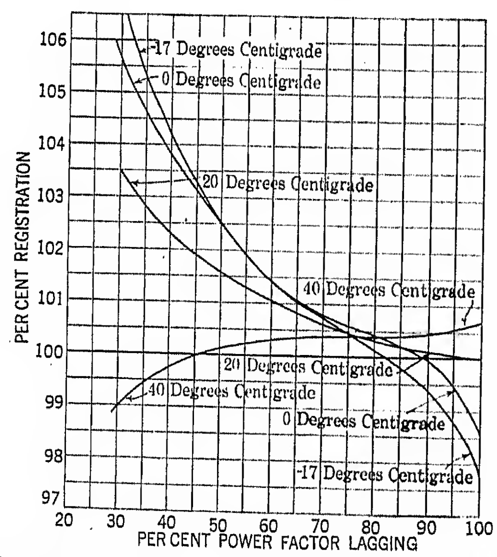

Fig. 10—Effect Upon the Typical Performance Curves of the Compensating Device for Group II Errors

in such a way that it moves in or out with decrease or increase in temperature.

The compensating method found most effective for Group II errors consisted in mounting the phasing plate on bimetal strips in such a way that it moves up or down with increase and decrease in temperature.

A meter equipped with these devices and carefully adjusted will not vary over one-half of one per cent between 100 per cent and 50 per cent power factor over a temperature range of 40 deg. cent. to −18 deg. cent. From 50 per cent power factor to 30 per cent power factor, a change of about one per cent in registration takes place. Six meters equipped with these devices did not vary more than $\pm \frac{1}{4}$ per cent at unity power factor and did not exceed ± 1 per cent at thirty per cent power factor over the above mentioned range of temperature.

It should be noticed that even this change is relatively

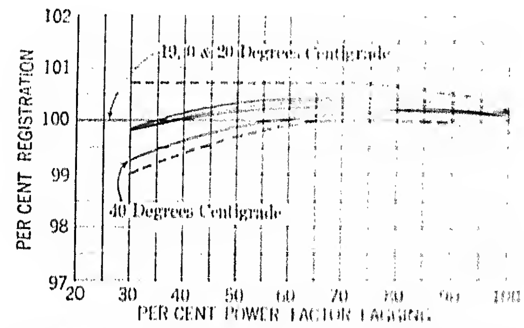

Fig. 11—Effect Upon the Typical Performance Curves of Both the Devices Properly Adjusted

small when compared to the variation in an uncompensated meter.

Ordinary handling and transportation of meters was not found to have any effect upon the compensating devices.

Appendix I

Vector Diagram of the Watthour Meter

In order to discuss the sources of temperature errors intelligently, it is necessary to have in mind the relations that exist between the many fluxes, currents, and voltages that are present in a watthour meter.

Fig. 13 shows the fluxes that are present in a watthour meter whose magnetic circuits are as shown, and with but minor modifications, will suffice for most present-day meters.

Fig. 12 shows the relative phase relations of these various fluxes, currents, and voltages.

It must be kept in mind during the discussion of these figures that they are purely theoretical, that many of the quantities shown are, from a practical point of view, negligible, and that therefore only an approximate attempt was made to draw these figures to scale.

Considering, first, the potential circuit with the lag plate removed, V is the applied voltage which causes the no-load current I_0 to flow. This current has both a core loss and magnetizing component not shown in the figure.

The current I_0 produces the flux Φ and what leakage flux exists, Φ_L. The flux Φ sets up a back e. m. f. at right angles to it, which requires the primary component E to balance it. By adding E to the voltage

drop of the potential winding, which consists of $I_0 R_1$ in phase with I_0 and $I_0 X_1$, at right angles to I_0, the diagram closes on V.

The flux Φ divides at a (see Fig. 13), into two fluxes Φ_1 and Φ_2, of which Φ_1 is much the larger, due to the low reluctance of its path as compared to that of Φ_2. However, vectorially $\Phi_1 + \Phi_2 = \Phi$ as shown in Fig. 12.

If, now, the lag plate is placed in circuit as shown, Φ_2

The currents I_2, I_2', and I_D must have a primary equivalent to balance them. This primary load current will change the position and magnitude of I_0 to I_p. This change will also change $I_0 R_1$ to $I_p R_1$, and $I_0 X_1$ to $I_p X_1$, both in magnitude and position. Assuming for the sake of simplicity that E is fixed in position and V fixed in magnitude, these changes will have the effect of moving V to V^1 and decreasing E to E^1. This decrease in E is the fallacy in the above assumption for it must be accompanied by a decrease in Φ. Even assuming that the primary equivalent to I_2, I_2' and I_D is so small that it is negligible, there is still a decrease in E due to the shifting in phase of I_0 alone. Of course a shift in I_0 the other way would produce an increase in Φ.

Of the flux Φ_2', Φ_{2L}' leaks across the gap without cutting the disk. The balance Φ_{1D} cuts the disk, inducing in it a voltage E_D which will cause eddy currents I_D to flow. The reactance of the disk will cause the current I_D to lag behind the voltage E_D thereby creating another impedance triangle composed of $I_D R_D$ and

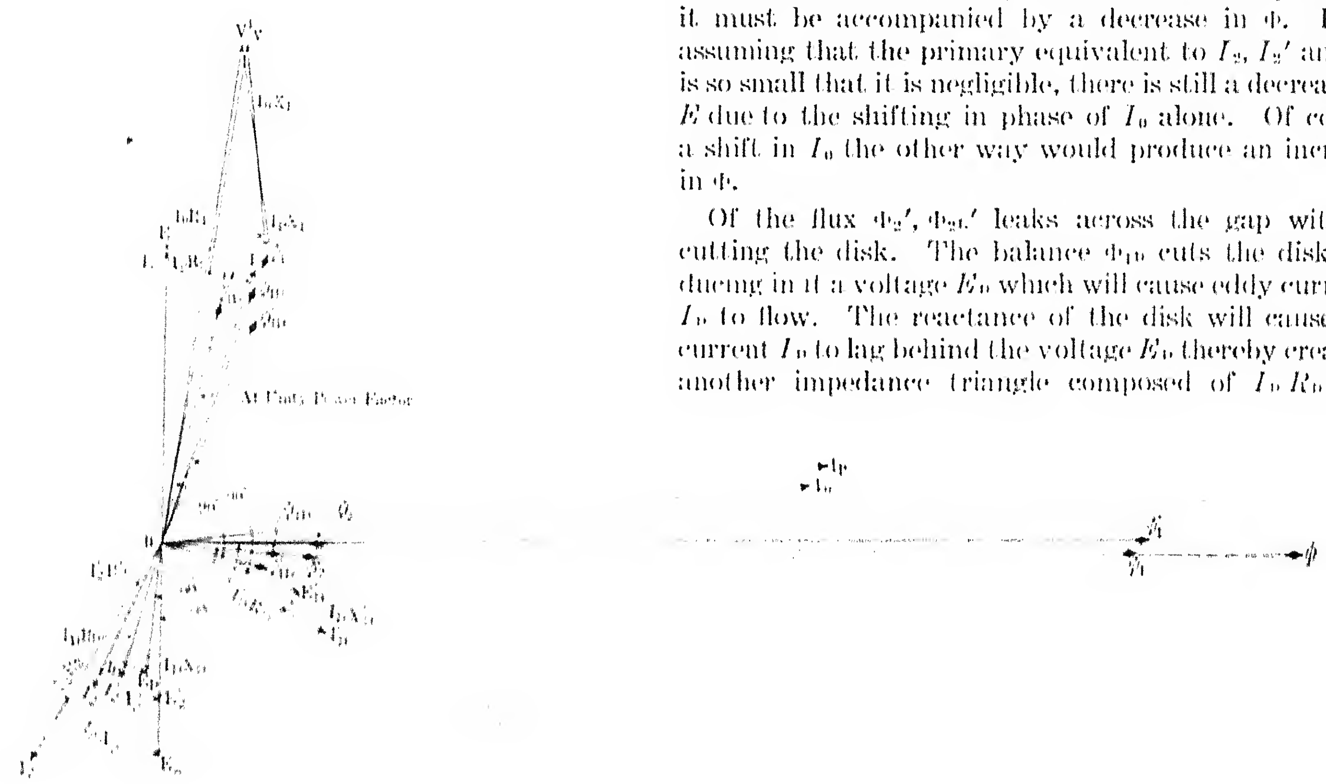

FIG. 12—A THEORETICAL VECTOR DIAGRAM OF AN INDUCTION TYPE WATTHOUR METER

will induce in it a voltage E_2. The voltage E_2 causes a current I_2 to flow. Since the lag plate is only one short-circuited turn, the voltage E_2 is used up in the $I_2 R_2$ and $I_2 X_2$ voltage drops of the lag plate.

In like manner, the flux Φ_2 will induce in the light-load plate a voltage E_2'. This voltage will cause a current I_2' to flow. Since the light-load plate is also only one short-circuited turn, the voltage E_2' will be used up in the $I_2' R_2'$ and the $I_2' X_2'$ voltage drops of the light-load plate.

The currents I_2 and I_2' will both produce a m. m. f. which when combined with the m. m. f. producing the flux Φ_2 will produce some other flux Φ_2'. Some of this change is transmitted to Φ_1, which now becomes Φ_1'. Assuming for the moment that the sum of these new fluxes, Φ_1 and Φ_2', is again vectorially equal to Φ, the relation will be shown by the heavy lines in Fig. 11. As will be pointed out later, this assumption is not quite true, but is a very close approximation[5].

5. "Theory and Operation of Split-Phase Magnet," *Electrical World*, Vol. 68, No. 21, Nov. 18, 1916.

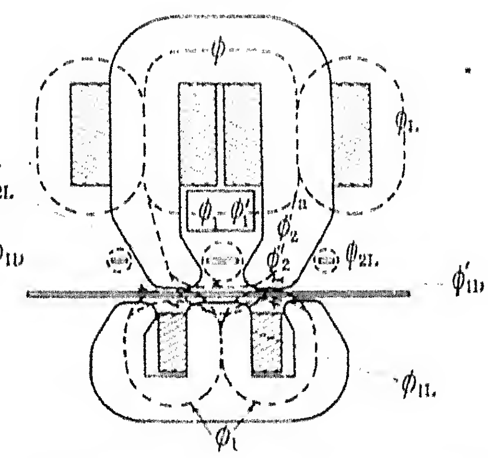

FIG. 13—FLUX DISTRIBUTION IN AN INDUCTION TYPE WATTHOUR METER

$I_D X_D$ closing on E_D. The eddy currents I_D produce a flux Φ_{1D} which reacts with the flux Φ_{2D} to produce a flux Φ_{1D}'. In other words, the disk reacts upon the potential circuit in much the same way as the lag plate and

light-load plate did. In effect it is a third secondary.

The line current I in the series coil which in general will lag behind the applied voltage V^1 by some angle θ will produce a flux Φ_I which will not be exactly in phase with I but will lag behind slightly. Part of this flux will leak across the gap. The balance Φ_{ID} will cut the disk, inducing in it an e. m. f. E_D' which sets up eddy currents I_D'. These eddy currents act in a similar way to the eddy currents I_D to produce the impedance triangle consisting of $I_D' R_D$, $I_D' X_D$, and E_D'. The flux set up by these eddy currents will react with the flux Φ_{ID} to produce the flux Φ_{ID}'. At unity power factor when I is in phase with V^1, Φ_{ID}' will take up some position as shown by the dotted line.

The process of lagging a meter places a 90-deg. relation between the flux Φ_{ID}' in its unity power factor position and the flux Φ_{1D}' by varying the magnitude of I_2.

By adding to the meter the permanent magnet circuit whose function it is to produce a drag upon the disk proportional to its speed, the circuits of the watthour meter are complete.

Appendix II

Sources of Temperature Errors

It is evident that any changes in the magnitude of the driving or dragging fluxes or in the fundamental 90-deg. relation referred to in Appendix I, will change the registration of the meter. This fact suggests a convenient grouping of the sources of temperature errors in watthour meters, Group I to contain those factors which produce a change in the magnitude of either the driving or dragging fluxes or both and Group II to contain those factors which produce a change in the phase position of the driving fluxes.

Furthermore, the effect of Group I and Group II factors will be different on an increase in ambient temperature from that on a decrease in ambient temperature and the effect of Group II factors will be different on lagging power factors from that on leading power factors. There are, therefore, four combinations possible, as follows:

Combination I—Increase in ambient temperature with lagging power factors,

Combination II—Increase in ambient temperature with leading power factors,

Combination III—Decrease in ambient temperature with lagging power factors,

Combination IV—Decrease in ambient temperature with leading power factors.

For the purpose of the following discussion, consider Combination I. Also consider each effect as existing independently of every other effect, although, of course, they will exist simultaneously in the meter.

It is well understood that an increase of temperature will produce a decrease in the permeability of magnet steel, with a consequent increase in reluctance and decrease in flux. In the case of the permanent magnet this will speed up the meter as it is the dragging flux that is reduced, but in the case of the potential and series elements it will decrease the speed of the meter, as here it is the driving flux that is decreased.

Since most permanent magnets are bent, expansion caused by an increase in temperature will tend to widen temporarily the gap between the poles. The effect of this upon the speed of the meter will depend upon the design of the drag magnet circuit. In general, it can be said that meters using the flux in the gap between the poles for their dragging effect will increase in speed while meters which use a shunted portion of this flux to produce the dragging will slow down.

The effect of an increase in temperature upon the exciting current I_0, Fig. 12, due to changes in the iron losses was determined by experimenting with a transformer and found to be two-fold. There is first a shift downward in phase position and second an increase in magnitude in such a way as to decrease the core loss component and increase the magnetizing component of I_0. As previously pointed out, the effect of the first of these is to increase the length of the vector E^1 through a shift in the impedance triangle and the second to decrease the length of this vector. These changes must be accompanied by corresponding changes in the magnitude of Φ and, therefore, the speed of the meter.

An increase in temperature will increase the resistance of the lag and light-load plates, thereby decreasing the eddy currents set up in it. This in turn will decrease choking effect of these plates upon the flux producing these eddy currents, allowing more of it to pass to the disk. This will speed up the meter.

An increase in the resistance of the potential winding will cause the exciting current to shift more nearly in phase with the applied voltage. This shift as before decreases E^1 through a shift in the voltage triangle of the potential coil. This must be accompanied by a decrease in Φ and, therefore, the speed of the meter.

In Group II, there is first an increase in the resistance of the potential winding. This will cause the speed of the meter to decrease since it causes a decrease in the 90-deg. relation between the driving fluxes.

The effect of the change both in phase position and in magnitude of the exciting current will cause the meter to decrease in speed since both tend to decrease the 90-deg. relation between the driving fluxes.

The increase in resistance of the lag and light-load plates causes a decrease in the lagging effect and a consequent decrease in the speed of the meter.

An increase in the resistance of the disk will cause a decrease in the eddy currents I_D and I_D' (Fig. 12) set up in the disk and a consequent decrease in its speed. This change, however, is balanced by a corresponding decrease in the dragging effect of permanent magnet which speeds up the disk by exactly the same amount.

Hence there is no Group I error due to the change in resistance of the disk.

An increase in the resistance of the disk will also cause

I_0 and I_0' to shift towards E_0 and E_0', respectively. This will shift Φ_{1n}' and Φ_{1o}' in the same sense, thus tending to maintain the 90-deg. relation between them.

These two fluxes do not shift by the same amount, however. Since I_0' is the only current producing a m. m. f. affecting the phase position of Φ_{1o}', its effect is more pronounced on Φ_{1n}' than is the m. m. f. of I_0 upon Φ_{1n}'. The result is a decrease of the 90-deg. relation between these two fluxes and a consequent decrease in the speed of the meter.

This effect can be demonstrated by using disks of different resistances in the same meter. In the particular experiment tried, a maximum shift in the position of the disk in the gap accounted for only 50 per cent of the change in registration due to a change in the resistance of the disk. The balance must be due to a greater shift in Φ_{1n}' than in Φ_{1o}', thereby decreasing the 90-deg. relation between them and consequently the speed of the meter. This is a Group II error.

Table I gives a summary of the above discussion using Combination I. The first seven errors comprising Group I are independent of the power factor, operate at all power factors, and are constant at any given temperature. The remaining errors comprising Group II are a minimum at unity power factor, but increase with a decrease in the power factor.

The effect of Combination II on Table I will be to reverse the effect of Group II errors, of Combination III to reverse the effect of both Group I and Group II errors, and of Combination IV to reverse the effect of Group I errors.

Since the analysis of the sources of error in this investigation is only incidental to the development of methods of compensation, not enough work was done to claim that the above discussion and the summary in Table I cover all of the possible sources of error due to temperature. For example, the effect of temperature on the light-load plate has not been considered, except as it functions as a part of the artificial lagging of the meter.

Discussion

W. H. Pratt: I think it should be emphasized that the present paper, except so far as it describes a particular mechanism for effecting compensations, is a restatement of material most effectively presented by Kinnard and Faus at the midwinter convention two years ago. Previous to that time, meters having much smaller Group II errors than those used for a background of this paper were used in predominant numbers, and since then the whole output of one of the largest producers of meters has been substantially without Group I errors. So that, presented at this time, the background of this paper must not be looked upon as a picture of general present-day practise.

The treatment of potential-circuit resistance, while perhaps not in error, tends, I think, to give a wrong impression and seems to be somewhat of an apology for high resistance in the potential circuit, whereas it was shown beyond peradventure in the Kinnard-Faus paper that resistance in the potential circuit is the outstanding source of Group II errors. Of course it is not possible to produce meters with zero resistance in the potential circuit, but this is not necessary. It is quite possible to make meters with a resistance so low that the use of manganin lag plates is convenient and the residual Group II errors are of almost vanishing value.

The results shown in Fig. 11 of the paper are excellent, but it appears that they are the results of painstaking individual adjustment. At present meters are in use which, however, even surpass this Fig. 11 performance, not as the result of adjustment but by reason of proper regard taken in the design of the various sources of error. They are inherently without errors exceeding 0.2 or 0.3 per cent, within the limits of application ordinarily prevalent. To be sure, they are portable test meters, though similar meters for switchboard use arranged for connection to 2-stage current transformers are also in service. Incidentally, manganin lag plates are used in these meters. It does not appear that the author advocates for general use the forms of compensation he describes. It seems that it would be necessary to use them with great caution, for there must be an ever present menace of maladjustment and disarrangement. Be that as it may, were I to venture a prediction in regard to future meter practise, I should say that in all probability in the not distant future, meters which have temperature characteristics not greatly inferior to the best performance here shown will be in general and extensive use.

As pointed out in the Kinnard-Faus paper, sources of error should be eliminated, and only when further elimination is impossible should recourse be had to compensation.

B. J. Brown: In regard to the paper by Mr. Canfield, how long have these compensating devices been in use? Time shows any small mechanical troubles, and often time only will develop them.

I. F. Kinnard: In my opinion, the most outstanding feature of the paper is the fact that the conclusions reached by Mr. Canfield agree substantially with the findings made by Mr. Faus and myself several years ago, in so far as classification of temperature errors into two distinct groups is concerned.

It is rather unfortunate that Mr. Canfield's analysis is entirely qualitative, since the listing of so many errors as he shows in Table I is likely to be misleading and does not give any sort of an idea as to just how important each error is from the standpoint of the meter's operation. In looking down this list, we see under Error 1, "Changes in the magnetic properties of the permanent magnet." As a matter of fact, this is by far the greatest source of Group I errors with which we have to contend. The other six errors listed under this group are of very little practical importance. We have determined this from exhaustive tests on a large number of meters, by means of which was made a quantitative study of the magnitude of the various errors involved. This error due to the changes in the magnetic properties of the permanent magnet with temperature, is something that is quite fundamental and cannot readily be eliminated. It therefore seems feasible to use some sort of a compensating device in order to keep the braking flux constant over wide variations in temperature.

Now in regard to Class II, errors or those errors which cause a shifting in the phase relationship of fluxes with variations in temperature; Mr. Canfield has given an exhaustive list of possible sources of error of this nature. I have found, however, that there is only one really important source of error of this nature with which we have to contend, one which not only causes a shifting in phase relationship of fluxes with varying temperatures but which is reflected in various other factors of the meter's performance. I am speaking of the resistance of the potential windings. In an ideal meter, we should have all reactance and no resistance in the potential windings; that is, we want the flux to be in quadrature with the applied voltage. If it is not, we have to use some sort of a device to "lag" the useful portion of this flux through a small angle, with which all meter men are familiar. The only practical reason, therefore, for our having to put up with temperature errors of this nature is the existence of resistance in the potential windings.

I say this without hesitation, because meters are in actual service in which the potential coil resistance has been reduced to the point where the lagging can be accomplished by means of a manganin lag plate and the resulting errors are no longer of any commercial or practical importance whatsoever.

It is true that the compensation for both Class I and Class II errors, which the author has described in this paper, will work providing everything is in very nice adjustment, and he should be complimented on this solution. As someone has mentioned in a previous discussion, however, the real way to get rid of errors of any kind is to eliminate them at their source rather than use a compensation whereby it is endeavored to force two wrongs to make a right.

A. R. Rutter: The paper presented by Prof. Canfield is of great value, I think, not only in adding additional data to our literature on the watthour meter by discussing the temperature compensation, but by discussing the vector diagrams of the induction type watthour meter in dealing with the various vectors of eddy currents, of fluxes and of the current, and of voltage. The induction type watthour meter is usually regarded as a very mysterious piece of apparatus, so that a paper which presents a good analysis of the performance of the meter is a real addition to the literature on the subject.

Prof. Canfield refers to Fig. 6 of the paper and states that the results obtained in using a method of compensating for the Class II errors by lagging both the current and voltage fluxes gives a slight improvement for these errors. I think it is possible to interpret from his curves in Fig. 6 that if the compensation for Class I errors, (which are shown in his Fig. 8) were added to the compensation for Class II errors (as shown in Fig. 6), it should produce a very well compensated meter. I am familiar with results of this method, which produced meters which were carefully compensated for Class II errors by lagging both the current and voltage fluxes. This method has the advantage that compensation is obtained by changes in material and not by shifting mechanical parts.

C. T. Wallis: I have been working with alloys which change their magnetic properties with temperature, and observations over a period of about seven years have shown these to be very constant indeed.

With regard to the use of bi-metallic compensators which depend upon the expansion and contraction of two dissimilar metals these are rather erratic in their action. Considered strictly from a mass-production standpoint the air-gap between the magnet and the shunt which is carried on the bi-metallic strip must be adjusted very carefully at some definite temperature. On the other hand, the use of a permanently fixed magnetic shunt which changes its properties with temperature has none of the above disadvantages.

D. T. Canfield: In reply to Mr. Brown's question, I should like to say that the meters described in my paper have not been in commercial use at all. They have been used in my laboratory, however, for a matter of 2.5 or 3 years.

As Mr. Kinnard points out, I have no method other than a guess in my process of analysis of determining the relative magnitude of the several errors mentioned in Table I. I have no doubt whatever as to the overall error of the meter as a whole. That has been very definitely determined by me on all makes of meters a number of times, so that I do know, and did know at the time that this work was started, the amount of overall error that actually existed.

I claim that this resultant effect, in the last analysis, is the important feature. It is instructive and interesting only more in an academic way than in a practical way to analyze this overall error into its several component parts, and that is why I made no attempt to do it quantitatively.

As Mr. Pratt points out, the ideal way to eliminate error is to do away with the source of error, but as he also points out, it is not possible to eliminate the errors completely in this way. No claim is made in my paper that the method of compensation used by me is the only one. In fact, my Fig. 5 shows that the method proposed by Mr. Pratt is effective in reducing Group II errors.

Mr. Rutter's remarks concerning Fig. 6 and the method of compensation therein illustrated are well founded. The particular meter used in this experiment was of an obsolete variety which had the desired compensation as far as Group II errors were concerned but was decidedly off on Group I errors. As far as this figure is concerned the compensation of Group I errors would not materially affect the slope of the curves.

This does not detract, however, from the merits and advantages of this method of compensation. It is necessary only to obtain the proper proportion of the counteracting lagging devices to give theoretically perfect performance.

As Mr. Wallis points out, it is necessary to carefully form and age the bi-metal strips used on the compensating devices. When this is done, I have found no indication of subsequent change.

Current Analysis in Circuits Containing a Resistance Modulator

BY L. S. GRANDY[1]

Associate, A. I. E. E.

Synopsis. *The function of a resistance modulator is to produce in an electric circuit a current which is a copy of an exciting impulse such as speech or light waves. The principal example is the carbon granule telephone transmitter.*

It is desirable that the electric current be an exact copy of the exciting impulse. There is inherent in such a device however, a distorting effect, for the current copy is produced by reason of Ohm's law and thus is an inverse function of the modulated resistance and not a true copy of it. The amount of distortion arising from this effect depends upon the electrical constants of the modulator and its associated circuit.

The study quantitatively analyzes this distorting effect by two methods in a circuit containing a modulator, a battery, and a resistance for single frequency modulation, and by one of the methods for double frequency modulation. An analysis is also developed for a special test circuit.

The study shows that the relation between modulators and circuits is a design problem.

Introduction

In the sense used in this study a modulator is a device used to transform electrical energy supplied to it into a time copy of a desired mechanical impulse or so to modulate an electrical current that the result will be an electrical copy of an exciting wave. The exciting impulse may be any function of time. If the current to be modulated is supplied by a constant difference of potential it may be modulated by introducing into the circuit either a resistance or an electromotive force varying in accordance with the exciting impulse. The result will be a modulated current by reason of Ohm's law. The present subject is limited to modulation by the resistance method.

Two applications of the resistance modulator are the carbon-granule telephone transmitter and the selenium light-sensitive cell. Either of these pieces of apparatus forms a unit in a system which fails to transmit perfectly the exciting wave. In the case of the telephone, the characteristics of the speech input are not faithfully reproduced in the sound output at the receiver. The difference in characteristics or quality is termed distortion.

In order to perform a useful function a resistance modulator must be provided with a transmitting system that will cause the exciting wave to act on the resistance unit, and this system always causes distortion. Again using the carbon transmitter to illustrate; distortion of the voice wave occurs in the air transmission leading up to the button diaphragm because of mechanical characteristics of an air column, in the diaphragm because of its own mechanical qualities combined with clamping difficulties and in the carbon because of its mechanical behavior and because carbon does not have a linear pressure-resistance relation. However, these causes of distortion are all subject to modifications which will diminish such distortion.

For the purpose of the study a perfect resistance modulator is assumed. The resistance element gives a change of resistance which is an exact copy of the exciting wave. Thus the assumed perfect modulator represents the limit in quality which improved materials and design may produce in such a device. But, a resistance modulator gives a current wave in the output circuit which in form is an inverse function of the exciting wave and not a true copy of it. The result is distortion, such distortion being inherent in the nature of the device. In order to analyze the effect quantitatively, an exciting wave following the sine law is assumed. By assumption it produces a corresponding wave of resistance modulation. Then the resistance of the modulator will be a constant quantity plus the modulating resistance and may be written:

$$R_0 + r \cos \omega t.$$

The distortion effect is graphically illustrated in Fig. 1.

The amount of distortion occurring in a transmitting circuit due to modulation is determined by both the modulator and circuit electrical constants. The study contemplates a critical analysis of the modulated current from the quality standpoint. The usual method of analysis by harmonic components has been employed.

Simple Series Resistance Circuit

(First Development. Single Frequency)

Considering the most simple possible circuit, a battery, a resistance, and a modulator in series.

Equation,

$$i = E/(R_x + R_0 + r \cos \theta)$$

Let

$$R_x + R_0 = R \text{ and } r/R = K$$

By simple division:

$$i = E/R \{ 1 - K \cos \theta + K^2 \cos^2 \theta - K^3 \cos^3 \theta + K^4 \cos^4 \theta + \ldots \}$$

The series converges. Proof

$$U_{n+1} < U_n \text{ and } L_{n \succ \infty} U_n = 0$$

$$U_{n+1} = (r/R)^{n+1};\ U_n = (r/R)^n;\ (r/R)^{n+1} < (r/R)_n \text{ if } r < R$$

Also

$$L_{n \succ \infty} (r/R)^n = 0 \text{ if } r < R$$

1. University of Missouri, Columbia, Mo.

Note: Since this paper was written, the study has been extended to the series circuit containing resistance and inductance.

Presented at the Regional Meeting of District No. 7 of the A. I. E. E., Kansas City, Mo., March 17-18, 1927.

which is true always since the modulating resistance must be less than the total resistance.

Expanding: Whole expansion to be multiplied by E/R

Constant: $1 + K^2/2 + 3\,K^4/8 + 5\,K^6/16 + 35\,K^8/128 + 63\,K^{10}/256 + \ldots$

Fundamental: $-\cos\theta\,(K + 3\,K^3/4 + 5\,K^5/8 + 35\,K^7/64 + 63\,K^9/128 + \ldots)$

2nd Harmonic: $\cos 2\,\theta\,(K^2/2 + K^4/2 + 15\,K^6/32 + 7\,K^8/16 + 105\,K^{10}/256 + \ldots)$

3rd Harmonic: $-\cos 3\,\theta\,(K^3/4 + 5\,K^5/16 + 21\,K^7/64 + 21\,K^9/64 + \ldots)$

4th Harmonic: $\cos 4\,\theta\,(K^4/8 + 3\,K^6/16 + 7\,K^8/32 + 15\,K^{10}/64 + \ldots)$

5th Harmonic: $-\cos 5\,\theta\,(K^5/16 + 7\,K^7/64 + 9\,K^9/64 + \ldots)$

6th Harmonic: $\cos 6\,\theta\,(K^6/32 + K^8/16 + 45\,K^{10}/512 + \ldots)$

7th Harmonic: $-\cos 7\,\theta\,(K^7/64 + 9\,K^9/256 + \ldots)$

8th Harmonic: $\cos 8\,\theta\,(K^8/128 + 5\,K^{10}/256 + \ldots)$

9th Harmonic: $-\cos 9\,\theta\,(K^9/256 + \ldots)$

10th Harmonic: $\cos 10\,\theta\,(K^{10}/512 + \ldots)$

Each harmonic becomes an infinite series; hence an approximation. The expansion of a power of the cosine results in a single term for every even or for every odd harmonic starting with the same numbered harmonic as the power developed and going on down to the fundamental if an odd power or to the constant term if an even power. Thus in the expansion given the series become more approximate by twos.

From this solution a very clear mental picture of the process of modulation may be gained. The fundamental or first harmonic is the result of the direct current flowing across the varying resistance of the modulator, the second harmonic, and the second constant term result from secondary modulation, that is, the fundamental flowing through the modulating resistance. Thus by reason of the eighth harmonic there arises the first term of the ninth series, the second term of the seventh, the third term of the fifth, the fourth term of the third, and the fifth term of the first series.

Simple Series Resistance Circuit

(First Development—Double Frequency)

Equation

$$i = E/(R_x + R_0 + r_1 \cos\alpha + r_2 \cos\theta)$$
$$= E/(R + r_1 \cos\alpha + r_2 \cos\theta)$$
$$= E/R\,[1/1 + K_1 \cos\alpha + K_2 \cos\theta]$$

Where

$$\alpha = 2\,\pi f_1 t \text{ and } \theta = 2\,\pi f_2 t$$

By division:

$$i = E/R\,[1 - (K_1\cos\alpha + K_2\cos\theta) + (K_1\cos\alpha + K_2\cos\theta)^2 - (K_1\cos\alpha + K_2\cos\theta)^3 + (K_1\cos\alpha + K_2\cos\theta)^4 + \ldots]$$

Writing in harmonic components: (Fourth order modulation)

The whole expansion must be multiplied by E/R.

$$1 + K_1^2/2 + K_2^2/2 + 3\,K_1^4/8 + 3\,K_2^4/8 + 3\,K_1^2 K_2^2/2$$
$$- [K_1 + 3\,K_1^3/4 + 3\,K_1 K_2^2/2]\cos\alpha$$
$$- [K_2 + 3\,K_2^3/4 + 3\,K_1^2 K_2/2]\cos\theta$$
$$+ [K_1^2/2 + K_1^4/2 + 3\,K_1^2 K_2^2/2]\cos 2\,\alpha$$
$$+ [K_2^2/2 + K_2^4/2 + 3\,K_1^2 K_2^2/2]\cos 2\,\theta$$
$$- [K_1^3/4]\cos 3\,\alpha - [K_2^3/4]\cos 3\,\theta + [K_1^4/8]\cos 4\,\alpha$$
$$+ [K_2^4/8]\cos 4\,\theta$$
$$+ [K_1 K_2 + 3\,K_1^3 K_2/2 + 3\,K_1 K_2^3/2]\cos(\alpha + \theta)$$
$$+ [K_1 K_2 + 3\,K_1^3 K_2/2 + 3\,K_1 K_2^3/2]\cos(\alpha - \theta)$$
$$- [3\,K_1^2 K_2/4]\cos(2\,\alpha + \theta) - [3\,K_1^2 K_2/4]\cos(2\,\alpha - \theta)$$
$$- [3\,K_1 K_2^2/4]\cos(2\,\theta + \alpha) - [3\,K_1 K_2^2/4]\cos(2\,\theta - \alpha)$$
$$+ [K_1^3 K_2/2]\cos(3\,\alpha + \theta) + [K_1^3 K_2/2]\cos(3\,\alpha - \theta)$$
$$+ [K_1 K_2^3/2]\cos(3\,\theta + \alpha) + [K_1 K_2^3/2]\cos(3\,\theta - \alpha)$$
$$+ [3\,K_1^2 K_2^2/4]\cos(2\,\alpha + 2\,\theta)$$
$$+ [3\,K_1^2 K_2^2/4]\cos(2\,\alpha - 2\,\theta)$$

This development is the explanation for sub-frequencies and odd multiple frequencies in the output circuit of a resistance modulator even though the instrument be acted upon by pure waves. These odd frequency components of current may become quite large. Assuming constants of $E = 12$, $r_1 = 80$, $r_2 = 20$, $R_0 = 100$, and $R_x = 100$ where r_1 is associated with the frequency f_1, giving the time angle α and r_2 is associated with the time angle θ, a current i will flow equal to $65.82 - 24.32\cos\alpha - 7.49\cos\theta + 5.71\cos 2\,\alpha + 0.45\cos 2\,\theta + 2.98\cos(\alpha + \theta) + 2.98\cos(\alpha - \theta) - 0.72\cos(2\,\alpha + \theta) - 0.72\cos(2\,\alpha - \theta) + \ldots$ where the values are in milliamperes.

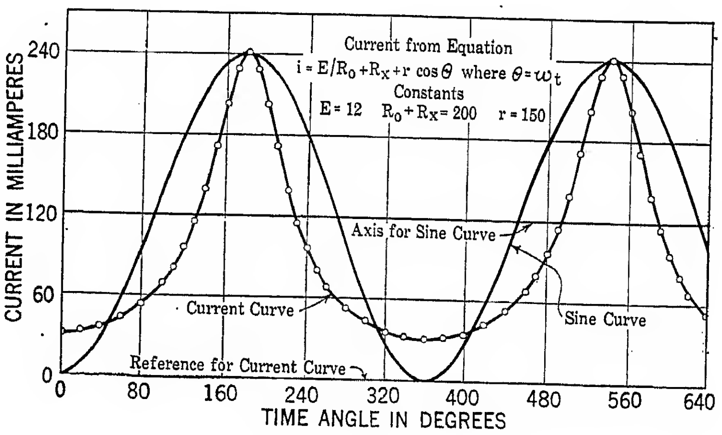

Fig. 1

A particularly valuable feature of mixed frequency modulation analysis is that it offers the possibility of measuring distortion in an actual instrument. By exciting an instrument with two pure waves of known magnitudes and with frequencies prime to each other and measuring one of the combination frequencies in the output and comparing with the calculated value a definite knowledge of what the instrument has done may be gained.

Simple Series Resistance Circuit

(Second Development)

Equation

$i = E/(R_0 + R_x + r\cos\theta)$

$\quad = E/R\,[1/(1 + K\cos\theta)]$ where $r/R = K$

Examining for the constant term of a harmonic series:

Constant

$$= E/R \cdot \frac{1}{2\pi}\int_0^{2\pi} d\theta/(1 + K\cos\theta) = E/R\,[1/\sqrt{1-K^2}]$$

Examining for the coefficient of the nth harmonic:

$$A_n = E/R \cdot \frac{1}{\pi}\int_0^{2\pi} \frac{\cos n\theta}{1 + K\cos\theta} \cdot d\theta$$

$$= E/R\,\frac{2(-1)^n}{\sqrt{1-K^2}}\left[\frac{1-\sqrt{1-K^2}}{K}\right]^n$$

Writing the series:

$$i = E/R\left\{1/\sqrt{1-K^2} - 2/\sqrt{1-K^2}\left[\frac{1-\sqrt{1-K^2}}{K}\right]\cos\theta\right.$$

$$+\frac{2}{\sqrt{1-K^2}}\left[\frac{1-\sqrt{1-K^2}}{K}\right]^2\cos 2\theta$$

$$-\frac{2}{\sqrt{1-K^2}}\left[\frac{1-\sqrt{1-K^2}}{K}\right]^3\cos 3\theta$$

$$\left. + \ldots \frac{2(-1)^n}{\sqrt{1-K^2}}\left[\frac{1-\sqrt{1-K^2}}{K}\right]^n\cos n\theta\right\}$$

Sample calculation:

Assumed constants:

$R = 200$ ohms, $r = 80$ ohms, and $E = 12$ volts.

Writing current in milliamperes:

$i = 65.4666 - 27.364788\cos\theta + 5.719110\cos 2\theta$
$\quad - 1.195278\cos 3\theta + .249818\cos 4\theta - .052216\cos 5\theta$
$\quad + .010912\cos 6\theta - .002281\cos 7\theta + .0004767\cos 8\theta$
$\quad - .00009964\cos 9\theta + .00002082\cos 10\theta + \ldots$

Dropping the constant term and writing the harmonics in per cent of the fundamental:

$i = -100\cos\theta + 20.90\cos 2\theta - 4.37\cos 3\theta + .914\cos 4\theta$
$\quad - .191\cos 5\theta + .0399\cos 6\theta - .00834\cos 7\theta + \ldots$

Fig. 2 illustrates the manner in which the first three distorting harmonics change relative to the fundamental when modulator and circuit constants remain the same but the degree of modulation, *i. e.*, r, changes. Calculations were based upon the same assumed constants as in the example above with r changing in value from zero to 190 ohms. The latter value represents nearly complete modulation of all resistance in the circuit. Complete modulation is the limit which may be approached. It is interesting to note that if complete modulation could be realized all harmonics would be present and equal in value.

Fig. 3 is similar to Fig. 2. in that it shows the manner of variation of the first three distorting harmonics relative to the fundamental but with R_x, the resistance of the circuit external to the modulator, as the variable and the modulating resistance r held constant at 100.

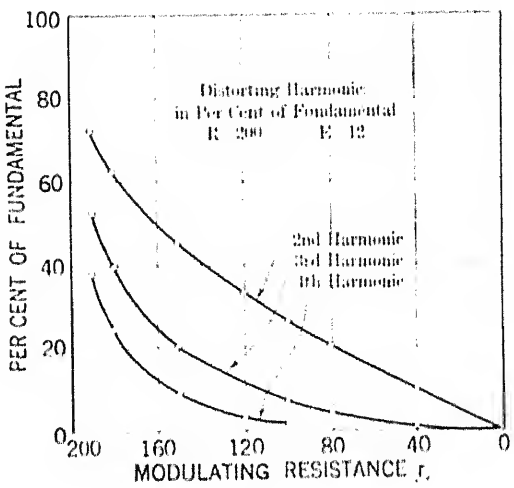

Fig. 2

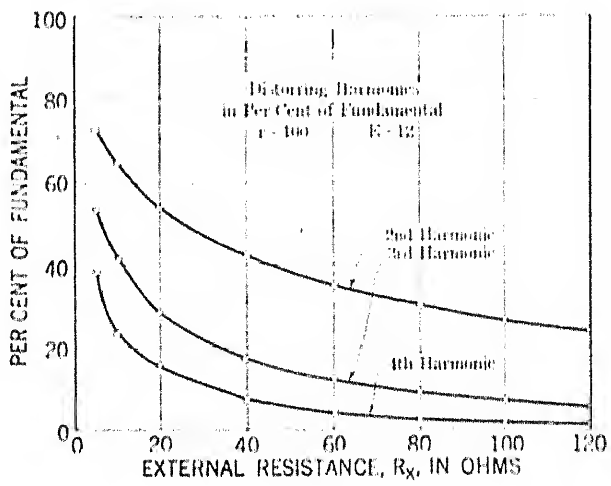

Fig. 3

R_0 is held at 100. As R is the sum of R_0 and R_x it must change. It may be noted that the division of the total circuit resistance between the modulator and the external circuit is of no consequence except that r is limited by R_0.

Diminution Factor in Simple Series Circuits

The equation of the current was found to be:

$$i = E/R\left\{1/\sqrt{1-K^2} - 2/\sqrt{1-K^2}\left[\frac{1-\sqrt{1-K^2}}{K}\right]\cos\theta\right.$$

$$+\frac{2}{\sqrt{1-K^2}}\left[\frac{1-\sqrt{1-K^2}}{K}\right]^2\cos 2\theta$$

$$-\frac{2}{\sqrt{1-K^2}}\left[\frac{1-\sqrt{1-K^2}}{K}\right]^3\cos 3\theta$$

$$+ \ldots \frac{2(-1)^n}{\sqrt{1-K^2}}\left[\frac{1-\sqrt{1-K^2}}{K}\right]^n \cos n\,\theta$$

From an examination of the equation it is seen that each succeeding harmonic differs in magnitude from the preceding harmonic by the multiplying factor $[1-\sqrt{1-K^2}]/K$. Since K is the ratio of modulating resistance to the total circuit resistance it is always less than one and approaches one as its limit. Thus the multiplying factor is also always less than one approaching one as its limit and accordingly for the purpose of this discussion has been termed a diminution factor.

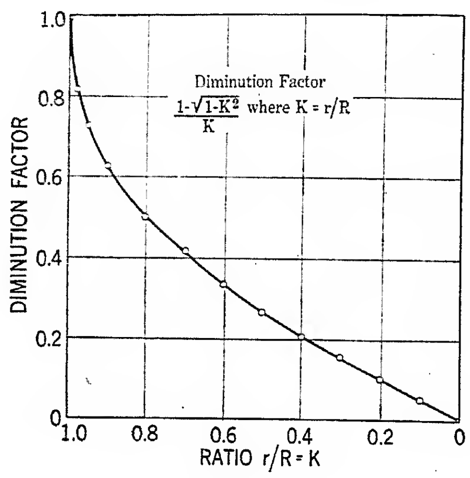

Fig. 4

The factor describes the quality of an operating circuit by giving the magnitude of the second which is the first distorting harmonic relative to the fundamental. The sum of the distorting harmonics compares with the fundamental as $(C + C^2 + C^3 + \ldots C_n)$ compares with one. As the argument of the diminution factor is K the criterion of quality in a circuit is the ratio of r to R. In Fig. 4 the diminution factor has been plotted against the ratio.

Test Circuit

A circuit of special interest for test purposes, because the direct and alternating components of current are separated, is one consisting of a battery, a heavy inductance unit, and a modulator all in series and with a circuit consisting of a large condenser connected in series with a resistance unit in parallel with the modulator. The circuit is shown in Fig. 5. In order to effect an analysis an assumption is made, that no alternating current can flow in the battery circuit because of a preponderately heavy inductance and that no direct current can flow in the receiving circuit because of the condenser. The condenser is made so large that it imposes no appreciable impedance to alternating currents of frequencies dealt with. Although not rigorously true the assumption can be closely approached in a test circuit.

The voltage across the modulator may be written:

$$V_0 + v = (I_0 + i)(R_0 + r\cos\theta)$$

From Kirchoff's law $v = -\,i\,R_x$

Substituting and solving:

$$i = \frac{V_0 - I_0(R_0 + r\cos\theta)}{R_0 + R_x + r\cos\theta}$$

The mean voltage across the modulator may be arrived at in terms of the steady current flowing and the circuit constants. Solving the first equation for v:

$$v = R_x\,\frac{(V_0 - I_0 R_0) - I_0\,r\cos\theta}{R_x + R_0 + r\cos\theta}$$

Summing up v over a complete cycle, setting the result equal to zero, and solving for V_0 there results:

$$V_0 = I_0\,\{\sqrt{(R_0+R_x)^2 - r^2} - R_x)\,\}$$

The equation for current may be simplified by transformation to:

$$i = \frac{\dfrac{V_0 + I_0 R_x}{R_0 + R_x}}{1 + (r/R_0 + R_x)\cos\theta} - I_0$$

$$= \frac{A}{1 + B\cos\theta} - I_0$$

The form of the equation is the same as that for the series resistance circuit except for a subtracting constant. The same methods may be used to expand it into harmonic series with the same characteristic results as were used for that circuit. Similar relations exist between harmonics. Using the second method the equation for current is:

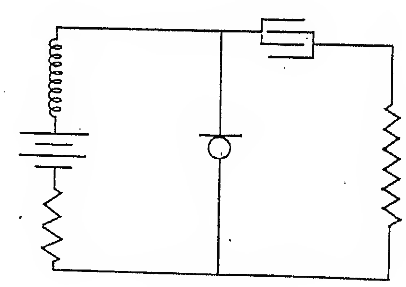

Fig. 5

$$i = \frac{A}{\sqrt{1-B^2}} - I_0 - \frac{2A}{\sqrt{1-B^2}}\,\frac{(1-\sqrt{1-B^2})}{B}\cos\theta$$

$$+\frac{2A}{\sqrt{1-B^2}}\,\frac{(1-\sqrt{1-B^2})^2}{B^2}\cos 2\theta + \ldots$$

Table of Symbols

R_0 = Average value of modulator resistance or value about which modulation occurs.

R_x = Resistance of receiver circuit.

R = $R_0 + R_x$.

r = Modulating resistance.

θ = $\omega t = 2\pi f t$ = Time angle in terms of frequency and time.

E = Battery electromotive force.
i = Current in receiving circuit.
α = $\omega t = 2\pi f t$ = Time angle with $f \neq$ to f in θ.
K = r/R.
V_0 = Constant component of modulator voltage.
v = Variable component of modulator voltage.
I_0 = Direct current.
C = Diminution factor = $[1 - \sqrt{1 - K^2}]/K$.

Discussion

R. M. Kerchner: It seems to me that some of Mr. Grandy's statements, while not incorrect, may be a little misleading, while some assumptions are made that exaggerate the poor qualities of the transmitter.

The statement that the current output wave is an inverse function of the exciting wave, while I think it is true, is, however, likely to give a wrong physical conception. Physically, the qualitative results of the exciting wave are similar to those of the output wave, that is, when the exciting wave has a high value the output wave has also a high value and similarly with low values. From his statement we might get the idea that if the output wave is an inverse function of the exciting wave, the output wave is small when the exciting wave is large, and vice versa. Technically, however, Mr. Grandy's statement, I think, is correct.

I disagree, however, with the statement that distortion is due to the fact that the pressure resistance relation of the carbon-granule transmitter is not linear. It is by assuming that this relation is linear that the results tend to magnify the distortion due the output current being an inverse function of the exciting wave. As a matter of fact, if the pressure-resistance relation were a rectangular hyperbola and there were no resistance outside of that in the transmitter, the output wave would be a true image of the exciting wave, mechanical distortion neglected. This is shown as follows.

Let p be the pressure on the diaphragm at any time.

Let p_0 be the pressure about which the pressure variation occurs.

According to the assumption $r\,p = c$

$$r = \frac{c}{p}$$

Assuming a sinusoidal exciting wave the pressure would be $p = P_0 + p_0 \sin\theta$ where p_0 is the modulating pressure.

Hence

$$r = \frac{C}{p} = \frac{C}{P_0 + p_0 \sin\theta}$$

and

$$I = \frac{E}{r} = \frac{E(P_0 + p_0 \sin\theta)}{C} = \frac{E\,P_0}{C} + \frac{E}{C}\,p_0 \sin\theta$$

which shows the output wave to be of the same form as the exciting wave if the pressure resistance relation is a rectangular hyperbola, hence not linear. That the relation is actually a curve of the same general trend as a rectangular hyperbola, namely, concave upward, can be seen by a consideration of the limits of the resistance as the pressure is 0 and become infinite.

Actually, however, distortion will also exist with such a relation since the whole curve is shifted upward by an amount depending on the constant resistance in the circuit of the transmitter. Under these conditions it can be shown that the current wave due to a sinusoidal exciting wave would be

$$I = \frac{E(P_0 + p_0 \sin\theta)}{R_x P_0 + R_x p_0 \sin\theta + C}$$

which on account of the second term in the denominator will not give a pure sine wave.

From this it can be seen that the ideal condition would be to have the pressure-resistance relation of the transmitter follow the law of a rectangular hyperbola, with no resistance in the exterior circuit instead of a linear relation as Mr. Grandy implies. This, I believe, explains in part the fact that the distortion actually realized is not as great as might be suspected from simply an analysis of the expression $\dfrac{E}{R_x + R_0 + r\cos\theta}$ given in Mr. Grandy's paper.

The conclusion that might be inferred from this discussion is that a transmitter that varies the e. m. f. in the circuit would lend itself more readily to production of distortionless output waves. This suggests that the magneto transmitter operates on a principle that underlies distortionless reproduction of diaphragm variations.

L. S. Grandy: Commenting on Mr. Kerchner's discussion; the original statement, that the current wave in the output circuit is an inverse function of the exciting wave, is misleading if not wrong. It was intended to state that the current wave is an inverse function of the modulating resistance.

A linear pressure-resistance relation was assumed to be ideal because any other relation would mean the introduction of harmonics into the variations of the modulating resistance so that resistance change would not be a copy of the exciting wave. Mr. Kerchner has shown that if a rectangular hyperbolic pressure-resistance relation could be realized, an instrument, in an hypothetical case, could be made to produce an output current wave that would be a true image of the exciting wave and that such a pressure-resistance law would permit the building of instruments that would presumably materially reduce distortion.

It is thought probable that for every combination of circuit and modulator constants there exists a law of pressure-resistance change that would produce distortionless reproduction of the exciting cause or at least, permit a reproduction with a minimum of distortion. Upon the linear assumption a diminution factor was defined as that factor which gives the relative magnitude of each succeeding harmonic relative to the preceding. Distortionless reproduction would be attained if the diminution factor was made zero. Referring to Fig. 4, such a situation would be approached if R, the resistance of the output circuit, was made very large in proportion to the modulating resistance r. This is the condition under which the carbon radio microphone operates as its output is impressed upon a vacuum-tube circuit of very high impedance. Thus the linear pressure-resistance relation becomes the perfect relation for that particular combination of modulator and circuit constants. As the carbon microphone gives very excellent results from the quality standpoint and as such results depend upon a linear relation it is thought that the pressure-resistance law for carbon must not depart very far from the linear form. It is true as Mr. Kerchner points out that at limiting conditions the law for carbon must depart from the linear form, but for pressures actually used, limiting conditions are not likely to be encountered. The pressures involved are of a very low order of magnitude. The writer has had other evidence that, while not at all conclusive, was strongly suggestive of the linear relation for carbon.

A magneto type, or a condenser type of modulator is very desirable from the quality standpoint. As pointed out in the first paragraph of the paper, such an instrument modulates current supplied to it by voltage changes in the circuit making the modulated product a direct function of the modulating change. However, it is impossible to get enough energy from the exciting cause into such an instrument to produce modulated currents of a magnitude that can be used in most applications. On the other hand the carbon instrument acts as a modulator and a very large amplifier at the same time.

Cab Signals for Railway Signaling

BY T. S. STEVENS[1]

Synopsis.—There is described in this paper a system of continuous signals operating within the cab of a railway locomotive. This system was developed in an effort to provide more reliable and safer signals than the common semaphore or light signals. The particular type of system is called the three-speed, continuous-control signal system. It has been adopted quite extensively by the Atchinson, Topeka, and Santa Fe Railway System.

* * * * *

PROBABLY every signal engineer has worried about the difficulty of placing wayside signals on a railroad so that they can be seen and the indication properly read at a sufficient distance for proper control of the train. There are two forms of wayside signals, the semaphore and daylight light signal. The first displays its indications by a movable arm attached to a mast. The second displays its indications by colored lights which, by virtue of special lenses, can be seen in ordinary day light at sufficient distance. Particularly with semaphores, the question of background is very essential. It is not quite so essential in connection with light signals, but even with these devices it is often difficult to place signals on a crooked piece of track so that there will be sufficient view of them. Fog is another agent which interferes to a great extent with a view of semaphores and with a view more or less of light signals; although in a fog, a light signal can be seen much the farther.

Then again any form of wayside signal is only intermittent in its indication. A train arrives at a signal which is displaying a certain indication. It passes it and the indication is lost except in the memory of the the engineman.

Thus, many years ago, we dreamed of the possibility of having a signal right ahead of the engine which would change under changing conditions or continuously display the same indication if the condition did not change. Much research work was accomplished and ultimately it was found possible, through means of practically wireless circuits, to provide a signal in the cab of the engine which would keep the engineman informed continuously of the condition ahead regardless of whether he was moving or standing still.

The type of cab signaling adopted by the Santa Fe is generally called *Three-speed continuous control.* It employs no wayside signals and all information is obtained from the signals in the engine cab.

Fig. 1 indicates a train proceeding along the track receiving a high-speed indication from the track ahead. Directly at the rear of the train, a zone of low-speed control is set up and just behind that, a zone of medium-speed control, so that a train following will receive a medium-speed indication and then a low-speed indication over sufficient length of track so that it can easily be brought to rest before getting within dangerously close proximity of the first train.

The three-speed, continuous control system necessarily requires the establishment of three different electrical conditions in order to provide the three controls. These three conditions are brought about by the proper control of a-c. circuits in the rails which establish magnetic fields around the rails and affect receiving apparatus mounted at the front and rear of the locomotive. The energy picked up by these receivers is amplified in two stages and used to operate the engine relay on the locomotive.

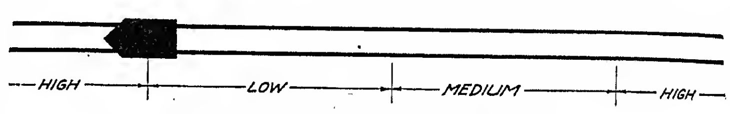

Fig. 1—Automatic Train Control

The railroad tracks are divided into track sections, or "blocks," by insulated joints located approximately 4000 ft. apart. Each section is equipped with an individual set of controlled circuits, two separate circuits being used as follows:

Fig. 2 shows the circuits mentioned above. *A* is the "Track Circuit" in which a small transformer feeds current into the rails, and this is received at a track relay at the other end of the section. The current in the track circuit flows through a limiting impedance coil to the track, down one rail, through the track relay or the axles of any train which may be in that particular section, and back through the other rail. Incidentally,

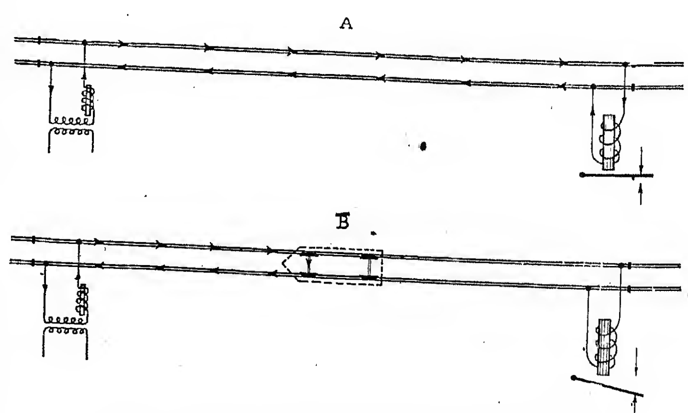

Fig. 2—Alternating Current Track Circuit

1. Signal Engineer, Atchinson, Topeka, & Santa Fe Railway System.

Presented at the Regional Meeting of District No. 7 of the A. I. E. E., at Kansas City, Mo., March 17 and 18, 1927.

quite a large part of the total current may leak from rail to rail through the ground.

B shows the same track circuit occupied by a train moving from right to left, and it will be noted that the current is shunted away from the relay by the axles of the train so that the armature of the relay drops by

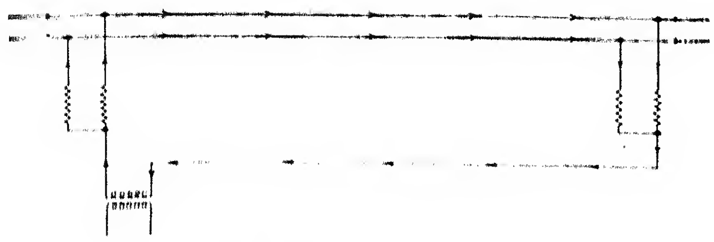

Fig. 3 Loop Circuit

gravity on the back contacts instead of the front contacts. These contacts are used to control circuits in such a way as to indicate the presence or non-presence of a train on the particular track section concerned.

Fig. 3 is the "Loop Circuit" in which current travels down both rails in the same direction. It leaves the loop transformer at one end of the circuit, divides through two resistance coils and flows down both rails in both directions under the train. At the end of the track section it is again brought together through two resistance coils and returns over a wire installed on the pole line.

Fig. 4 shows in a diagrammatic way the engine receiver, of which one is mounted in front of the first pair of wheels on the locomotive and another at the rear of the tender with a vertical clearance of about six in. above the rail. This is a structure of laminated iron with coils mounted thereon in such a manner as to pick up energy from the magnetic field around the rails. The "Track Receiver" being at the front of the locomotive picks up track energy before it is shunted by the wheels. The coils on the track receiver are connected in such a manner that the voltages induced in them are additive when the current is passing through the two rails in a direction opposite from that indicated for the track circuit in Fig. 1.

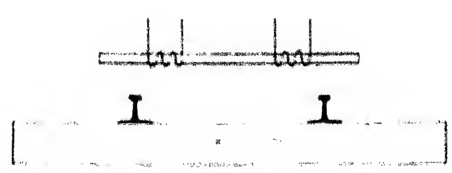

Fig. 4 Engine Receiver

The "Loop Receiver" being mounted on the rear end of the tender is out of the zone of track circuit current because this has been shunted through the wheels of the locomotive. The coils of the loop receiver are connected in such a manner that the voltages induced in them are additive for currents passing through both rails in the same direction. Thus they pick up energy from the loop circuits which is shown in Fig. 2.

The "High-Speed" indication is established when the track is unoccupied for a specified distance ahead. It is brought about by energization of both the track circuit and the loop circuit with the normal direction of current flowing in each circuit.

The "Medium Speed" indication is established when the track is occupied at a specified distance ahead. This is brought about by energization of both the track and the loop circuits with the current in the latter circuit reversed.

The "Slow Speed" indication is established when the track is occupied at a specified shorter distance ahead. This is brought about by de-energization of either the track circuit or the loop circuit.

The method of controlling the track circuit and loop circuit automatically by the presence of a train on the track will be explained in detail a little later.

The train control engine relay is a two element affair, one element of which is energized by induction from current in the track circuit shown in Fig. 1 except when this current is shunted away from it by the wheels and axles of a train. The other element is energized by induction from current in the loop circuit shown in Fig. 2. The operating part of the relay is a vane somewhat similar to that used in a watthour meter. In order to obtain three indications, it is necessary to provide a means for this disk to be operated in two directions in order to close different contacts. It must also be actuated by gravity to a point where it opens both of these contacts and closes another. In order to accomplish this, suitable means are provided to reverse the relative polarity of the current in the loop circuit.

Fig. 5 shows the circuit used on the locomotive. Directly under the train control relay is shown the contacts which bring about the display of the different lights in the cab signal. The letter in the indicator used on the Santa Fe means *low*, *medium* and *high* describing the speeds which are authorized. In this same connection, the relay controls two electropneumatic valves designated as "Control Magnets," which, in turn, set up conditions through which the speed of the train is actually controlled automatically regardless of the action of the engineman.

The author does not intend to give a full description of this automatic control, but it is interesting to a mechanical engineer and the author will be glad to arrange for answers to any questions which may be asked.

Fig. 6 illustrates in greater detail than Figs. 1 and 2, the circuits used on the roadway. In this connection, it will be noted that a three-phase line is used to energize the system. This line is very nearly balanced by using one of the three phases for a five-mi. stretch, the next phase for the next five miles and the third phase, for for the next five miles. It will be noted also that the secondaries of the line transformers are divided into two circuits, each of 110 volts, in order to provide a con-

venient way for reversal of current polarity in the loop circuit without a complicated pole changing device.

Now, as to the circuits on the roadside which bring about the different indications: In the following discussion, the current which is permanently applied to the rails will be designated as the "track circuit current" and that which is controlled through contacts will be called "loop current."

In order to provide a high-speed indication, both of these currents must be present, and the loop current must be of the proper relative polarity. To provide a medium-speed indication, both of these currents must be present and the relative polarity of the loop current must be reversed. There are two ways of providing the slow-speed indication: One is shown between locations 1 and 2, where the current is shunted away from the relay by the train. Under these conditions, if another train enters this section, there will be no track circuit current available. The other is shown at location 2. At this point contact A is open and therefore no energy is applied to the primary of loop transformer B. In either case, one element of the engine relay is de-energized and its rotor drops by gravity to the low speed contact.

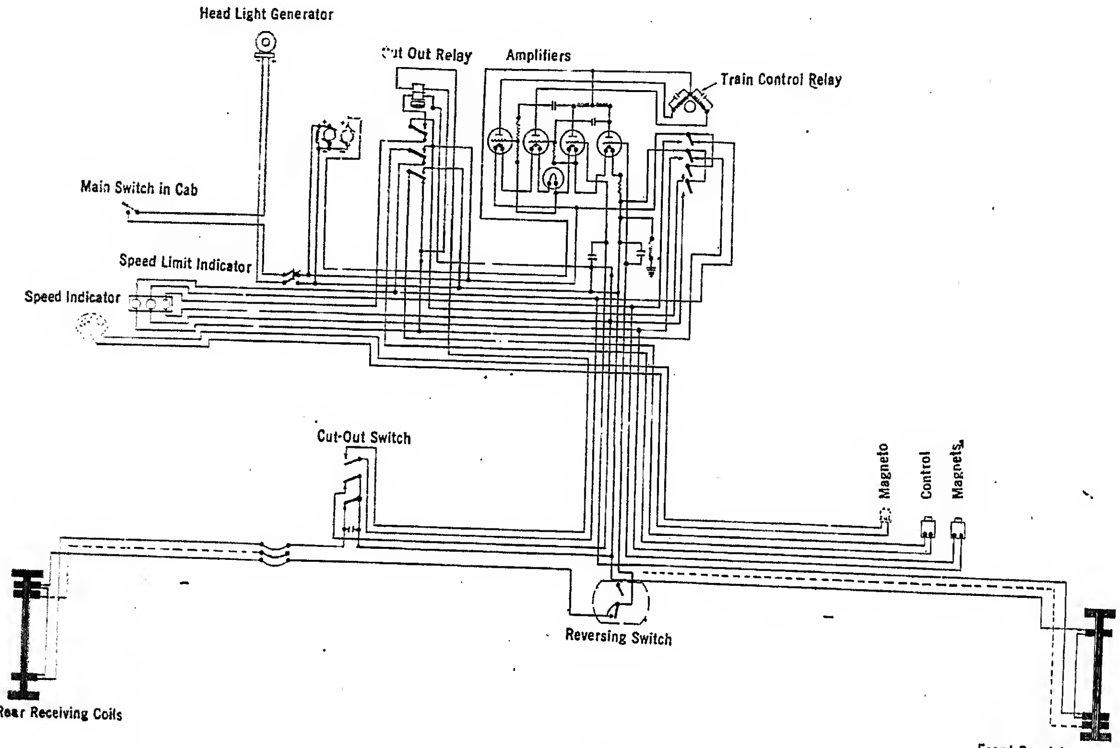

FIG. 5—CIRCUIT DIAGRAM AUTOMATIC TRAIN CONTROL

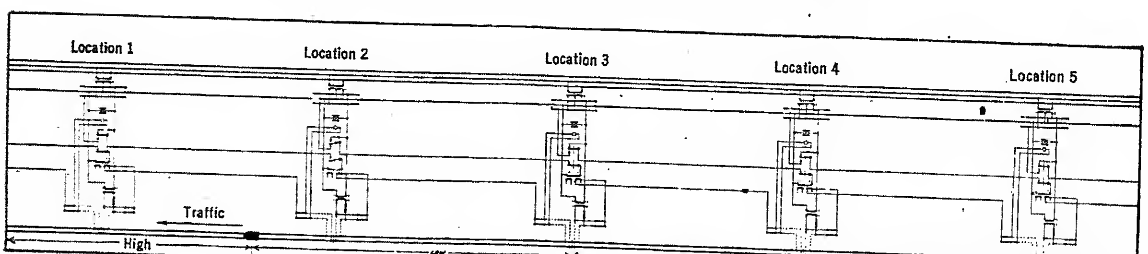

FIG. 6—TYPICAL TRAIN CONTROL ROADWAY CIRCUITS

The method of providing a medium-speed indication is shown at location 2. It will be noted at location 1 that contact C is connected to wire $B\ X$ which, in turn, is connected to the line transformer on the relatively plus side. At location 2, the corresponding contact at D is dropped and is now connected to wire $N\ X$ which is connected to the relatively minus side of the transformer. In this way, the relative polarities between the track circuit current and the loop current have been reversed, which in turn reverses the engine relay.

The trade name of the particular scheme as described is "Continuous Control" because of its continuous indications. It seems easy as here described, but a great many years were spent in research work before a simple description of this kind became possible.

Various new problems confronted us when we had

the opportunity to study the problem in connection with an actual installation. Very interesting studies have been made about the various paths which a current will take when a conductor is grounded as all steam railroad rails must be grounded more or less through the ties and ballast. The problem of providing safe operation, with due consideration for the inductive effects of adjacent power lines of the same frequency was very interesting. The real reason for all the above was to provide a means of controlling a train automatically regardless of the carelessness of the engineman or the fact that he might become incapacitated due to sudden illness or death, but it has lead several railroads to consider the desirability of providing signals in the cab of the engine rather than on the wayside and in this sense has had a good effect.

Whether the automatic control of a train will ultimately be successful is debatable, but at present it looks as if it is a factor in railway operation which has come to stay.

There are various other schemes now in use which are very interesting from a technical standpoint, but all of these involve intermittent controls. None of them provides an adequate means for the use of cab signals without the addition of wayside devices. They simply provide for a check on the engineman should he disobey a signal indication. They are not self checking, as is the device described above, and therefore as a means of adding to the efficiency as well as safety of train movements they seem incomplete. Only time will show whether this idea is correct or not.

Discussion

F. E. Snell: Though continued development of the semaphore and light type of signals resulted in the production of a highly efficient unit, it yet has some serious drawbacks as pointed out by Mr. Stevens. These unfavorable conditions, attendant on wayside signals, which could not be remedied by electrical means, naturally resulted in the development of a cab signal. The cab type of signal may also offer a solution to one of the problems with which we are confronted in Cleveland, and which, no doubt, affect other operators of rapid transit lines in metropolitan areas, where a portion of the right-of-way is through the less polite residential sections. I refer to the malicious destruction of signal equipment by trespassers, particularly small boys who throw stones, using the wayside signal light lenses as targets.

It would be interesting to hear, not only of the problems presented by the inductive effects of adjacent power lines of the same frequency as the signal current, but also something regarding the ability of the engine equipment to function properly under severe conditions to which it is no doubt subjected. In other words, do vibrations, bumps, etc., cause excess relay or lamp failures when compared with the wayside type of signal?

Wishing to give the traveling public the greatest possible protection, signal engineers have experimented with, and developed, various forms of automatic train control, the ultimate success of which, Mr. Stevens states, is debatable. Our company has had no occasion, of course, to consider such a system, but from the wonderful progress made in the signal field in a comparatively short time, as well as in other branches of the electrical industry, I can see no reason why continued experimenting and future developments will not soon result in more efficient and reliable methods of signaling and automatic control of trains.

O. S. Major: As presented by Mr. Stevens, the cab-signal system appears to be comparatively simple, but when one digs into the problem a little deeper and considers various traffic conditions to be contended with and traffic reversal as used on the Santa Fe, situations sometimes arise which are extremely complicated.

Other general types of automatic train control not taken up by Mr. Stevens include the intermittent inductive, intermittent contact (ramp type), continuous two-speed, and continuous stop; they are all intended to accomplish the same general purpose, namely, enforcing of obedience to, or cognizance of, signal indications.

In the intermittent contact or ramp type, ramps are placed at intervals along the roadway which make contact with a shoe on the locomotive. The ramp is energized or deenergized, depending upon track conditions ahead or wayside signal indication; the shoe, on passing over the ramp, completes electrical circuits on the locomotive which in turn control relays and valves, causing a reduction of brake pipe pressure under certain conditions.

In the intermittent inductive types, several methods are used to impart an electrical impulse to the locomotive circuits through an air-gap to a receiver mounted on the locomotive which in turn controls electropneumatic valves causing a reduction of brake-pipe pressure under certain conditions of track and signal indications.

The track element, or inductor, in one device consists of permanent magnets and electromagnets, placed adjacent to one another in such a manner that when energy is applied to the electromagnets, the field of the permanent magnet is suppressed or flattened out to the extent that the locomotive receiver or valve in passing over it will not receive an impulse, which would be the condition set up for a clear block. The energy supplying the electromagnets is selected through certain relays and contacts in such a manner that if the track ahead is *not* clear, this circuit will be open, the field of the permanent magnet will not be suppressed and the locomotive receiver or valve on passing through this field is subjected to the effects of these lines of force. The action of the locomotive receiver or valve is purely magnetic, embodying the principles of north and south poles bucking and helping one another. An air valve with pressure on one side working against a magnet on the other side vents pressure to atmosphere when the magnetic effect on the valve is diminished or neutralized on account of passing over the extended field of the track element.

Another type of intermittent inductive train control uses an inert track element or inductor which imparts an impulse to a receiver mounted on the locomotive when the receiver passes over it. The inductor consists of a laminated iron core around which wire is wound. The receiver consists of a primary and secondary winding on a laminated U-shaped core. The primary is constantly energized from the headlight generator, thereby forming an electromagnet. If the leads to the track element or inductor are closed, as in clear block conditions, the engine circuits are not materially disturbed when the receiver passes over the inductors. However, if the winding on the inductor is open, as in the caution or stop block condition, the reactance of the inductor is changed as well as the reluctance of the magnetic circuit, between receiver, air, and inductor, and a current is induced in the secondary circuit of the receiver, opposite in polarity to and larger than the normal holding current of engine-control relay, which drops this relay and causes an electropneumatic valve to function resulting in a reduction of pressure. Acknowledging and forestalling devices can be provided on most of the devices which enable the engineman to forestall an automatic application of the brakes, providing he is sufficiently alert to perform a certain duty in a specified length of time at a certain place.

The Chicago & Northwestern has installed a system of continuous control which is rather unique in many respects, in that the operating mechanism controlling the speed of the train in a yellow or caution block is a function of both speed and distance. The mechanism is driven from the axle. A lever or arm, working on a sliding governor, opens and closes certain contacts at various speeds and when a yellow block is entered, another arm or lever engages a worm gear which operates the arm to open and close certain other contacts at predetermined intervals of space or distance, the worm gear being also axle-driven. Another set of arms or levers combines the speed and distance features and operates still another set of contacts. The combination speed and distance contacts provide a means for compelling the engineman to control the speed of his train in conformity with a predetermined tapered speed curve, and require that the speed of his train be below a certain low speed at a particular point. If the speed of this train is not below the low-speed limit at a particular point or place, he will be penalized with an automatic application of the brakes which he cannot release until his train has come to a stop. Cab signals are also provided in this installation, but I believe the old wayside signals, which are of the disk type, are still in service.

In the systems of continuous control, I find that some roads reverse the polarity of the loop circuit and some reverse the track circuit in order to get the normal, neutral, and reversed positions of the engine train-control relay.

The device Mr. Stevens refers to as the "Coder Device" which he states the Santa Fe is testing should fill a long-felt need if it proves satisfactory. It eliminates the loop circuit and renders the locomotive apparatus immune to picking up stray alternating currents of commercial frequencies.

I am rather inclined to agree with Mr. Stevens that in the last analysis continuous control is the end to which we should work as it paves the way for the ultimate elimination of wayside signals and provides a continuous check on the integrity and continuity of the track as well as the engineman.

An automatic train-control device using radio frequencies has been under development and test for some time on the P. M. Railway with encouraging results, but I am not advised as to the present status of this device. Considering the rapid progress and development in radio in the past few years, it is not entirely impossible to conceive of automatic continuous radio train control.

A. Herz: Mr. Stevens has made it clear that the locomotive signals depend on the magnetic field impulse transmitted through several inches of space, usually six in. or more over each rail, making a total air-gap of over one ft. The train control signal current used by the railroad is weak, in fact, not over one ampere. The power interests transmit large quantities of current over wires often located adjacent to railroad tracks, since the conditions of supply and demand make this necessary. These power wires are located at a distance making an air-gap many times greater than that used by the railroad interests in sending the train control impulse through space from rail to locomotive. However, it is quite impossible to transmit these large currents without setting up the usual magnetic fields around the conductors, which will in many instances cut the railroad tracks and thus create a very weak current flow along these tracks quite similar to that made use of by the railroad for this train control. This is especially pertinent and has a great bearing on the whole problem, since in some instances the railroad makes use of 60-cycle current and since the receiving devices and the whole set-up is such as to respond to the impulses from a 60-cycle magnetic field, so that the normal magnetic field liberated by the power wires may also influence the signals in the same manner, and very often in an undesirable manner.

That this is actually the case has been demonstrated in various localities. Some recent experimental work on a parallel between a continuous inductive type of train control installation and a power line along the edge of the right-of-way demonstrated that a comparatively small current, I believe it was on the order of seven amperes, carried on the power lighting circuit, produced enough current in the rails actually to set up a false clear signal on the locomotive. The almost obvious reason for such a failure, of most dangerous nature, is the simple fact that the field of the power line had the same frequency as the field used in the track circuit to transmit the signals.

I want to draw attention to the obvious danger of having these devices set up so that they are responsive to the normal stray fields of the commercial power systems which are today almost universal. If the magnetic field made use of by the train control signal employs a materially different frequency, such interference can be absolutely prevented. This has been proven and is practically self-evident. As a matter of fact, some train control systems now being installed and also some now in use operate at 100 cycles, instead of 60 cycles. Some will go so far as to use 100 cycles plus mechanical tuning, that is, to employ an interrupted 100-cycle current, the rate of interruption being such that a mechanically resonant relay will respond to it and none other. This will provide a double element of safety or protection against possible interference from commercial power systems. However, there is probably a good deal of experimental work which must be done before the continuous inductive train control system is really perfected for general adoption.

T. S. Stevens: The relays for controlling automatic block signals on electrically operated railroads are designed so that they can be operated not only on direct-current operated railroads by alternating currents but on alternating-current propulsion railroads by the use of relays of a different frequency, centrifugal relay, sensitive to a different frequency from that used for propulsion. So the complete track circuit is used in that way.

Mr. Snell spoke of operating cab signals on electrically operated railways and it is rather interesting because this is probably the most interesting electrical development of the age.

I don't want to start a discussion about frequency because it is too deep. The effects of the use of any frequency, whether it happens to be a different frequency from that of the power companies or the same, are not thoroughly known. What corrections can be made with the same frequency and still provide safe operation, are still doubtful. Whether the 100 cycles will not lead us into other difficulties is not known. A device of some kind which involves only very, very low frequency may be developed in the future, but we are pioneering.

I want to say in favor of Mr. Herz that he has been and we also have been working along amicably toward a settlement of this problem and no doubt will get to the solution of it some time.

Carrier-Current Selector Supervisory Equipment

BY C. E. STEWART[1] and C. F. WHITNEY[1]
Applicant for Membership Non-Member

Synopsis.—The rapid advances made in the application of automatic principles to the control of electrical energy have produced many new and novel installations. This paper describes a supervisory system which centralizes the control and indication of all power used in operating a modern interurban railroad. Supervision is accomplished over a single circuit consisting of one insulated wire with ground return. A single frequency carrier current is used for transmitting all signals over the circuit connecting all stations. Considerable attention has been given to make the equipment simple in design, rugged in construction, easy to install, and convenient to maintain.

* * * * *

THE application of automatic substations for supplying energy to suburban and interurban electric traction systems has undoubtedly added a very vital chapter in the economic life of these systems. From an operating viewpoint, however, the automatic station equipment has entirely eliminated the human intelligence at the station so essential to the former method of operation. In its place we have left a number of inanimate devices, arranged in electrical circuits to respond to certain definite electrical and mechanical laws. Thus, we obtain operations in a predetermined definite sequence, dependent upon the changes of the master devices within the substation.

Such a system operates very satisfactorily and would meet all requirements were it not for the occasional unusual occurrence which is foreign to any predetermined set-up, but which is nevertheless vital to unit operation. For example, to meet emergency conditions in this class of service, it is essential that means be provided for quickly opening all feeders supplying a particular trolley section. In many installations where load conditions permit, it has also been found profitable and advisable to shut down and lock out certain automatic substations during light load periods.

There is a demand, therefore, for some means of supervising these unattended automatic substations from a central point or dispatcher's station. A new class of equipment was developed several years ago, and is known as "automatic supervisory equipment." This equipment provides a dispatcher with a means of selectively controlling devices in the substations and automatically gives him a visual indication of the substation apparatus by means of standard indicating lamps located in cabinets at his office.

One of the most interesting and unique applications of automatic supervisory equipment to interurban railway service is that installed on the Chicago South Shore and South Bend R. R. which runs between Chicago and South Bend, Indiana. This gives supervision over a 1500-volt, d-c. electrification with converter and mercury arc rectifier substations. There are eight substations located between Hammond, Indiana, and South Bend, a distance of about 65 mi. The stations named in order along the right of way are as follows: Hammond, Gary, Wycliff, Furnessville, Michigan City, Tee Lake, New Carlisle, and Grandview. Columbia Avenue and Michigan City substations are manually operated but have automatic reclosing d-c. feeder equipment.

The power dispatcher is located in the Hammond Substation. He has direct supervision over the high-tension incoming line breakers and machine equipments. An indication is also given him of the d-c. feeder breakers in all eight substations.

The train dispatcher is located near the Michigan City substation. He has supervision over the d-c. feeder breakers in all eight substations and also indication of the machine equipments.

The supervisory equipment is of the carrier-current selector type and operates over one line wire and ground. A single No. 6 B and S copper wire is strung on standard 2300-volt insulators for the entire distance, For about five miles at one end of the system this wire is carried on the same pole as the 33,000-volt power circuits.

With the above picture in mind, it is interesting to note the following special conditions which effected, to a large extent, the choice of this particular class of equipment.

1. A problem was presented due to the severe sleet and ice conditions peculiar to this section of the country. Line wires as ordinarily constructed for telephony are subject to many breakages during the winter months. An attempt was made to increase the reliability of operation by installing larger wire and using distribution insulators. The choice of the No. 6, B and S line wire was due, therefore, to its mechanical qualities rather than its electrical characteristics, although the latter are highly desirable.

2. On account of the increase in cost of the specially constructed circuits, it was necessary, therefore, to use a minimum number of line wires, running between stations.

3. Since the supervisory circuits were exposed to high tension disturbances, it was essential to provide protection to connected apparatus. Where line wires are connected metallically to sending and receiving equipments we have a very serious problem of obtaining proper protection. Protection of equipment so con-

1. Both of the General Electric Co., Schenectady, N. Y.

Presented at the Regional Meeting of District No. 7, of the A. I. E. E., Kansas City, Mo., March 17-18, 1927.

nected presents an entirely different problem from that experienced in telephony. It is impossible to use line insulating transformers and drainage coils are undesirable on account of the resultant losses. The use of insulating transformers is not possible where the operation of the system is dependent upon d-c. lock-out or holding circuits.

The supervisory equipment line wires can be run, in many instances, in lead sheath cable in order to obtain proper protection to the equipment. The cost of such construction becomes prohibitive on a right-of-way of this mileage.

4. The carrier-current system provides a satisfactory solution to the protection problem. The coupling between the station's equipment and the external circuit is readily made by means of high-voltage condensers which, from the standpoint of protection, serve, in effect, the same purpose as the insulating transformers. Low-frequency drainage units serve to remove the electrostatic induction from the line wires, and standard protective apparatus, consisting of gaps to ground, fuses, arresters, and choke coils, can be employed to protect against unusual disturbances.

Carrier-current equipment as designed will satisfactorily operate over any circuit which will offer low impedance to the high-frequency carrier current. The equipment can be coupled, therefore, through suitable condensers to the high-tension power lines. In the installation referred to, the transmission lines did not offer a satisfactory circuit because of their interconnections and possible separation along the right-of-way.

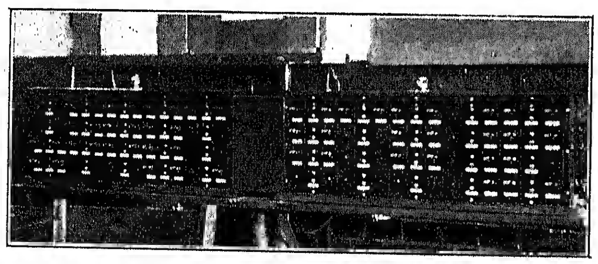

Fig. 1—Dispatcher's Key Cabinet (Columbia Ave. Substation, Hammond, Ind.)

The cost of the necessary by-pass equipment to secure a satisfactory carrier-current circuit was prohibitive.

A very important feature in connection with the design of this apparatus is that all devices are panel mounted. This applies to all equipment with the exception of the dispatcher's office key and lamp cabinet. The equipment is mounted on standard 90-in. switchboard panels. The panels are completely wired and all external circuit connections are made to standard connection blocks on the back of panel. Installation costs are reduced, therefore, to a minimum as it is only necessary to interconnect between major apparatus in the stations. All installation wiring can be of the standard control size ordinarily used on power switchboards.

The carrier-current system uses the same equipment which has been used so successfully for a number of years in the selector system. A carrier-current panel is added to the standard selector equipment at each station.

In the 90-in. carrier-current panel, a cover over the back affords protection to vacuum tubes, condensers, and variometers. On this panel are mounted the selectors and polarized relays which set up the indication circuits on the key and lamp cabinet in accordance with coded signals received from the substations.

Fig. 1 shows a key and lamp cabinet. For each

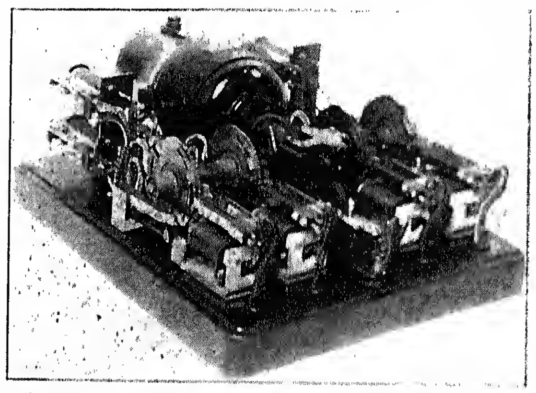

Fig. 2—Substation Motor Sending Key

substation unit supervised this cabinet contains two manually-operated, spring-driven code-sending keys and two indicating lamps. It also contains the master operating key, checking keys, and common indicating lamps.

On a typical substation panel, the selectors in connection with an associated carrier-current panel respond to coded control signals from the dispatcher.

Mounted on this panel are the motor-driven sending keys (Fig. 2) which originate the code signals for each supervised substation unit. Associated with each motor sending key is a checking relay. This relay provides a means whereby the dispatcher can check the position of supervised equipment without operating it. This feature is important from a maintenance viewpoint because it provides a check on both the control and indication operation of the equipment.

All operating potentials are obtained from storage batteries. The supervisory system, therefore, is not affected by the momentary loss of the high-tension power circuits and renders reliable service under emergency conditions.

The selection of a carrier-current frequency is, in general, dependent upon the impedance characteristics of the circuit over which the equipment must operate. On an installation involving a number of stations it is desirable to obtain this from actual field tests at the time the equipment is placed in service. Such tests show that there are one or more frequencies to which the entire system will respond most effectively. The

carrier-current selector supervisory equipment, therefore, is designed so that frequency adjustments can be made over a wide range. Once the frequency is chosen for an installation, the tuning adjustments of all transmitters and receivers are locked in position and require no further attention.

The carrier-current circuits may be divided into two distinct divisions which may be designated as the transmitter and the receiver. The function of the transmitter is to transform the d-c. impulses originated by the code sending keys into a high-frequency form so that they may be impressed upon the carrier-current line. The function of the receiver is to take the high-frequency impulses from the line and, by means of a vacuum tube rectifier, reduce them to such a form that they may be used for operating the usual supervisory relays. Both the transmitter and the receiver depend upon the three-element vacuum tube or pliotron for their action.

The transmitter utilizes three vacuum tubes of the 50-watt size. One tube is used in the master oscillator circuit which generates the high-frequency oscillations. The other tubes form a part of the power amplifier circuit the function of which is to increase the output of the element. The master oscillator uses the Colpitts circuit for generating the high frequency. A 1000-volt, d-c. source is required between the plate and filament of the tube and a 10-volt, a-c. source heats the filament. The inductance of the oscillator circuit is in the form of a variometer having a movable rotor. Depending on the position of this rotor, the master oscillator can be made to generate any frequency between 20 and 80 kilocycles.

The elements of the two power amplifier tubes are connected in parallel and their plate and filament voltages are taken from the 1000-volt, d-c. source and 10-volt, a-c. source, respectively. The high-frequency voltage taken across one of the condensers in the oscillator circuit is applied between the grids and filaments of the power amplifier tubes. This high-frequency voltage applied to the grids results in a variation in the d-c. plate current to the power amplifiers of the same frequency. The primary of an output transformer is connected in the plate circuit of the power amplifiers and the high-frequency output of these tubes is utilized by connecting to the secondary of this transformer. The secondary is provided with taps so that the desired voltage may be obtained, the correct voltage being dependent on the line impedance at the frequency used. One side of the secondary of the output transformer is connected to ground and the other side through a coupling condenser to the carrier transmission line. A second variometer and a thermoammeter are in series with the coupling condenser. A resonant circuit is formed by the output transformer secondary, the output variometer, the coupling condenser, and the impedance of the line to ground. This circuit is tuned to resonance for the frequency generated by the master oscillator by varying the position of the rotor in the output variometer until maximum current is indicated by the output ammeter. The maximum input of power to the line at this frequency is then obtained. Two tubes are used in parallel in the power amplifier circuit in order that the desired output may be obtained from the transmitter without overheating the tube elements. The maximum output of the transmitter is 150 watts.

The high-frequency output from the transmitter is controlled by means of a relay called the transmitter keying relay. When the coil of the relay is energized, one pair of contacts completes the circuit from the 1000-volt, d-c. source to the plates of the transmitter tubes, causing the high frequency to be generated. A second pair of contacts connects the secondary of the output circuit to ground.

The 1000-volt, d-c. power for the plates of the transmitter tubes is derived from a 500-watt motor-generator set which is driven from a 120-volt storage battery. The motor is in reality a converter as it has slip-rings which supply 88 volts at 40 cycles. By means of a small transformer, this source is stepped down to 10 volts for lighting the filaments of the transmitter tubes. Two rheostats are mounted on the carrier-current panel, one for controlling the field current of the generator and the other is in series with the primary of the filament transformer for adjusting the filament voltage.

Test jacks and keys are provided on the panel to facilitate checking the operation of the transmitter. A jack, in series with the common grid connection to the tubes, allows a milliammeter to be connected in this circuit. If the master oscillator is not generating high frequency no reading will be obtained on this meter. If the master oscillator is functioning properly but the power amplifier is not, the meter will read about 80 milliamperes. If both master oscillator and power amplifier are functioning properly, a reading of approximately 150 milliamperes will be obtained. A jack across the filament circuit of the transmitter tubes provides for connecting an a-c. voltmeter in order to adjust the filament voltage. The output ammeter is normally shunted out of the circuit and is used for testing and maintenance purposes only. When it is necessary to start the transmitter for inspection purposes, a switch on the panel may be closed, operating the motor starting contactor. This switch also opens a circuit which delays the operation of the motor sending key until the inspection is completed. Another switch completes the circuit to the keying relay, causing the transmitter to generate and send out the carrier current. It is sometimes necessary for the maintainer to make inspections, on the back of the panel, which might cause him to come in contact with high potential circuits if the motor-generator were running. A switch is provided to open the circuit to the motor starting contactor, thus preventing the generating of high voltage until his inspection is completed. All of these test switches are

plainly marked with individual nameplates on the front of the panel.

The receiver is connected to the carrier-current line by means of a coupler which consists essentially of two coils so mounted that their inductive relation to one another may be varied. One terminal of the primary coil is connected to ground and the other terminal is connected to the carrier-current line through the coupling condenser. A variable condenser is connected across the terminals of the secondary coil forming a resonant circuit which may be tuned to the carrier frequency by adjusting the condenser to the proper capacity. The voltage across this resonant circuit is applied to the grids of the detector tubes which are of the 7.5-watt type and are slightly larger than the average tube used in radio broadcast receiving sets. There are two of these tubes in the receiver with their elements connected in parallel. Plate voltage is supplied from the 120-volt station battery and the filaments are lighted from a 24-volt tap on the same battery. The grids are connected through the secondary of the coupler to the low potential end of the filament resistor. This makes the potential of the grid minus 18 volts with respect to the filaments when no high-frequency voltage exists across the secondary coil. This prevents any current from flowing to the plate and consequently the detector relay, which is operated by this plate current, is not energized. When the carrier frequency voltage exists between the carrier line and ground, a voltage of this frequency is superimposed upon the d-c. voltage applied to the grid of the detector tube. Due to the characteristics of the vacuum tube, this a-c. voltage superimposed upon the negative 18 volts of direct current causes the average voltage of the grids to be increased, allowing plate current to flow and energizing the detector relay. A jack is provided in the plate circuit by means of which a five-milliampere ammeter may be connected in this circuit. This provides a means of checking the operation of the receiver as well as a means of tuning the receiver to the desired frequency. When carrier current is being transmitted from some other station the capacity of the receiver tuning condenser may be varied until a maximum plate current is obtained. This indicates that the receiver is tuned to the proper frequency.

Two detector tubes are used in order to give a maximum reliability to the equipment since the operation of the receiver depends upon the proper functioning of the detector tube. The action of the receiver is equally as satisfactory with either tube alone as with both tubes. The failure of one tube, due to a broken filament or loss of emission, does not impair the operation of the equipment and the maintainer, during his regular inspection, will discover and replace an inoperative tube. The detector tube is of sturdy design and in this class of service has a life of approximately one year.

When the detector relay is energized it completes a circuit from the 24-volt source to the reversing relay which, in turn, operates the selector according to the coded carrier-current impulses. The detector relay also breaks a circuit which prevents the dispatcher, or the motor key as the case may be, from using the associated transmitter for a definite time after the last carrier-current impulse. In order to prevent the receiver from detecting the carrier voltage generated by the associated transmitter, the keying relay is provided with contacts which disconnect the receiver from the carrier-current line and open the plate circuit of the detector tubes. In the dispatcher's station, the detector relay completes a circuit to a pilot lamp on top of the key cabinet, causing it to flash in accordance with the incoming code. The equipment is interlocked to prevent the dispatcher from using the transmitter while the receiver is in operation.

The operation of the system may be divided into two distinct functions; namely, the control operation and the indication operation. The control operation is originated by one of the dispatchers and is for the purpose of starting or stopping one of the machines, or closing or tripping one of the breakers assigned to his supervision. The indication operation is originated by the starting or stopping of some machine or the closing or opening of some breaker in an outlying station. Either type of operation requires the use of only the transmitter at the originating station and the receivers in all of the rest of the stations. All of the operations of either type are transmitted on a single carrier-current frequency. In order that only one transmitter may be in operation at a time, the transmitters are interlocked with the receivers.

Before any station may transmit a coded signal it must send out a short impulse of carrier current called

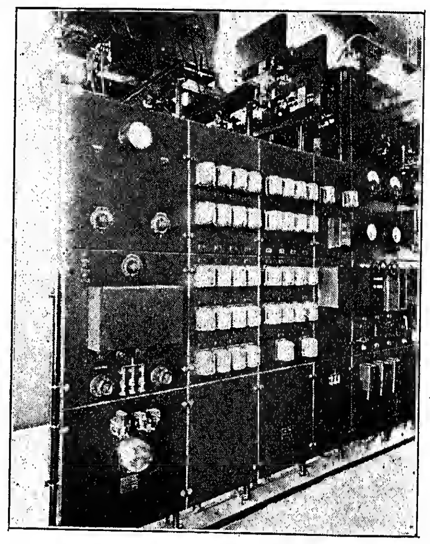

FIG. 3—DISPATCHER'S PANEL EQUIPMENT (COLUMBIA AVE. SUBSTATION, HAMMOND, IND.)

the locking impulse. This is detected by all receivers which immediately interlock their respective transmitters. A transmitter may function only in case its associated receiver has not detected carrier current on the line for a definite period of time. This allows for the completion of any code which might be in the process of transmission.

In order to demonstrate more clearly the working of the system, a complete operation of each type will be followed through.

Assume that the dispatcher at station No. 1 wishes to trip the a-c. incoming line breaker at station No. 4. The red lamp corresponding to this breaker indicates that the breaker is closed. If the white lamp on top of the key and lamp cabinet is not flashing, no signals are being received and the dispatcher can use the line. He turns the master key 90 deg. in a clockwise direction and releases it. The spring which is wound up by this turn revolves a contact wheel. While revolving, this wheel completes a circuit through auxiliary devices to start the motor-generator set. The generator lights the filaments of the transmitter tubes and supplies the 1000 volts d-c. for their plates. A timing relay is energized and at a definite later time, a circuit to the keying relay of the transmitter is closed for 0.2 of a second to send out the locking impulse. At the termination of this locking impulse the circuit is completed to a green lamp opposite the dispatcher's master key. This indicates to the dispatcher that his transmitter is now ready for operation and that he has control of the line. He now turns the operation key, which in this case would be labeled "Trip a-c. breaker, station No. 4." When released, this key keeps the motor-generator set running and operates the keying relay in accordance with the code setting on its impulse wheel. This causes impulses of carrier current to be sent out over the line. The detector relays in all of the other stations are operated in accordance with this code and the selectors at all these points are actuated. Only the selector in station No. 4, however, closes its contact and trips the a-c. incoming line breaker. When the key released by the dispatcher completes its rotation, circuits are opened which shut down the motor-generator set and extinguish the green lamp opposite the master key.

Whenever a supervised unit at an outlying station changes its position, a circuit is established to the motor driven sending key. A circuit is also made to start the motor-generator set and energize a timing relay. If there has been no carrier current on the line for a definite period of time, this timing relay completes a momentary circuit to the keying relay and sends out the locking impulse. This prevents any other station from obtaining the line during the transmission of the coded signal. As soon as the locking impulse has been sent, the code wheel associated with the supervised unit is released. As this revolves it operates the keying relay which transmits the coded group of carrier-current impulses.

These impulses of carrier current are received on the detector circuits in all other stations. Only one selector in the dispatcher's office notches up and completes its contact. Depending upon the code received, a circuit is established to light either the red or green indicating lamp on the dispatcher's key and lamp panel. In addition to any change made in the dispatcher's indicating lamps, there is also a bell which calls his attention to any change in the position of his supervised units.

When any station has completed the transmission of a signal the motor-generator set comes to rest and all associated transmitting circuits are de-energized. Only the receiving tubes in the entire equipment require current continuously.

It is expected that this class of supervisory equipment operating over a well constructed line wire will prove more dependable than a system operating over several wires between the respective stations. Experience indicates that more difficulties are encountered due to the line wires than with the actual selector equipment. Great care has been taken to obtain simplicity of circuits, well constructed and reliable devices as well as a design layout which invites and facilitates proper maintenance.

In conclusion, supervisory systems of reliable design have centralized in the person of the dispatcher, the human intelligence which was removed from the substations by the advent of the automatic station equipment. The dispatcher is able to operate his system more efficiently and is prepared to meet promptly any special problems which may arise. The supervisory and automatic equipments are waiting night and day to give immediate response to his orders.

Discussion

R. J. Wensley: There are many applications for remote control of power apparatus where the distance is such that control conductors become prohibitively expensive. Such applications are usually in connection with high-voltage systems where inductive interference would be severe should control circuits be constructed along the transmission right-of-way. The Alabama Power Company solved such a problem in a very ingenious manner. They have an extensive 110-kv., "H"-type wooden-pole transmission system. Their southern loop is to be sectionalized at intervals of about 15 mi. by motor-operated disconnecting switches. As there are several hundred miles of this loop, the construction of separate control circuits would have been very expensive.

The standard practise of the Alabama Power Company is to install two ground wires on the tops of the two poles of the "H" frame. These wires serve as static guards and as return circuits for the ground relays. In addition, these wires are now used for the supervisory control of the section switches.

To enable their use, insulators were installed and all direct ground connections were removed. Transformers were installed at each section switch with center taps on the primary windings, these taps being grounded. The control is effected by impulses of 500-cycle and 650-cycle energy.

The control equipment is an adaptation of the Westinghouse

audible system. Motor-generator sets provide the two frequencies. The impulses are originated by an ordinary automatic telephone dial.

Selection is obtained by dialing impulses of one frequency. Answering signals are received by audible signals originated by a buzzer at the distant point which checks both the station called and the device selected. Operation is obtained by application of the second frequency by means of the control key on the dispatcher's cabinet.

The impulses of the two frequencies are received on tuned relays. These relays are tuned to resonance by condensers in series with their coils and will not operate unless the frequency is within about 50 cycles of the point of resonance. The selective equipment is operated by a local 12-volt battery. This same battery is used for the motor of the disconnecting switch.

The batteries are to be charged at certain central locations and distributed by trucks at regular intervals. An experimental installation for trickle charging from the drainage current in the ground connection of the transformer primary is now being tried. This involves a special transformer and a Rectox rectifier. If successful, this method will eliminate the handling of batteries. The receiving equipment illustrated is located in a substation, but at most of the locations there is no station and the equipment is housed in an outdoor steel switchhouse converted for the purpose.

All control connections to the ground wires are made through transformers. Spark-gaps on both primary and secondary guard against actual crosses between the ground wires and the 110-kv. lines. A series relay short circuits the transformer primary when the current exceeds its safe rating.

Mercury Arc Power Rectifiers
Their Applications and Characteristics

BY O. K. MARTI[1] and H. WINOGRAD[1]

Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis. *Steel-enclosed mercury arc rectifiers, due to their advantages over rotary converters in efficiency, ease and reliability of operation, and ability to produce high d-c. voltages, are gradually replacing other forms of converters in all fields of application. There are at present 600,000 kw. of rectifier installations, distributed over different parts of the world. Statistical data are given showing the growth of installed rectifier capacity since 1911, the distribution of rectifiers over various fields of application, and their increasing use at higher voltages for railways. The high efficiency and reliability of rectifiers at high voltages will undoubtedly influence the selection of systems and voltages for main-line electrification. Comparative operating figures are given for rectifiers and motor-generator sets at 3000 volts d-c. Several types of Brown Boveri rectifiers and their load curves are shown. Due to the fact that the d-c. voltage of a rectifier consists of portions of sine waves, the voltage wave is somewhat undulated. The magnitude of the undulations depends on the number of phases and varies with the load. The effect of the undulations in the voltage wave on the shape of the current wave for various types of loads is discussed, and oscillograms of the voltage and current waves of a rectifier feeding a railway load under various conditions are shown. The effects of the undulations on different kinds of load batteries, lighting, and power circuits and on communication circuits paralleling the d-c. feeders are discussed briefly.*

DIRECT current, in spite of the many advantages of alternating current, has its own numerous and valuable characteristics and uses. Among these might be mentioned trolley and other city railway lines, interurban and main-line railroads, rolling mills, special drives requiring the facility of control made available only by the use of direct current, electrochemical applications, and so forth. The generation of d-c. power at ordinarily used voltages would be very uneconomical due to the small power involved for particular requirements. Furthermore, at the voltages at which it is at present generated and used, transmission of the d-c. power over long distances could be accomplished only with considerable losses. The only solution of this problem, therefore, is to generate alternating current, transmit it at high voltages to the site of its application, and there convert it by the best means available into the desired d-c. voltages. Rotating converters have been the only means commercially available for this purpose, until the comparatively recent advent of the steel-enclosed mercury arc power rectifier.

On account of its newness in the commercial field, there was at first a lack of confidence in the rectifier. This, however, has been dispelled by its advantages and successful operation in all parts of the world and in every field of application. Contrary to the rotating conversion apparatus, the electrical energy is not first changed into a mechanical form and then changed back again to the electrical form, but the conversion occurs directly with no intermediate stages. The losses and other disadvantages accompanying conversion by means of rotating machinery are either greatly reduced or eliminated entirely. In a rectifier there are no iron, windage, friction, or ventilation losses, and those which do occur (losses due to the voltage drop in the arc) do not vary as in the usual electrical machines and apparatus, as the square of the current, but only as a linear function and independent of the voltage. Two important properties of the rectifier are dependent on this last mentioned fact: the efficiency remains practically constant at all loads, and since the losses in the rectifier proper are practically constant at all operating voltages, the efficiency increases as the operating voltage is increased. This characteristic of the rectifier—a high efficiency at partial loads—is of particular importance in cases when the conversion machinery has to be operated under conditions which impose a low annual load factor, as in the supply of d-c. power to rolling mills, dredges, elevators, and especially for traction motors. For the last mentioned application, the simplicity and rapidity of the starting operation are also outstanding advantages. These advantages, together with others, have proved the rectifier to be superior to the rotary converter, and have contributed to the great popularity which rectifiers have gained during recent years.

As an example of the superiority of the mercury arc rectifier, it may be mentioned that the chief reason for not using d-c. voltages above 1500 volts for traction lies in the fact that this value is already close to the maximum which can reliably and safely be applied to one commutator of rotating converters. For higher d-c. voltages, two machines must be connected in series, which greatly reduces the efficiency, appreciably increases the initial cost of the installation, and introduces further operating difficulties. With rectifiers, this is not the case, as a single cylinder is capable of producing many times this voltage.

The fact that today there are in service throughout the world steel-enclosed rectifiers with a total capacity of more than 600,000 kw. is without doubt a proof of the soundness of the basic design of these devices. In Fig. 1 are shown the total installed capacities from year to year, and the fact that the steepness of the rise becomes greater year by year indicates the possibility that

1. Both of the American Brown Boveri Electric Corp., Camden, N. J.

Presented at the Regional Meetings of the A. I. E. E., Kansas City, Mo., March 18, 1927 and Bethlehem, Pa., April 21-23, 1927.

this device will soon largely replace all other forms of converters.

The field of application of the steel-enclosed mercury arc power rectifier is already very wide, as is clearly illustrated in Fig. 2. Mercury arc rectifiers are naturally used with greater advantage where their peculiar qualities meet the requirements of the service in question. To these classes of service belong installations subjected to large fluctuations in load and to heavy and short current peaks, such as main-line railways, street cars, subway and elevated railroads, rolling mills and the like. A comparison of the shaded areas in Fig. 2 shows that the use of rectifiers for street car and railroad service is twice as great as for all other purposes combined. The next largest field of application is for power and light. Then follow motors for rolling mills, special drives, shovels, dredges, elevators, and mining locomotives. The smallest application of rectifiers,

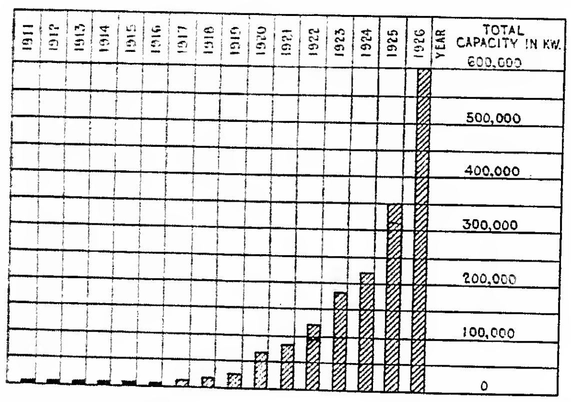

Fig. 1—Growth of Total Capacity in Kw. of Rectifiers Installed

because it is the newest, is for electrochemical purposes. Successful load tests have been carried out with rectifiers at d-c. voltages of 5000 volts and 8000 volts for special electrolytic purposes. Considerable study is being devoted to this field, and attention has naturally been given to assure safety of operation at the high voltages mentioned. These tests have shown that the limits of d-c. voltages for which rectifiers can be used are still unknown.

Installations on a commercial scale were begun in Europe in the year 1912, and then only in capacities of 100 kw. One of the earliest installations is shown in Fig. 3, which is for a municipal lighting plant, the direct current being employed for power and lighting purposes. This plant consists of four 6-anode rectifiers, each rated for 150 kw. at 220 volts. The supply current is three-phase, 50-cycle, 5250-volt. This installation was made in 1914 with three cylinders, the fourth being added later on.

Attention may be called to the fact that the principal elements in the design of the Brown Boveri type of rectifier have changed little during the past twelve years. This is evident at once when Fig. 3 is compared with Fig. 4, showing the relative sizes of the different types of rectifiers made at present by the Brown Boveri companies. Inspection of Fig. 3 and Type C in Fig. 4 reveals that the relative dimensions and arrangement of the various elements are practically identical in the 1914 and the present designs. In spite of the fact that there has been no great change in the basic structure of the rectifier, many refinements have nevertheless been

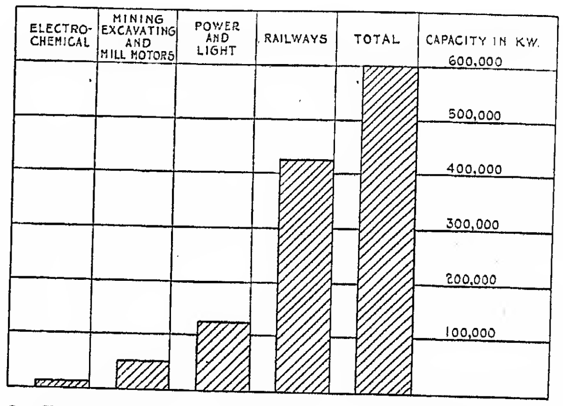

Fig. 2—Distribution of Rectifiers Installed According to Classes of Service

made in the design of such details as cooling, anodes, seals, etc., and in the development of more suitable material. Improvements have also been made in the auxiliaries, which, together with the improvements in the rectifier proper, allow a far better utilization of the

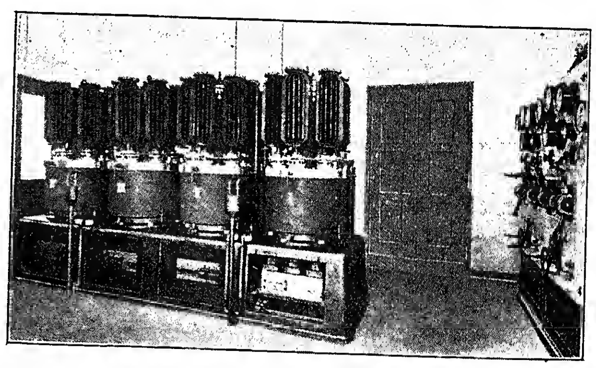

Fig. 3—One of the Earliest Rectifier Installations

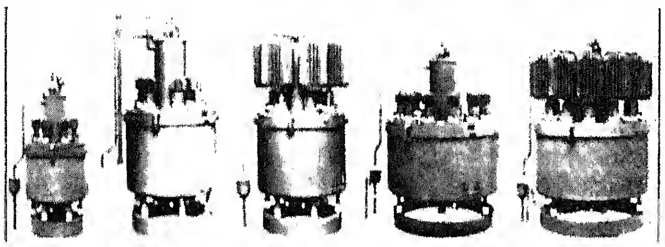
device. These facts are mentioned merely to remove any possible impression which may exist that the mercury arc power rectifier is still an unfinished product in its first stages of development.

Operating Features

The following figures might be of interest in connection with the operation of rectifiers.

The number of rectifiers operating in parallel with rotary converters and batteries, either in substations or over feeders, is about 900, distributed over approximately 450 installations, with a total rated capacity of more than 450,000 kw. Parallel operations of rectifiers with each other, with rotary converters, d-c. generators,

or batteries, is governed by the same principles as govern the parallel operation of d-c. generators. In accordance with the fundamental principles on which the operation of the rectifier depends, energy cannot flow from the d-c. to the a-c. network, since the current can pass only from the anode to the cathode. This fact is of considerable importance because a satisfactory parallel operation of rectifiers connected to two independent a-c. networks is thereby possible. The



A B C D E

Fig. 4 Relative Size of a Series of Brown Boveri Type Rectifiers

two networks are not restricted, in that they must have the same frequency, nor does a change in frequency affect safe operation, because a change in the frequency in one network will not cause motoring or other troublesome and dangerous occurrences in the rectifier, as would be the case in synchronous converters should they be connected to independent networks.

In regard to the adaptability of the rectifier to full automatic control, the fact that the total number of fully automatic substations reaches the appreciable figure of 100 may be of interest. Due to the simplicity

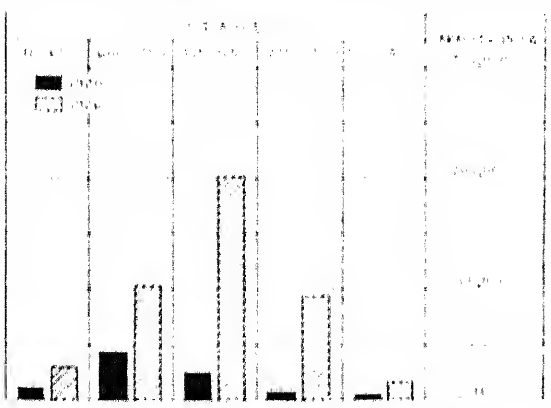


Fig. 5 Distribution of Rectifiers Installed for Railway Service According to Voltage

and speed of starting and stopping a mercury arc rectifier, this device lends itself to automatic control much more readily than a synchronous converter.

Another outstanding feature of the characteristics of the rectifier may be brought out here. As can be seen from Fig. 2, the application of rectifiers for railway service is far greater in respect to total capacity than for any other field; in fact, twice as much as for all other applications together. A most interesting fact in relation to railway service is illustrated in Fig. 5, in which the total capacity rating of rectifier installations for railway service—including city, interurban, and main-line—at different voltages is given, for the years 1920 (solid areas) and 1926 (shaded areas), respectively. The solid areas show that the voltages most frequently used in 1920 lay between 600 and 750 volts, while the shaded areas show that in 1926 the average choice lay between 775 and 1250 volts. It is unquestionably true that the influence of the outstanding rectifier characteristics, consisting of reliable and safe operation at voltages above 600 volts and increased efficiency at the higher voltages, accounts in great part for this fact. The authors firmly believe that an even more pronounced effect of these characteristics on the selection of voltages for the electrification of railroads will soon be noticeable, and thus the mercury arc power rectifiers will soon exert an influence on the question of d-c. versus a-c. systems.

In support of this, the following figures, which show the advantages of a 2000-kw. mercury arc rectifier as compared to a 2000-kw. motor-generator set at 3000 volts d-c., both at nominal rating, may be adduced. Assuming a load factor of 40 per cent, which is common in railway service (800 kw. for 24 hours), a total of 19,200 kw-hr. is obtained, and, assuming a load characteristic of two hrs. at 150 per cent load, eight hrs. at 50 per cent load, eight hrs., at 30 per cent load, four hours at five per cent load, and two hrs. at no-load, the table below will illustrate the large saving which can be effected by employing a rectifier in place of a motor-generator set for this particular load characteristic.

Time (hrs.)	Load kw.	Efficiencies Rectifier	Efficiencies M. G.	Losses in kw hr. Rectifier	Losses in kw hr. M. G.
2	3000	97.0	90.8	185	600
8	1000	96.8	86.4	264	1260
8	600	95.5	81.8	266	1070
4	100	82.5	46	82	470
2	0			38	232
				795	3632

Hence, the saving effected during 24 hrs. amounts to 2837 kw-hr., and per year to 1,035,000 kw-hr. Assuming the cost of power to be one cent per kw-hr., an annual saving of about $10,000.00 would be obtained, which would pay for the substation in a few years.

Additional savings in the annual costs would result from the use of a rectifier of the above rating in place of a motor-generator set on account of the lower initial cost of the rectifier, which is about 55 per cent of the cost of the motor-generator set, and on account of the lower cost of the substation, since the building required by the rectifier would be smaller, and would not need special foundations nor cooling ducts.

Load Characteristics

The mercury arc rectifier is inherently a machine with a continuous rating, due to the very small masses

which can absorb and store up the heat produced during its operation. Due principally to the absence of all rotating parts, however, it has a high momentary overload capacity and can respond very quickly to these overloads due to the absence of the inertia of a magnetic field. Standard types of Brown Boveri rectifiers are shown in Fig. 4; their current and kilowatt ratings at various voltages, up to 5000 volts, are given by the curves in Fig. 6. At present they are built for voltages from 220 volts to 5000 volts d-c., and in capacities from 220 kw. to 2700 kw. The ratings given in Fig. 6 are

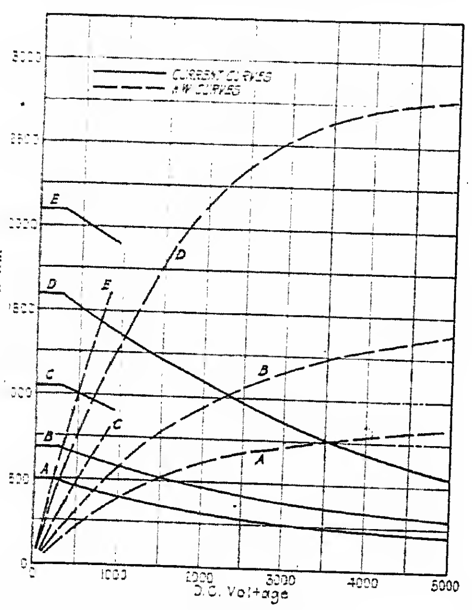

Fig. 6—Load Curves of Brown Boveri Rectifiers Shown in Fig. 4

reduced somewhat if overloads of appreciable duration are required. In order to give a picture of the overloads which can be cared for by rectifiers, the following figures have been noted: Type D, shown in Fig. 4, has a continuous capacity of 1500 kw. at 1500 volts, with an overload capacity of 2250 kw. for 15 min., 3000 kw. for five min., and 4500 kw. for one minute. The significance of these figures may be better appreciated if it is realized that it would be possible to start and run a train of average size with one such unit, since it does not take more than 5 to 10 minutes to bring such a train up to speed.

It can be seen from Fig. 6 that the output for a given cylinder increases with the voltage. In spite of this fact, rectifiers are at present rated on the basis adopted for the rating of electrical apparatus and machinery before the advent of the mercury arc power rectifier. The authors believe that, in view of the fact that the field of application of rectifiers is constantly enlarging, it would be justifiable to take steps to work out standards of rating for rectifiers based on their peculiar characteristics rather than on those of rotating machinery. The curves for Types D and E show the characteristic fact that with increasing voltage the kilowatt output increases in a straight line at first, but that the rate of rise decreases with further increases in the voltage.

The rectifier transformer serves the same purpose as the transformer for a synchronous converter; namely, to obtain the proper d-c. voltage and to split the primary power into the desired number of secondary phases. As is illustrated in Fig. 8, the d-c. voltage, during conversion, retains the caps of the sine wave of the a-c. supply voltage. It will be shown later that, in consequence of this, the amplitude and the frequency of the ripples depend on the number of phases, and that increasing the number of phases reduces the magnitude of the undulations. This is one of the reasons why the number of phases employed with rectifiers is relatively large: usually not less than six, and often as high as twelve. As the number of phases is increased, however, many complications enter into the design of the transformer, and its utilization decreases. This latter fact can easily be realized from a consideration of Fig. 8. The interval per cycle, during which the arc is maintained between the cathode and any one anode, decreases with a larger number of phases so that the time of utilization of each phase is shortened. During the other intervals, the phases are not under load and hence not fully utilized. Therefore, for a given d-c. output, the rating of the transformer will increase with the number of phases (see curve 3, Fig 9) which necessitates limiting the number of phases for economic reasons, at a reduction in the smoothness of the d-c. voltage wave. It is

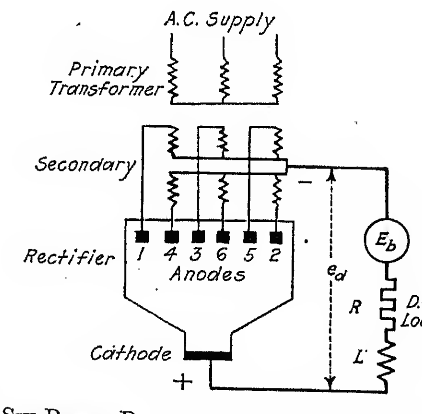

Fig. 7—Six-Phase Rectifier With Generalized D-c. Load

therefore necessary to take into account a certain amount of undulation in the voltage wave of all rectifiers, and accordingly we shall look into this question more thoroughly in the next part of this paper.

The various applications and present status of steel-enclosed mercury arc rectifiers have been dealt with in the first part of this paper. We shall consider now the characteristics of the rectifier as affected by the character of the load and electrical conditions on the d-c. side, for the various applications.

Voltage Wave

In a preceding paper by one of the present authors[2], the current and voltage relations in circuits of polyphase rectifiers were derived with the assumption that the direct-current wave is a straight line. While this assumption leads to sufficiently accurate results, for all practical purposes, insofar as the relations of voltage, current and power on the d-c. and a-c. sides of the rectifier are concerned, and is entirely justified when there is a considerable amount of inductance on the d-c. side, yet in some cases the undulations in the d-c. current and voltage waves become a factor worth considering, as will be brought out later on.

In a polyphase rectifier, the load current at any

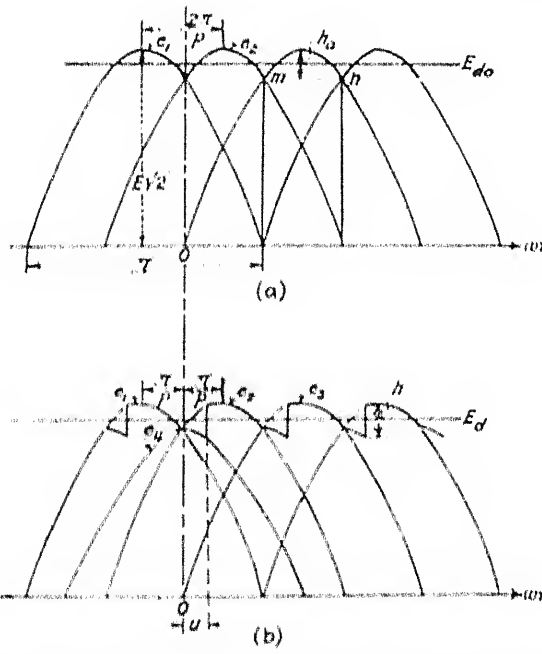

Fig. 8 Rectifier D-c. Voltage Wave at (a) No Load, and (b) Full Load

instant is carried by the anode having the highest positive potential with respect to the neutral of the transformer secondary. The d-c. voltage wave at no-load has the form shown in Fig. 8A. The undulation of the (voltage) wave is formed by the caps of sine waves of the transformer secondary phase voltages. As each phase assumes a maximum positive potential once during every cycle, the number of pulsations per cycle must be equal to the number of phases, and the frequency of pulsation or the number of pulsations per second must be equal to the product of the frequency of the a-c. supply and the number of secondary phases.

If the transformer, the a-c. line, and generator supplying the rectifier were free of reactance, each anode of a p-phase rectifier would carry the whole d-c. current during $\frac{2\pi}{p}$ part of a cycle only; thus, in Fig. 8, the whole load current would be transferred instantly from phase 2 to phase 3 at m and from phase 3 to phase 4 at n. Under such conditions, the d-c. voltage wave under load would have the same form as at no load.

Due to the unavoidable reactance present in the transformer, the current cannot die down nor build up instantly in any phase. As a result, there are intervals during which two adjoining phases carry current simultaneously, as the current in one phase is dying down and the current in the other is building up. This period of overlapping between two adjoining phases begins at the intersection of their respective sine waves and continues until the current in the leading phase becomes zero. The angle of overlap u is given by the expression

$$\cos u = 1 - \frac{I\,X}{E\sqrt{2}\sin\frac{\pi}{p}} \tag{1}$$

in which I is the direct current, X the reactance per phase of transformer secondary[3] at the primary frequency, E the effective value of phase voltage, and p the number of secondary phases.[4]

The d-c. voltage during the period of overlapping is equal to the mean of the overlapping phase voltages.

Using the point of intersection of phase voltages e_1 and e_2 (Fig. 8B) as the origin, these voltages may be expressed by

$$e_1 = E\sqrt{2}\cos\left(\omega t + \frac{\pi}{p}\right) \tag{2}$$

$$e_2 = E\sqrt{2}\cos\left(\omega t - \frac{\pi}{p}\right) \tag{3}$$

The d-c. voltage during the period of overlapping is

$$e_u = \frac{e_1 + e_2}{2} = E\sqrt{2}\cos\frac{\pi}{p}\cos\omega t \tag{4}$$

When the period of overlapping is over, the d-c. voltage is equal to the voltage of the working phase.

The average d-c. voltage E_d (including the constant drop in the arc), is given by the expression

$$E_d = \frac{E\sqrt{2}\sin\pi/p}{\pi/p} - \frac{I\,X}{2\,\pi/p} \tag{5}$$

The first term to the right of eq. (5) is the average d-c. voltage at no-load; the second term is the voltage drop at load current, I. The rectifier d-c. voltage wave under load is shown in Fig. 8B. Oscillograms Nos. 1 and 2, Fig. 13, show rectifier voltage waves at no-load and full load, respectively.

The magnitude of the angle of overlap, and therefore

2. *Rectification of Alternating Currents*, by O. K. Marti, Trans. A. I. E. E., 1926, Vol. 45, p. 668.

3. Including equivalent reactance of transformer primary and line.

4. For derivation of eqs. (1) and (5) see paper mentioned in footnote 2.

the shape of the d-c. voltage wave under load depend somewhat on the nature of the load. Eq. (1) was derived on the assumption that the current curve is a straight line. The angle u will be greater or less than that given by eq. (1) depending on whether the current during the period of overlap is greater or less than the average current. The difference, however, is negligible, and the voltage wave is assumed to be independent of the character of the load.

The total height, h, of the ripple in the voltage wave is equal to the difference between the maximum and minimum ordinates of the wave. From Fig. 8B, it is readily seen that for values of $u < \frac{\pi}{p}$, the maximum ordinate is equal to the amplitude of e_2, while the minimum ordinate is equal to the value of e_u for $\omega t = u$. Therefore,

$$h = E\sqrt{2} - E\sqrt{2}\cos\frac{\pi}{p}\cos u$$

$$= E\sqrt{2}\left(1 - \cos\frac{\pi}{p}\cos u\right) \tag{6}$$

Expressing h as a fraction a of the average d-c. voltage at no-load (see eq. (5)),

$$a = \frac{h}{E\sqrt{2}\sin\frac{\pi}{p}/\frac{\pi}{p}}$$

$$= \frac{E\sqrt{2}\left(1 - \cos\frac{\pi}{p}\cos u\right)}{E\sqrt{2}\sin\frac{\pi}{p}/\frac{\pi}{p}}$$

$$= \frac{1 - \cos\frac{\pi}{p}\cos u}{\sin\frac{\pi}{p}/\frac{\pi}{p}} \tag{7}$$

For values of $u > \frac{\pi}{p}$, the maximum ordinate is equal to the value of e_2 for $\omega t = u$, and the minimum ordinate to the value of e_u for $\omega t = u$. Therefore

$$h = E\sqrt{2}\cos\left(u - \frac{\pi}{p}\right) - E\sqrt{2}\cos\frac{\pi}{p}\cos u$$

$$= E\sqrt{2}\sin\frac{\pi}{p}\sin u\,. \tag{8}$$

$$a = \frac{E\sqrt{2}\sin\frac{\pi}{p}\sin u}{E\sqrt{2}\sin\frac{\pi}{p}/\frac{\pi}{p}} = \frac{\pi}{p}\sin u \tag{9}$$

The variation of the ripple in the d-c. voltage wave with the number of phases, at no load, is shown by Curve 1 in Fig. 9. In the same figure are plotted the frequency of the main ripple and the ratio of the transformer rating to d-c. load, to show the effect of the number of phases used on these quantities. The magnitude of the ripple naturally decreases as the number of phases is increased; but to counterbalance that, the size of the transformer increases with the number of phases. Furthermore, the frequency of the ripple increases with the number of phases, which is often objectionable.

In Fig. 10 are shown the variations of the voltage ripple of a six-phase rectifier with the load on the rectifier. The curves have been plotted from eqs. (7) and (9). The load is expressed as a ratio, I/I_s. This ratio is deduced by rewriting eq. (1) as follows:

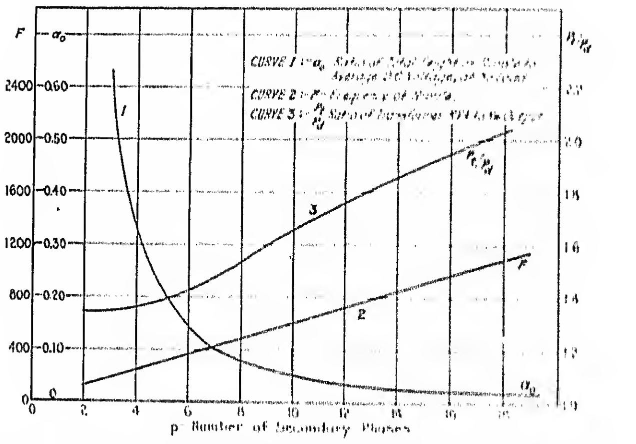

FIG. 9—CURVES SHOWING VARIATION IN RIPPLE HEIGHT, RIPPLE FREQUENCY, AND TRANSFORMER KV-A. WITH THE NUMBER OF PHASES USED.

$$\cos u = 1 - \frac{I}{\frac{E\sqrt{2}}{X}\sin\frac{\pi}{p}} = 1 - \frac{1}{\sin\frac{\pi}{p}}\cdot\frac{I}{I_s} \tag{10}$$

where $I_s = \frac{E\sqrt{2}}{X}$.

The point on the abscissa corresponding to full-load current of a rectifier is determined by the value of X, and therefore depends upon the design of the transformer. The smaller the value of X for a given transformer rating, the larger is I_s and therefore the smaller the ratio I/I_s at full load. The value of I/I_s corresponding to full load is approximately 0.05.

CURRENT WAVE

It was shown above that the form of the rectifier d-c. voltage wave depends on the number of phases used and on the design of the transformer, and that it varies with the magnitude of the load; but is practically independent of the nature of the load. The wave consists of a d-c. component equal to the average value of the voltage, on which is superimposed an alternating component

made up of the upper portions of sinusoidal waves. The alternating component is irregular in shape and cannot be expressed by a continuous function. It may be resolved into harmonic components by means of a Fourier series. The first harmonic has a frequency equal to the product of the frequency of the a-c. supply and the number of phases used; it is therefore the pth harmonic with respect to the a-c. voltage supplied to the rectifier. The frequencies of the higher harmonics are multiples of the frequency of the first harmonic and since the positive and negative portions of the wave are not symmetrical, there are even multiples as well as odd. Thus, the d-c. voltage wave of a six-phase rectifier supplied by a 60-cycle system has an alternating component consisting of sinusoidal waves of frequencies 360, 720, 1080, etc., cycles.

The general equation of the d-c. voltage of a p-phase rectifier, expressed in a Fourier series, is

$$\begin{aligned} e_d = {} & E_d + A_{p1} \sin p\,\omega\,t + A_{p2} \sin 2\,p\,\omega\,t \\ & + A_{p3} \sin 3\,p\,\omega\,t + \dots \\ & + A_{pn} \sin n\,p\,\omega\,t + \dots + B_{p1} \cos p\,\omega\,t \\ & + B_{p2} \cos 2\,p\,\omega\,t + \\ & + B_{p3} \cos 3\,p\,\omega\,t + \dots + B_{pn} \cos n\,p\,\omega\,t + \dots \end{aligned} \tag{11}$$

The voltage curve may be analyzed to determine the amplitudes of the various harmonics by any one of the well-known methods of analysis.

A typical analysis of the alternating component in the d-c. voltage wave of a 60-cycle 6-phase rectifier under load, with and without a series reactor on the d-c. side, is given in the table below:

Order of harmonic	Frequency in cycles per sec.	Per cent amplitude of harmonic to d-c. voltage	
		Without reactor	With reactor
First	360	8.46	2.36
Second	720	1.70	0.40
Third	1080	0.95	0.28
Fourth	1440	1.05	0.17
Fifth	1800	0.71	0.12
Sixth	2160	0.58	0.10
Seventh	2520	0.45	0.09
Eighth	2880	0.39	0.08

When the voltage wave with its d-c. and a-c. components is known, the shape of the current wave may readily be determined when the constants of the load are known.

A six-phase rectifier with a generalized d-c. load is shown in Fig. 7. The load may consist of one of the following combinations.

1. Resistance only (R).
2. Resistance and back-e. m. f. ($R + E_b$).
3. Resistance and inductance ($R + L$).
4. Resistance, inductance, and back-e. m. f. ($R + L + E_b$).

1. *Resistance only.* With a load consisting of resistance only, such as a lighting or heating load, the current wave has the same shape as the voltage wave; *i.e.*, the harmonic components in the ripple bear the same ratios to the average value of current as in the voltage wave.

2. *Resistance and back-e. m. f.* With a load consisting of resistance and a constant back-e. m. f., such as a battery, the shape of the current wave depends upon the relative magnitude of the average d-c. voltage, E_d,

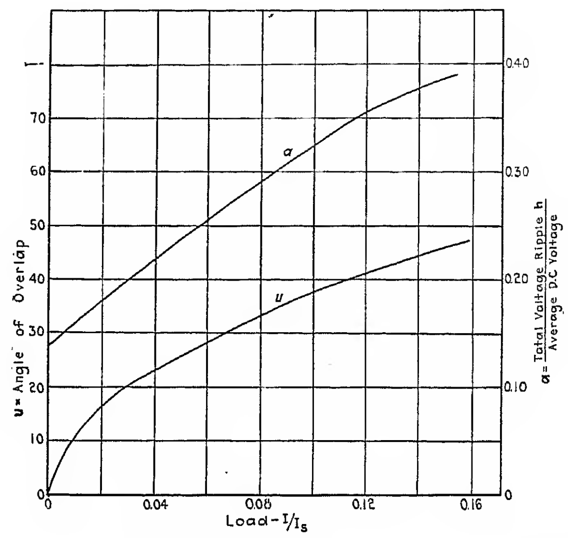

FIG. 10—CURVES SHOWING VARIATION OF THE ANGLE OF OVERLAP AND HEIGHT OF RIPPLE WITH THE LOAD

and the back-e. m. f., E_b. The conditions are shown in Fig. 11. The current is produced by the portion of the voltage wave lying above the line $b\,b'$, the average value of which is $E_d - E_b$. The ratio of the height h of the ripple to this voltage is greater than its ratio to E_d (eqs. 7 and 9) in the proportion of $\dfrac{E_d}{E_d - E_b}$. The ripple in the current wave, therefore, has the same shape as that of the voltage wave; but the percentage of

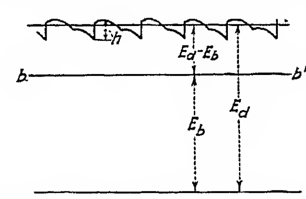

FIG. 11—VOLTAGE CONDITIONS OF RECTIFIER SUPPLYING A LOAD HAVING A BACK ELECTROMOTIVE FORCE

the current ripple is greater than that of the voltage ripple in the ratio, $\dfrac{E_d}{E_d - E_b}$.

3. *Resistance and inductance.* With a load consisting of resistance and inductance, such as a lighting or heating load fed over a line having a certain amount of inductance, or with a series reactor connected into the d-c. circuit for smoothing out the wave, the average d-c. current is equal to the ratio of average d-c. voltage to the resistance: $I_d = E_d/R$. The amplitude of the nth

harmonic in the current ripple, however, is equal to the height of the corresponding harmonic in the voltage ripple divided by the impedance of the circuit to that harmonic:

$$I_n = E_n / \sqrt{R^2 + X_n^2}$$

From the above,

$$\frac{I_n}{I_d} = \frac{R}{\sqrt{R^2 + X_n^2}} \cdot \frac{E_n}{E_d}$$

$$= \frac{1}{\sqrt{1 + X_n^2/R^2}} \cdot \frac{E_n}{E_d}, \qquad (12)$$

i. e., the percentage of the nth harmonic in the current wave is less than that of the corresponding harmonic in the voltage wave by the ratio of $\dfrac{1}{\sqrt{1 + \dfrac{X_n^2}{R^2}}}$, in which $X_n = p\,n\,L$ is the reactance of the circuit to the nth harmonic. It is seen from the above that the inductance has a smoothing effect upon the current wave, and the smoothing action is greater for the higher harmonics.

4. *Resistance, inductance, and back-e. m. f.* This type of load is by far the most common load supplied by rectifiers, as it is characteristic of all d-c. motors. While starting, when the speed of the motor is zero, the back e. m. f. is also zero, and the load conditions are as given under 3. When the motor is running, a back e. m. f. is generated, in opposition to the applied e. m. f.; the voltage conditions are then as shown in Fig. 11. The current is produced by the portion of the voltage curve lying above line $b\ b'$, as for load 2. The load here, however, is inductive and the current wave is consequently smoothed. The average d-c. current,

$$I_d = \frac{E_d - E_b}{R}$$

The amplitude of the nth harmonic in the current wave,

$$I_n = E_n/\sqrt{R^2 + X_n^2}$$

$$\frac{I_n}{I_d} = \frac{R}{\sqrt{R^2 + X_n^2}} \cdot \frac{E_n}{E_d - E_b}$$

$$= \frac{1}{\sqrt{1 + \dfrac{X_n^2}{R^2} \cdot \left(1 - \dfrac{E_b}{E_d}\right)}} \cdot \frac{E_n}{E_d} \qquad (13)$$

From eq. (13) it is seen that the percentage of the nth harmonic in the current wave is smaller than the corresponding harmonic of the voltage wave in the proportion of

$$\frac{1}{\sqrt{1 + \dfrac{X_n^2}{R^2} \cdot \left(1 - \dfrac{E_b}{E_d}\right)}}$$

the symbols having the same meaning as in eq. (12).

The series d-c. motor, used for railways, hoists, etc., is the most common motor fed by rectifiers; in fact, it is the favorable characteristics of the series, d-c. motor for traction purposes which have brought about the present large scale conversion from a-c. to d-c. The series motor is also the most favorable load for smoothing out the ripples in the current wave, due to the inductance of the series field of the motor. In oscillogram No. 3, Fig. 13, are shown the voltage and current waves of a rectifier supplying a railway load. The oscillogram was taken on a 1500-volt rectifier at 200 per cent of the rated load when the voltage ripple is greater than at rated load, and shows the smoothing effect of the series motor on the current wave.

A further smoothing out of the current, and also of the voltage wave supplied to the line can be realized by connecting a reactor into the d-c. lead of the rectifier. The smoothing of the voltage wave is produced by the a-c. voltage drop across the reactor, due to the ripple in the current. The effect of the reactor on the current

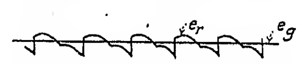

FIG. 12—VOLTAGE CONDITIONS OF RECTIFIER OPERATING IN PARALLEL WITH ROTARY CONVERTER OR D-C. GENERATOR

and voltage waves supplied to the line by a rectifier is shown in oscillogram No. 4, Fig. 13. The oscillogram was taken at approximately the same load and under the same conditions as oscillogram No. 3, except that a series reactor of approximately 3 millihenrys was connected into the circuit when oscillogram No. 4 was taken.

When a rectifier operates in parallel with a rotary converter or a d-c. generator which has a smoother voltage wave than the rectifier, the resultant line voltage and current waves are smoother than those of a rectifier alone. This condition is shown in Fig. 12. In this sketch, e_r is the voltage wave of the rectifier and e_g that of the rotary machine. For the sake of simplicity, the commutator ripples of the rotary machine are not shown. The smoothing of the voltage wave is produced by the interchange of a small alternating current between the rectifier and the rotary machine.

The interchange current is produced by the alternating component in the difference of the two voltage waves. The a-c. voltage drop in the reactance of the rectifier transformer, produced by the a-c. current component flowing between the rectifier and rotary machine, reduces the ripple in the voltage wave of the rectifier. In this respect, the rotary acts somewhat as a shunt

condenser across the rectifier in that it absorbs an alternating component.

When a series reactor is connected into the d-c. lead of a rectifier operating in parallel with a rotary, the wave of line voltage is improved on account of the additional drop in the reactor due to alternating interchange current.

The above conditions are clearly shown in oscillo-

No. 5. Waves of voltage and current supplied to railway load, rectifier working in parallel with rotary converter in the same station.
No. 6. Waves of voltage and current supplied to railway load, rectifier working in parallel with rotary converter in the same station and with a series reactor in the rectifier circuit.

grams 5 and 6, Fig. 13. Oscillogram No. 5 was taken with a rectifier operating in parallel with a rotary in the same station. Oscillogram No. 6 was taken at about the same current and under the same conditions as oscillogram No. 5, except that there was a series reactor in the rectifier circuit.

The effect of various load conditions on the wave form of rectifier voltage and current having been discussed, it might be of interest to mention here that extensive tests have been carried out to determine the effect of the undulations in the waves upon the load connected to a rectifier. For this purpose, batteries and shunt-wound and series-wound motors were connected, first to a battery (*i. e.*, a constant d-c. voltage supply), then to a rectifier fed, respectively, by a single-phase, three-phase, and six-phase a-c. supply. With six-phase operation, no difference in the efficiency as compared to operation on a battery could be noticed in the case of either motor; nor did the undulations have any effect upon commutation.

It can readily be seen that the undulations in the d-c. voltage will have no effect upon the usual lighting circuits, since the frequency of the undulations is high and their magnitude small as compared to the 60-cycle a-c. voltage used for lighting.

The presence of these ripples in the d-c. voltage wave of a rectifier, particularly the harmonics lying within the audible frequency band, has raised the question of their influence upon neighboring communication circuits. This influence has been detected in connection with about 5 per cent of all installations and was found to be due either to close spacing between communication circuits and rectifier feeders, to bad insulation conditions, or to a grounded method of operation on part of the communication system for certain types of service. The cause of the interference is similar to that which results in disturbances in communication or signaling circuits which parallel high-voltage supply lines at small separations and for long distances; *i. e.*, induced or leakage currents and voltages due to harmonics in the voltage wave. When, as in the case of street railway systems, one side is permanently grounded, the ripples may appear in the communication circuits, especially when the method of operation or interconnection involves grounded equipment, wet soil conditions aggravating the case materially. The problem may be solved by the elimination of the exposure, the employment of a non-grounded method of operation or interconnection, or the utilization of a so-called filter, which consists of a combination of inductance and capacitance, so arranged in the circuit as to smooth out the high-frequency ripples in the voltage wave of the rectifier. To the knowledge of the authors, such filters have been found necessary in but few cases. The subject is merely mentioned here, as a thorough discussion of the question would lead beyond the scope of this paper.

Discussion

PAPERS ON MERCURY ARC RECTIFIERS

(MARTI AND WINOGRAD[1], SHAND[2], BETCHER[3])
KANSAS CITY, MO., MARCH 18, 1927
BETHLEHEM, PA., APRIL 21, 1927
(DISCUSSION AT KANSAS CITY)

B. Blasser: A limited study on the application of mercury arc rectifiers to a city street railway system brought out some interesting comparisons that might be of interest.

On the property of the Kansas City Public Service Company the daily load factor is almost constant for any week day, varying between 49 and 51 per cent. With this condition, it is a simple matter to construct typical load curves for any season from the average output over the period under consideration as compared to the output on the maximum day in the year.

For the purpose of this discussion the four curves in the accompanying Fig. 1 were constructed; (1) the maximum day in the year taken from hourly readings, (2) the typical winter day which is 81 per cent of the maximum day, (3) average day for the year, 70 per cent of the maximum day, and (4) a typical summer day, 61 per cent of the maximum day.

For a single-unit substation in an outlying district, the time of operation may be somewhat different from a centralized substation and with the application of a 750-kw. unit to the load of 1000 amperes for the maximum hour as shown by Curve No. 1 it

is assumed that the station will be shut down whenever the load drops to 200 kw. This operation would give 20.5 hr. operation on the maximum day and 17.75 hr. per day in the summer time. If it should be necessary to operate this station through the "owl" period at less than 200 kw., the comparative results would be materially changed. The dotted line shows the approximate load that would be carried by the machine on the "owl" if this station had its proportionate share of the total load. The 24-hr. operation would give a station load factor of 51 per cent as compared to a load factor under proposed operation of 60.8 per cent on maximum day and 65.5 per cent load factor during proposed summer operation.

In comparing the operation of 750-kw. synchronous converters with 750 kw. rectifiers, the daily load curves shown were used to determine total loss for the day and the difference between the loss with converters and the loss with rectifiers (expressed as a percentage of total output) was plotted against the average load of the machine for the four typical loads shown, Fig. 3A. Positive values show rectifier more efficient and negative values show converter more efficient.

This set of curves shows the effect of load factor and more variation in performance between converters and rectifiers is obtained on 60-cycle systems than on 25-cycle systems.

A similar set of curves, Figs. 2 and 3B, was plotted for a 1500-kw. station using a single-unit converter and two 750-kw.

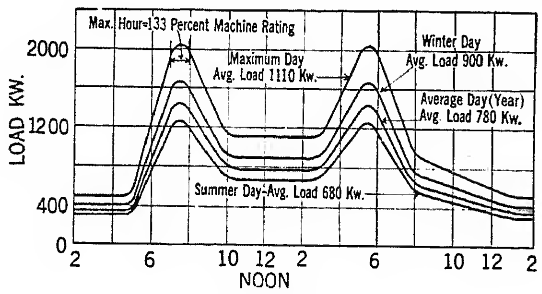

FIG. 1

rectifiers in parallel. It was assumed that the rectifiers were operated as a 1500-kw. unit and that one element could not be shut down during periods of light load. The loads were taken as double the values of the load curves shown for the 750-kw. station except that it is assumed that the station is located at an intermediate point between outlying district and downtown making it necessary to operate the station during the "owl" period. It is also assumed that this station will pick up load from surrounding districts so that it will carry a minimum load of 50 kw.

Even with the additional period of light-load operation, the 25-cycle converter is almost as efficient as the rectifier for the year's operation and is more efficient during the winter period.

On 60-cycle systems, the rectifier is more efficient than converters although the margin is less with the double-unit station.

For the 1500-kw. station, another set of curves, Fig. 3C, was made up with the assumption that one of the 750-kw. rectifiers could be shut down for all loads under 750 kw. This eliminates the loss of one unit over a considerable period of time and results in an increase in efficiency for the rectifier. This operation gives about the same percentage of saving as was obtained with the 750-kw. single-unit station.

From the standpoint of station losses, I should conclude that the application of rectifiers on 25-cycle systems would be justified only after their satisfactory operation in service had been proved, but that the margin of saving when applied on 60-cycle systems is sufficient to justify the expense of trial installations. The tendency of 60-cycle converters to flash over is a further incentive to the trial application of rectifiers on that frequency.

Rectifiers have not been in service for sufficient time in this country to obtain maintenance costs that are truly comparative with other types of apparatus and until this information is available comparisons of total operating costs will have an unknown factor that might lead to erroneous conclusions.

R. G. McCurdy: I wish to discuss briefly the effect on inductive coordination between electric street railway circuits and telephone circuits induced by the use of mercury arc recti-

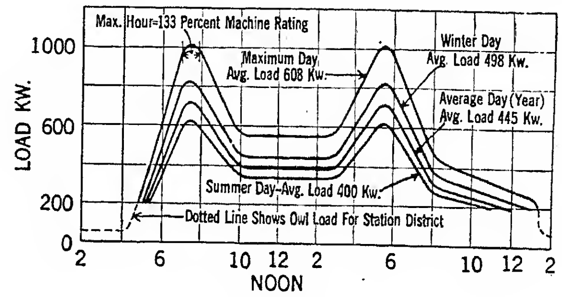

FIG. 2

fiers. In his paper Mr. Shand refers to the importance of this problem and it is mentioned briefly in the paper by Messrs. Marti and Winograd. It may be of interest to consider the relative advantages of rotating machinery and mercury arc rectifiers in this respect, along with the relative advantages from the power standpoint. It would be unfortunate in this respect if such a new development should result in a general increase in the a-c. components on street railway circuits in the range of frequencies employed in the telephone circuits, thus increasing the inductive influence of the street railway circuits.

In considering this problem, it should be remembered that the distribution system of the street railways is a system having one side connected to ground. For given magnitudes of voltages and currents of voice frequencies, the inductive effects are much more severe than with circuits which are connected to ground

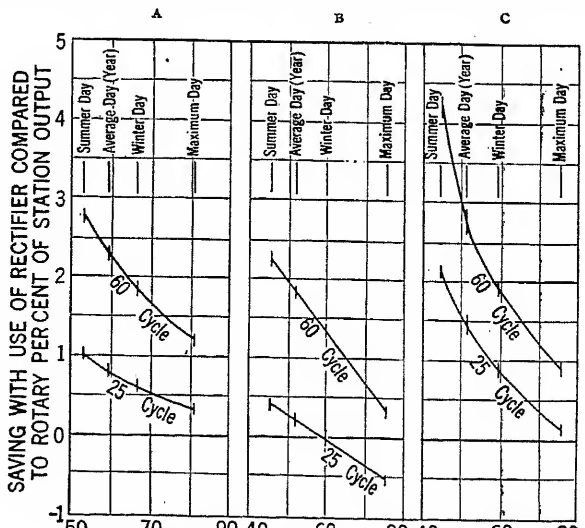

FIG. 3

only at neutral points. Moreover, it is of course impossible to employ transpositions in the trolley circuits to reduce coupling with neighboring communication circuits.

As brought out in the paper by Messrs. Marti and Winograd, there are present in the voltage wave shape on the d-c. side of the rectifier, ripples whose magnitude and frequency depend upon the frequency of the fundamental a-c. supply and the number of phases. The fundamental frequency of the ripple is equal to the

CALCULATED DATA USED FOR CURVES USED IN DISCUSSION OF APPLICATION OF MERCURY ARC RECTIFIER

	Load, kw., max. hr.	Hours oper.	Avg. load, kw.	Load factor per cent	Machine factor	Saving with rectifier, per cent 60 cycle	Saving with rectifier, per cent 25 cycle
750-Kw. Station—Outlying District							
Maximum day	1000	20.5	608	60.8	81	1.23	0.35
Average winter day	840	20.0	498	61.5	66.5	1.85	0.64
Average day for year	700	18.88	445	63.5	59.4	2.30	0.83
Average summer day	610	17.75	400	65.5	53.3	2.80	1.02

Maximum day	2000	24	1110	55.5	76	0.32	−0.52
Average winter day	1620	24	900	55.5	60	1.30	−0.05
Average day for year	1400	24	780	55.5	52	1.80	0.20
Average summer day	1220	24	680	55.5	45.5	2.30	0.42
1500-Kw. Station—Intermediate District, Single Unit 750-Kw. Rectifier Up to 750-Kw. Load							
Maximum day	2000	24	1110	55.5	76	0.90	0.10
Average winter day	1620	24	900	55.5	60	1.90	0.89
Average day for year	1400	24	780	55.5	52	2.75	1.40
Average summer day	1220	24	680	55.5	45.5	4.20	2.15

product of the fundamental frequency of the a-c. supply and the number of secondary phases. The fundamental ripple contains both odd and even harmonics. As the number of phases increases, the magnitude of the fundamental ripple decreases, as is shown by Curve I of Fig. 9 of the paper. Thus in a 6-phase rectifier, supplied from a 60-cycle source, the fundamental frequency of the ripple is 360 cycles, and in a 12-phase rectifier, 720 cycles, the magnitudes of the 720-cycle component in the 12-phase rectifier being considerably less than that of the 360-cycle component in the 6-phase rectifier. If there were 24 phases, the fundamental frequency of the ripple would be 1440 cycles and its magnitude would be much less than that of the 720-cycle ripple present in the 12-phase device.

In the table on the seventh page of the paper by Messrs. Marti and Winograd are shown amplitudes of the harmonic components of the voltage from a 6-phase, 60-cycle rectifier including the harmonics up to the eighth. It will be noted that the magnitudes of these harmonics fall off with increasing frequency. The second harmonic, 720 cycles, is about one-fourth of the 360-cycle component while that of the 1440-cycle component is about one-eighth. It will be seen, therefore, that the 6-phase rectifier has all the harmonic components that the 12-phase rectifier contains and in addition contains 360, 1080 and other odd harmonic multiples of 360 cycles.

As brought out in the papers, there is usually considerable series inductance in the feeder circuits and load of street railway systems. The percentage harmonic in the current is usually less, therefore, than it is in the voltage, the percentage of current harmonic with respect to voltage decreasing with increasing order. In a particular instance which I have in mind, the impedance of the load for the harmonic frequencies was equivalent to an inductance of about one millihenry.

In the table on the seventh page of the paper, to which I previously referred, there is shown also the effect on the wave shape of a series reactor. The rectifier itself at voltages of about 600 has a low internal reactance as compared with the reactance of the feeders and the load. The rectifier acts, therefore, practically as a constant-potential generator of these frequencies. As the impedance of the load varies for these frequencies, the harmonic voltage impressed upon it does not change appreciably. If a series reactor is inserted, it is evident that the total harmonic current and the harmonic voltage impressed upon the load will be reduced in the ratio which the total impedance of the load and series reactor bears to the impedance of the load. In the case cited in the paper by Messrs. Marti and Winograd, the series reactor was about three millihenrys, the load impedance being about one millihenry. There is thus a reduction of about four to one in the harmonic voltages impressed upon the load. It is evident that if the load impedance were larger or the series reactor smaller, the reductions obtained would also be smaller.

It is known, of course, that there are also harmonic ripples present in the d-c. sides of rotating apparatus for converting from alternating to direct current. It will be of interest, therefore, to compare mercury arc rectifiers with rotating converting apparatus in this respect. To date in this country there has been a number of installations of mercury arc rectifiers on street railway systems from which experience has been obtained. These experiences have indicated that the inductive influence on telephone lines of street railway systems will be increased by a factor of between five and ten to one by the use of a mercury arc rectifier not equipped with auxiliary devices for correcting the wave shape, as compared to the influence when rotating converting apparatus is employed. The general experience with induction from street railway systems supplied by rotating converting equipment has been that the noise is largely due to commutator ripples from the car motors. When mercury arc rectifiers are used, the source of the noise has been due chiefly to the harmonics from the rectifier, the effects from the car motors being overshadowed.

The impedance of rotary converters to the harmonic frequencies is of the same order of magnitude as the internal impedance of the rectifier. When a rotary converter and a mercury arc rectifier are operated in parallel in the same substation through a reactor, the harmonic currents circulate locally and do not get out to the feeders. Under such conditions, the noise effects on the telephone lines will be very much reduced. When rectifiers and rotary converters are operated in parallel in different substations without a series reactor, harmonic currents are exchanged between the rectifier and the converter, which are determined by the magnitudes of the harmonic voltages from the rectifier and the impedance of the feeders between the two substations. The harmonic currents taken by car motors are small as compared to these currents. When these tie feeders are involved in telephone exposure, the effects are particularly severe, the noise being practically constant in magnitude and independent of load so long as the rotary converter and the rectifier are connected to the line.

All types of telephone circuits are affected by these induced disturbances, including interoffice trunk circuits used for private-branch exchanges and party-line subscribers' circuits. Individual subscriber circuits are also affected under some conditions. These circuits are affected even when they are carried in underground cables.

Reference is made in the paper to a small percentage of cases involving mercury arc rectifiers which have given telephone troubles, but, as I understand the matter, this figure is based

upon European experience. So far, experience in this country has indicated that the percentage which will require remedial measurements will be very much higher than that. Our experience has been that where these mercury arc rectifiers are connected without auxiliary devices for modifying wave shape to street railway circuits involved in telephone exposures, severe noise is caused in the telephone circuits. In two or three instances it has been necessary to temporarily shut down the mercury arc rectifier until a remedy could be applied.

In cooperation with the manufacturers of these rectifiers, and with the street railway companies that are particularly involved, work is being carried on by the American Telephone and Telegraph Company and Associated Telephone Companies to determine remedial measures. Consideration is being given both to measures that may be applied to telephone circuits so that they may withstand a higher degree of inductive influence, and to corrective measures which may be applied to the mercury arc rectifiers to reduce their inductive influence.

In reference to the latter, consideration is being given to the use of filters. One particular arrangement which is being investigated consists of a series reactor having an inductance of about one millihenry, with three shunt branches, each consisting of inductance and capacity tuned for the 360-, 720-, and 1080-cycle components. This arrangement gives large reductions in the magnitudes of those particular harmonics and appreciable reductions in the magnitudes of the harmonics of 1440 cycles and above. With such a filter connected to the rectifier, its telephone interference factor will be reduced to that of a reasonably good rotary converter. Under such conditions it would seem to make no particular difference, so far as inductive coordination between the d-c. circuits and telephone circuits is concerned, whether the power were obtained from a mercury arc rectifier or from rotating converting equipment. At present, it is not possible to give any precise figures on what the cost of such a filter will be, but it does not seem that it will very materially change the cost comparisons between mercury arc rectifiers and rotary converters.

In addition to the effects involving the d-c. side of the rectifier, there is also a problem of wave-shape distortion on the a-c. side. The current input to the rectifiers from the a-c. supply contains harmonics of considerable magnitudes. The effects on the telephone interference factor of the voltage depends upon the relative ratings of the rectifier and the generating system and the impedances of the feeders to the harmonics. If the rectifier load is small as compared to the power capacity of the generating system and the feeder is short, the effect on the a-c. system is not large. If rectifiers form a large proportion of the load, such as might be the case with a main line railroad electrification, the effect on the a-c. voltage and current waves would be important and the difficulty of coordinating the a-c. supply circuits with neighboring telephone circuits would be materially increased. There is an important difference, however, in that these harmonics are in the balanced voltages and currents rather than in a circuit having ground as one side.

A. S. Biesecker: In connection with the first method of which you spoke—that is, the introduction of the reactance in order to smooth out the current curve—by what percentage is that going to affect the regulation?

R. G. McCurdy: The regulation of the rectifier is effected only by the d-c. resistance of the series reactor. The power losses in the shunt elements are entirely negligible. There seems to be no particular difficulty in designing the series reactor to have a voltage drop of 0.5 per cent or less of the rectifier voltage where this is 500 volts or above. With lower voltage rectifiers, of course, the loss in the series coil would be more serious.

G. E. King: What, in microfarads, is the capacity of the condenser you would have to put in there?

R. G. McCurdy: In the particular arrangement I have described, which is applicable to a 600-volt, 60-cycle, 6-phase rectifier, the series reactor is one millihenry and the reactor in each of the three shunt branches is two millihenrys; approximately 100 microfarads are required in the 360-cycle branch, 25 microfarads in the 720-cycle branch, and 10 microfarads in the 1080-cycle branch. A design involving more inductance and less capacitance would be more economical for higher d-c. voltages.

A. S. Biesecker: Does it require as much capacity as that for each installation?

R. G. McCurdy: That is one of the matters which must be determined by the cooperative studies by the manufacturers and street railway and telephone companies, to which I have referred. It is obvious, of course, that if the mercury arc rectifier were connected to a trolley system which is not involved in telephone exposures, no filter of any sort would be required. As a rule, however, wherever we find street railway systems, we are likely to find telephone systems in proximity so that some filtering equipment will be required. The total amount of capacity required will, of course, be determined by the reduction in harmonic voltages and currents which must be obtained.

O. S. Clark: Is the trouble caused by harmonics in the rectifier comparable with the trouble caused by harmonics in the rotary converter?

R. G. McCurdy: While there are occasionally encountered rotary converters which have fairly large harmonic components in the voltage wave, approaching those of the mercury arc rectifier, as a rule, rotating equipment has noise-producing harmonics amounting to not more than 10 per cent or so of a six-phase rectifier not equipped with correcting means. In a number of instances where rotating apparatus having these large harmonics has been encountered, these harmonics have been reduced by the application of auxiliary devices, such as resonant shunts. As a rule, there has been sufficient series impedance in the generator or converter to make it unnecessary to introduce a series reactor.

R. E. Curtis: The Luzerne County Gas and Electric Corporation has had experience with harmonic filters. We have installed a filter on a 25,000-kv-a. generator for this very trouble, and I wonder if the American Telephone and Telegraph Company is not in a position to stand the expense for any of these harmonic filters that are required.

R. G. McCurdy: I feel that this matter of the division of cost of coordinated measures between the power and telephone companies is somewhat beyond the scope of this discussion. It seems to me, however, that when any utility is considering the use of new apparatus or methods of operation resulting in operating economies to the particular utility employing it, a study should be made to determine what methods of inductive coordination would be required by the introduction of the new apparatus or methods. It seems obvious that over-all economies should be considered rather than the individual economy to any particular utility, and the introduction of any new devices or methods, which require for inductive coordination the expenditure of sums of money larger than the amount involved in the operating economies, is a step in the wrong direction. The whole matter of inductive coordination should be attacked from the standpoint of the best engineering solution using apparatus and methods in the plants of both utilities which will permit them both to meet their present and future service requirements effectively and at a minimum total cost.

Caesar Antoniono: We have been listening mostly to one side of the story, the manufacturers'. We have one of these rectifiers which was put in operation a year ago last June. At that time we had in Chicago the problem of handling the crowds of the Eucharistic Congress, which was one of the biggest tasks that any railroad ever undertook—to carry such a large number of people over such a distance in that time. This rectifier station was the last leg of the outfit. We had confidence in it. We had to install eight substations to take care of that load. About 18 mi. of double track were built to take care of that. So, this rectifier was very much depended upon.

Just to show you what we know about the rectifier and what we don't know—it seems there are many things we don't know about it yet. The theories presented here this morning I take with a grain of salt—some are true, or they appear to be true, so far as our experience goes.

At noon before the Eucharistic Congress we were still baking out the rectifiers, uncertain whether we were going to have them in service or not. It developed at noon that we had one anode leaking on one tank. Consideration showed that if we were going to take the tank apart again and try to re-seal the leaking anode, we would not be able to re-bake it in time to put it into service. That service was to begin at three o'clock the next morning, and this was noon.

It was decided, therefore, to take a chance, inasmuch as by keeping the vacuum pump running, it would keep the vacuum up. We put it into service that afternoon. It carried a light load—until 3 a. m. From then on, the rectifiers stood up under momentary peaks of 300 per cent load without a flicker or any effect apparently on the rectifier. The only trouble we got into right off—when it began to pick up the load—was heating. It seems that the way we had arranged the cooling water was not proper to take care of this load.

This substation was installed in the country and the cooling water is pumped continuously from a well. The first idea was that the well water was perhaps too cold to apply to the cathode and to the tanks and, therefore, it was considered the best policy to discharge the water back into the well case. Right away we warmed that too much. So, it was necessary to discharge the water outside and we went through that day without any hitch at all as far as the rectifier carrying the load was concerned.

It happened that a few weeks after that, the designer of that particular rectifier came on the job and we told him the anode was leaking. He said, "Well, if I had been on the job, it wouldn't have been put on the line." That anode was there until a month ago, when for some reason the factory decided to change it. It was considered that a perfect vacuum must be had to run. This rectifier had a leaky anode running for ten or eleven months without causing any trouble.

Now I am optimistic in believing the mercury rectifier has a field, and if some of the properties will make trial stations, I think that the troubles will be overcome pretty quickly.

We have been compelled by ordinances in some towns not to put up certain types of buildings in certain locations. That will ban the converters from those locations on account of the noise unless an expensive structure is designed to be sound proof.

There is another place where the rectifier adapts itself very readily to the load in certain conditions. This is at a railroad crossing. Our trains may approach a crossing at a speed of 75 mi. per hr. and then slow down to 15 mi. per hr. which is the ruling of the commission, in crossing the railroad. The result is when a train approaches the crossing, at a distance of about 2 mi. it shuts off the power and goes over the crossing without power. When it gets on the other side of the crossing power must be available. With the rotary converter station it is necessary to set the relays very high or slow, otherwise the station may shut down. It takes from 25 to 35 sec. to get the station back on the line. Rectifiers have proved to be better equipment for that class of service. The rectifier picks up the load right away when the trains get on the other side of the crossing, in about 10 sec. We haven't heard of any telephone interference. We have a private telephone cable for the railroad's use passing right by the station and there is no interference there. The telephone property is about ¾ mi. away and there is no interference at this time, although in that same vicinity we have had radio complaints on the rotary converters.

There are other things that appear to be in favor of the rectifier as against the converter. One thing we have to contend with in the rotary converter is flashing over and locking out. That seems to be in some cases quite serious.

Then, we have the commutator and brush troubles. Every one knows the troubles of the commutator of a high-speed machine. Also the a-c. brush is as much trouble to the converter man as the d-c. brush on account of serious dust. The dust spreads all over station equipment and causes troubles on contacts and insulation.

A question has been asked about the load division. This load division question brings us back again to what we don't know about the rectifier. We had a case where one starting anode stuck closed for over a week and would not draw an arc and pick up any load. During this time we assumed the two tanks were working though one was not. Without any apparent trouble one tank was doing the work both were supposed to do. We didn't know the difference.

As to repairs, as has been brought out, we have not had much experience on what repairs amount to, but the impression I got is that the repairs are not going to be anything as compared to those on rotary converters.

A. Herz: Mr. McCurdy mentioned something about telephone interference. On that subject Mr. McCurdy can tell you more than I can, but the audibility or sensitivity curve of the human ear is, I think very interesting. From analysis of the inductive influence liberated by these rectifiers, we know that a great percentage of induction is in the order of the 6th harmonic, that is, 360 cycles. Another large batch of it comes in at the 36th harmonic, that is, 2100 cycles. Between these there is a valley in this induction. This, of course, is a favorable circumstance and is a material help in the problem of inductive coordination.

It is an interesting fact that the inductive influence caused by the rectifiers is really in the valley of the sensitivity curve of the human ear. It may come in higher up again, as some claim that the human ear has two sensitive spots, one of which is much higher than the one I have mentioned.

Changing the subject, this matter of having substations 3½ mi. apart on heavy electrification raises the question where are we going to stop? If we increase our traffic we shall have to put in substations 1½ mi. apart, assuming the use of 700 volts or less on the trolley. The rectifier now gives us an opportunity to increase the voltage. I believe it is very opportune that it does. When you have to put substations in at spacing of 1½ mi. it is nearly time to increase our trolley voltage. Certainly 1500 volts is practically out of the question in city electrification on the streets; 1500 volts or higher is more applicable to interurban or main-line electrification and electrification outside of the cities.

I believe the Europeans have gone a little deeper than we have into the transformer construction layout used in connection with the rectifiers. If the transformer is the answer to some of the troubles we have we should have the transformers made in Europe or else our manufacturers might be induced to change to the better way.

The subject of speed of operation is vital. The rectifier can be placed in service in a few seconds. You have to pay no attention to synchronizing. As a matter of fact you can get a rectifier on as quickly as your switches will operate. With rotaries that is out of the question, especially with 1500-volt installations where you have two rotaries in series. The question of polarity on the rotaries is very important, but not so with the rectifier—it comes up correctly every time.

As regards noise both within the substation and outside, we must acknowledge that the advantages are all with the rectifier.

Flashovers have been mentioned. Flashovers on rotaries are bad—we know it. Flashbacks occur in rectifiers, but I feel confident that they are less serious to the system and I am sure they are not as hard on the operators.

In the matter of cooling these rectifiers, we have had certain difficulties caused by electrolysis. Parts of these rectifiers float

1500 volts above ground and when a semi-conductive cooling medium is used there will be some current leakage. I wonder why the manufacturers don't go to oil cooling, using the same oil over and over again and cooling this with water through cooling coils. That would mean a change in apparatus but I am quite sure it is feasible. Attempts to overcome this difficulty by the use of distilled water have been unsuccessful; within two weeks it becomes contaminated to such an extent that it is worse than Lake Michigan water normally is. So, I think serious consideration should be given to cooling methods, making use of oil.

W. C. DuVall: It seems to me in this big subject of rectification, it is going to be a matter of economics and I am quite confident that we are going to do in the future the same as we have in the past—engineers are going to find ways and means of correcting such things as telephone interference and other factors that would be in the way of progress.

The biggest thing that the rectifier is doing is to help fight the battle of electrification of railroads, alternating current versus direct current, and no doubt, we are going to sift it down to a field where the rectifier will take its place at one end, and the converters at the other. Just where that division is going to be it is hard to say, but in any event, I am sure engineers will find a solution.

W. B. Anderson: In the latter part of his paper, Mr. Shand mentions a series of tests on one of the old rectifiers, Unit No. 56, which was built by the Westinghouse Company in 1916. These and other later tests were made by the writer, who is associated with Mr. Shand, to obtain a direct comparison of certain features in the old and new designs. The older unit was operated for approximately three months. The results were such as readily to convince anyone that successfully operating steel-tank rectifiers were made by American manufacturers previous to their present commercial activity.

The vacuum chamber of Unit No. 56 is a drawn steel tank 19 in. in diameter and 26 in. deep, this being supported by an outer sheet metal casing which also serves as a water jacket. The two anodes are made of drawn steel and constructed to permit circulation of water for cooling. Steel anode shields are used and the cathode is not insulated from the rectifier tank. The unit is also equipped with a Pirani type of vacuum gage, the same principle now being applied to what is more commonly known as the "hot-wire" vacuum gage. All of the seals are made with "vacuum cement" a sealing compound developed especially for mercury-arc rectifiers. This cement is still one of the best materials that can be found for vacuum tight seals for certain applications.

As Mr. Shand states, this rectifier had been out of service for more than eight years. The tank was opened, cleaned, and reassembled, the only changes being the replacement of an old solder valve with a modern diaphragm-type valve. A set of vacuum pumps and a McLeod gage was added to make the rectifier an operative unit.

The rectifier was operated at different voltages from 175 to 750 volts and on continuous loads as high as 700 amperes It was operated 24 hr. per day for a week on a motor-generator set load of 600 amperes without a single interruption. Overloads as high as 1200 amperes were thrown on the rectifier for 5 min. with no apparent distress. Higher momentary overloads tending toward short circuits merely opened the circuit breakers. Operation was resumed as soon as the breakers could be closed again. Several times the pressure was allowed to increase until an internal short circuit occurred. Following these, the tank could be pumped out again in three or four minutes and operation resumed. The internal design with the steel shields seemed to withstand rather abusive operating conditions.

Two methods of supplying cooling water to the anodes were tried. In the first method, a part of the tank discharge water was passed through the anodes. This meant that with normal full load operating temperatures, the anode intake water temperature was about 35 deg. cent. When starting, the anodes were at room temperature or lower. The other method, which is similar to the practise of ten years ago, was to recirculate the anode discharge water, adding just enough make-up water to maintain a predetermined temperature. Before placing the rectifier in service, the anode water was heated to permit starting with warm anodes. The latter method proved much more satisfactory. Operation at uniform and higher anode temperatures was possible and the necessity of starting with cold anodes was eliminated.

With such an anode-cooling system, it was possible to collect some interesting data and verify certain ideas relative to the proper temperatures at which anodes should be operated. Several mornings when starting up after the rectifier had been standing all night, full load and overloads were thrown on the rectifier. With cold anodes, the first few minutes of operation were very unstable and internal short circuits frequently occurred. By preheating the anode water, operation was made stable and there were no short circuits.

For continuous operation, the anode water intake and discharge temperatures were limited to values corresponding to the limiting temperature of the seals. On several occasions, these temperatures were allowed to increase approximately 50 per cent for periods of about 2 hrs. following continuous operation at the first mentioned temperatures. The result was improved vacuum and increased stability under abnormal operating conditions as compared to similar operation with normal anode water temperatures. These tests demonstrated very forcibly the desirability of relatively higher anode temperatures.

As already mentioned, the loss in the rectifier was dissipated either in the anode or the tank cooling systems. Measurements indicated that at full load, approximately 65 per cent of the loss was dissipated in the tank cooling water and 35 per cent in the anode cooling water. These values represent continuous operation at the most satisfactory discharge water temperatures for this particular design.

One interesting and very noticeable thing connected with the operation of this old rectifier was a decided improvement in vacuum when it was placed on load after standing idle a few hours. This was apparently due to a redistribution of pressure.

As Mr. Shand has pointed out, one of the objectives of the older rectifier development was the perfection of a rectifier normally requiring no vacuum pumps. The tests on Unit No. 56 indicated that rectifiers can be made to operate for long periods without pumping. Rectifiers with such a high degree of vacuum tightness are not required now. Vacuum pumping equipment that is simple, compact, and reliable is available. With a rotating oil vacuum pump and a mercury diffusion pump such as used on modern steel rectifiers, it is possible to evacuate a tank of 13-cu. ft. volume from atmospheric to 0.001 m. m. of mercury pressure in 60 min.

E. F. Sipher: (communicated after adjournment) Mr. Shand has very accurately given the steps in the development and I believe that the decision to operate a rectifier with a pump running continuously is the turning point in the development. Until the latter part of the development described by Mr. Shand, we attempted to secure exceptional vacuum-tight joints because the pumps which were available then were very expensive and could not maintain a high vacuum against the small leaks. With the advent of the diffusion pump, about the time work was discontinued, the possibilities of operating with the pump running continuously and building rectifiers with a less perfect seal were being seriously considered.

If the operators will accept steel-tank rectifiers, which must be pumped frequently or continuously in order to maintain a vacuum, I can see no reason why it should not be possible to furnish rectifiers of considerable capacity, and which will operate satisfactorily, as it will no longer be necessary to build seamless drawn steel tanks, nor to construct extremely tight vacuum joints, which are inherently expensive and hard to maintain.

(Discussion at Bethlehem on Marti and Winograd Paper Only)

L. A. Doggett: Referring to the table, where the comparison is made on the efficiency basis between the rectifier and the motor generator set, it seems to me there ought to be another column in that table that would include the rotary converter, for it seems to me the rotary converter of a 3000-kw. size would have an efficiency of nearly 96 per cent which would make the efficiencies almost equal for the two rectifying devices.

A. J. Standing: There are three questions that probably have been covered in this paper but unfortunately I have not had an opportunity to read it. The first question is: Are rectifiers available in 25-cycle 6600-volt circuits? The next question is: Are rectifiers affected by changes in temperature? And the third question is: What is the maintenance on them and what troubles are they subject to?

J. T. Waugh: I would like to ask Mr. Marti what information he has on the reliability and maintenance of mercury-arc rectifiers, as found by experimentation or actual practise? Can he give us the relative cost between a rectifier with its transformer equipment and a motor-generator set of approximately 50 to 100 kw. and for say 220 volts d-c.

John Grotzinger: It is evident that the application of this rectifier to electric-traction substations is offering decided advantages.

Unfortunately this does not apply to industrial plants where d-c. at 240/120 volts is required for the operation of small and medium-sized variable-speed motors. I take it that for a three-wire system two rectifiers would be required, one on each side of the neutral, operating at 120 volts d-c.

At this low voltage there is no gain in efficiency over the motor-generator set and the cost of the rectifier would be excessive. The attractive feature in such an arrangement would be the freedom from the compounding trouble met with when operating several three-wire generators in parallel.

I would like to have Mr. Marti tell whether in operating several such units in parallel they divide the load uniformly, also what takes place in the case of a short circuit.

G. M. Kennedy: I want to know whether you use a three-phase transformer or a single-phase. Suppose we had a 300-kw. rectifier, what transformer capacity would we use with that?

W. H. Lesser: How does the attention required with these rectifiers compare with the attention that we need with an automatic motor-generator set or an automatic converter?

O. S. Clark: Fig. 5 shows increased tendency in Europe toward higher voltages. I wonder if this is being done to reduce distribution losses, or does it indicate a tendency to adopt the mercury-arc rectifier which operates more efficiently at the higher voltages.

D. C. Prince: On this question of telephone interference the General Electric Company has taken the position that we have to go halfway with the telephone company, and I believe all the rectifiers which we have put out are equipped with the reactance which Mr. Marti shows at the top of his figures.

On the question of filters it has been a matter of where the exposure has been bad, and in our installations in most cases the exposures have not been bad enough to require the filters. However, there seems to be still some hidden question regarding that, because one hears all sorts of stories about what interference this rectifier and that rectifier produces. So far, our rectifiers with the series line reactance have made no trouble in the places where they have been fed over heavy power lines, and it is observed that if the rectifier is supplied over a large power line, so that it is a relatively small part of a power load, the interference seems to be considerably less than where the rectifier is the only piece of apparatus fed over the entire line. A definite correction procedure will probably be developed as a matter of experience, and I don't believe the cost will be great. In most cases where we have had to put in the filters the cost has not been prohibitive.

Mention is made that a rectifier is naturally a continuous-rated machine. The rectifier itself is only a small part of the installation, and for that reason the characteristics of the rectifier are not necessarily imposed on the system as a whole; that is, if it were desirable to supply any particular 2-hr. rating, the fact that the rectifier might come to its final temperature inside of half an hour would not make it necessary to supply a complete installation on the basis of half an hour period overload; *i. e.*, the fact that the rectifier itself is a relatively small part of the whole makes it possible to discount its own particular characteristics by supplying a margin in rectifier capacity. We have installed in Chicago a rectifier with a capacity of 1500 kw., and this unit has repeatedly carried loads of over 9000 kw. with no ill effects whatever. We hope that the policy will be to install rectifiers of sufficient size to handle anything that can come, and then, as the device becomes more exactly known, it may be possible to make savings, but there again such savings will be only in the rectifier, which is but a small part of the whole installation.

Mr. Marti has also gone into this question of the rating of transformers. The transformer rating for a three-phase rectifier is somewhere around 130 per cent of the kw. capacity, and for a six-phase rectifier he has given the figures as somewhere around 150 per cent, and that leads to the question: Aren't we sacrificing something by going to polyphase operation; that is, to a higher number of phases? We have made an investigation to see if the advantage in wave form of the higher number of phases cannot be obtained with three-phase units, which have the advantage not only in that the transformer ratings are less, but the regulation also tends to be better and the telephone interference tends to be less. As a result, our standard rectifiers, instead of being six-phase or more, are all three-phase, connected through interphase transformers, either two or four units operating at an angular displacement to bring the total phases up to six or twelve.

Sidney Withington: (communicated after adjournment) There is no doubt that mercury arc rectifiers possess many material advantages as compared with rotary apparatus, either converters or motor-generators. They are relatively simple in their operation and, being static, are especially adapted to automatic substation operation; furthermore, they can, like transformers, be placed on the line instantaneously by the closing of a switch as required to take care of sudden unexpected loads. As Messrs. Marti and Winograd have pointed out, rectifiers are especially advantageous for high voltages, both from the point of view of their operating characteristics, and cost as compared to rotary apparatus. Then, too, as has been stated, they are very attractive as regards efficiency, especially at fractional loads. It should be borne in mind, however, that the relation between overload capacity and continous rating is relatively unfavorable as compared to rotary converters or motor-generator sets, especially for steam-railway electrification. Where the load increments are relatively large compared to the total load, and where, therefore, the peaks may be of but short duration, the overload capacities of rotary apparatus are of value, whereas the relatively small thermal capacities of the rectifiers are a limiting factor. In the case of urban traffic, where the load increments are a relatively small part of the total load, this feature is of less importance, and this is the field in which the greatest development of the rectifier will undoubtedly lie.

An important characteristic of mercury rectifiers is that if they are subjected to conditions which are too severe, they are not likely to be permanently damaged as are many other types of apparatus, but after a break-down due to overload may as a rule be immediately restored to service.

The question of overload characteristics is an important one, and it would appear to be opportune at this time to consider special ratings for mercury arc rectifiers which would recognize the relatively high continuous capacity as compared to their

overload capacity. Such data might well be included in A. I. E. E. Standards. At present a "nominal" rating which means little, is assumed in order that standard overload specifications may be met.

A limitation of the mercury arc rectifier is in its voltage regulation. There is, of course, no possibility of "over-compounding," and therefore there is a drop in bus voltage at heavy loads. This feature, however, especially in the case of street-railway loads, may be offset by scattering automatic rectifier substations about the territory served, utilizing high-voltage a-c. distribution. Such a plan would, of course, mean a relatively low load factor on each substation and, therefore, a considerably greater installed capacity would be necessary than if the apparatus were concentrated. It is probable, however, that before long, on account of quantity production and amortization of development expense, mercury rectifiers will be available at considerably lower cost than rotary apparatus, even for 600-volt service, and the excess capacity will thus be justified by the obvious advantages of small scattered substations.

It is probably going a little too far to say that the mercury arc rectifier will soon exert an influence on the much-discussed question of direct current versus alternating current for heavy traction systems. The electrification system finally adopted as a standard in this country will necessarily be capable of handling all branches of operation economically and reliably, including suburban service and "through" traffic of all kinds, over the same tracks. National standardization in this respect is nearly as important as track-gage standardization, and should rest on considerations which are broader than the economics of any one individual problem.

The chief limitations thus far with d-c. systems are not in the generation of power so much as in the flexibility of its distribution and use on the rolling stock, and with the increasing voltages mentioned by Messrs. Marti and Winograd, even though they may be practicable at the substations, problems will necessarily be met on the cars or locomotives in main motors and auxiliary facilities. Although it is of course impossible to predict what the future holds in store for us, nevertheless it may be said that the fundamental advantage of alternating current as compared with direct current in the present state of development of the art of electrification, is in the flexibility of the a-c. system, wherein it is possible on a single distribution system to operate motor cars, either singly or in multiple-unit trains up to ten or twelve cars, as well as high-speed "through" passenger trains, and extremely heavy-tonnage freight trains with concentration of 15,000 or 20,000 hp. in a single train. This degree of flexibility has thus far not been reached with any d-c. installation yet designed, and it does not seem probable that the mercury arc rectifier can change this phase of the situation very much, especially as it is, of course, impracticable to regenerate power and feed back into a transmission system through this type of apparatus.

O. K. Marti and H. Winograd: Mr. McCurdy answered practically all the questions on interference which were raised during the discussion, and he brought out very clearly the problems involved in mercury-arc rectifier installations in connection with communication systems. I should only like to follow up one point a little further. As he states, there are also harmonic ripples present in the d-c. sides of synchronous converters, and I might point out that interference is sometimes caused by synchronous generators and condensers. Up to the present time, no definite rule has been established by technical societies with regard to the permissible volume of this interference for any kind of machine, and it is therefore difficult to arrive at a proper conclusion in regard to the permissible magnitude of the ripples. In connection with the machines which cause interference, the noise-meter and the telephone-interference-factor meter are used to obtain some quantitative measure of the interference effect. Assuming, now, that the influence of the rectifier ripples is measured by this meter, and that we allow about the same telephone interference factor for rectifiers as for other machines, a filter equipment which is not prohibitive as to cost and maintenance can probably be found, especially since the recent improvements in condensers, due to the greater demand for them for radio and for power-factor correction, have improved their quality and also made them lower in price.

In regard to radio interference, I should like to mention that even if the mercury arc should radiate waves of the frequencies used in radio communication, they would probably be shielded by the steel tank. However, it does not radiate such waves, and no difficulty has to be feared in that regard. It might, however, be mentioned that a great deal of investigating has been done in this connection in Europe, Canada, and in this country, without any influence on radio being observed.

I had intended to discuss Mr. Butcher's paper quite thoroughly, but Mr. Herz and Mr. Antoniono, whose companies have had rectifiers in operation for an appreciable period of time, gave a much better comparison of the advantages and disadvantages of mercury-arc rectifiers and synchronous converters than I would have been able to give.

I should, however, like to make some remarks regarding the first cost and the cost of maintenance, as brought out in this paper. The maintenance cost of rectifiers and their automatic equipment is less than for synchronous converters, as was proved by many comparative studies made abroad and in this country. It is unjust to base a comparison in regard to maintenance on the experiences obtained with the few early trial installations in this country, and the comparison will come to be more in favor of the rectifier as this equipment and its characteristics become better known.

The cost of an installation as indicated on the last page of Mr. Butcher's paper, giving the cost of the building and foundation as $5000 for either a rectifier or a rotary converter, cannot be correct for two reasons: First, the number of cubic feet of space required for a rectifier installation of a certain rating is much less than for a converter installation, and, since there are no heavy moving parts in a rectifier, the foundation costs practically nothing by comparison. According to our estimate, the cost of a rectifier substation would be about two-thirds the amount stated in Mr. Butcher's comparative table. Since the heat produced by the losses in a rectifier is carried away by the water, no extensive space is required above the rectifier, as is necessary for the proper cooling of a synchronous converter. The cost of making a well in case no running water is available can be circumvented by using a recooling system, the cost of which is considerably lower than the cost of making a well as given in Mr. Butcher's paper. If the comparison had been made upon such a basis, it would have shown that the first cost of a rectifier installation compared to a converter installation for 600 volts, direct current, would be the same, or even less. There is a tendency, and I do not see any reason why it cannot be done, to increase the trolley voltage to 750, and even to 800 volts. At such a voltage the first cost of the rectifier will be less and the saving effected due to lower losses in rectifier and feeder will be extremely favorable.

Answering Mr. Clark's question, I believe the tendency toward higher voltages in Europe is accounted for by a desire to secure a higher rectifier efficiency and to reduce the distribution losses as well. In one case 800 volts was adopted in order to do away entirely with all feeders, the rectifiers working directly on the trolley line at 800 volts. The spacing of the substations is very close, being only about half a mile. The rectifiers are mounted right on the station platform, there being no enclosure other than a screen, and the transformers are mounted close to the rectifiers. In this case, almost the entire cost of a substation building and feeders was eliminated.

In answer to Mr. Lesser's question in regard to the attendance required, I should think that the same practise as applied to rotary-converter stations should be adopted for rectifiers. Due

to the fact, however, that a fully automatic rectifier installation is simpler and involves less automatic equipment, it requires less attention.

In this connection may be answered the last part of Mr. Standing's question about the troubles to which rectifiers are subject. The main trouble experienced with the rectifier itself has been back-fires, or arc-backs. By improvements in the design of the rectifier and its auxiliaries, these have been practically eliminated, and when they do occur, they have no serious consequences as the rectifier can be put back into service immediately. In automatic rectifier substations they are taken care of by automatically reclosing circuit breakers.

Mr. Grotzinger made a remark about the use of rectifiers for 240/120-volt, direct-current, three-wire systems for industrial plants. There are a number of such installations in service. Since the rectifier efficiency is considerably reduced at the lower voltages, on such systems the rectifier is usually connected to the outside wires, and a balancer, which may be a battery or a small motor-generator set, is used for obtaining the middle wire.

As for parallel operation, the rectifier is far better suited for such service than a rotary converter. Rectifiers will operate in parallel satisfactorily even if connected to two independent a-c. systems having different frequencies. Should the voltage be lowered, the rectifier cannot feed back, so that one rectifier cannot affect other rectifiers operating from the same or other a-c. networks. Frequently a power company would like to operate a rectifier from 25- and 60-cycle systems during certain periods. That, again, is an advantage of rectifiers, as they can operate equally well at 15, 25, 60, or even 100 cycles. The only factor which will be affected is the size of the transformer, which of course must be dimensioned for the lower frequency. This will cause a slight decrease in the efficiency of operation at lower frequencies.

In regard to the question of whether a rectifier transformer has to be rated for a higher capacity than a transformer for a synchronous converter, and to what extent the size is affected by the number of phases, see curve No. 3 in Fig. 9 of the paper. From this curve it is evident that a two-phase transformer, for instance, has a rating of 125 per cent of the d-c. output, and about 145 per cent of the d-c. output for six-phase rectification. As a rule, because of the simplicity of the interconnections between the phases and the lower cost, three-phase transformers are used with rectifiers.

If a rectifier is operated in a place where the temperature is high, its operation is entirely unaffected, as the heat generated by it is taken away by the cooling water and therefore the ambient temperature does not matter. This is another advantage of the rectifier; one can place it in a small space and does not have to bother with ventilators and ventilation ducts to remove the heated air from the room. Incidentally, the amount of noise generated by the vacuum-pump motor is so small that rectifiers may be located in places where rotary converters would be out of question. In fact, we have rectifiers operating in department stores, municipal buildings, hospitals, and other locations where the absence of noise is of prime importance.

In reply to Mr. Waugh's question regarding the relative costs of rectifiers and motor-generator sets for 50 and 100 kw., 220 volts, the price of rectifiers would be higher. For such capacities, rectifiers would be used only if other factors, such as noise, flexibility, or operation, etc., make their application advisable.

As to Mr. Doggett's remarks, I wish to say that the comparison of efficiencies in the paper concerns 3000-volt conversion, for which synchronous converters would not be used.

E. B. Shand: Mr. Marti has referred to the difficulties of the design of transformers when used with rectifiers,—a point which was also touched upon by Mr. Herz. I mentioned in my paper some extensive work on the investigation of rectifiers and circuits, and I believe that by adhering to the principles determined, these difficulties are not great; and in fact, they have not been found so. Where complex arrangements of the transformer windings are used, there naturally will be some undesirable complications. The transformer inductance determines, to a large extent, the voltage regulation of the rectifier, and it requires careful design to obtain the proper distribution of this inductance in the windings, particularly in the cases where complex schemes of connection are used. It may be said, therefore, that there is something to be gained in the choice of a simpler transformer arrangement.

Referring to Mr. Marti's remarks of the heat-storage characteristics of rectifiers as compared with rotating apparatus, I am not sure that I am in strict agreement. It must be remembered that water is the cooling medium of the rectifier and that water has a very great thermal capacity. Some calculations on this subject made some time ago indicated that the rectifier, with its cooling water, would have a slightly greater heat-storage capacity than a corresponding rotating machine. Of course, where the anodes are not equipped with water-filled radiators, the anodes will have a lower thermal capacity.

There is probably a certain amount of general misunderstanding on the subject of the meaning of the over-load capacity of normal-rated machines. Tests have shown that a rotating machine, such as a d-c. generator or synchronous converter, will reach very nearly its maximum temperature in 35 to 45 min., so that there is no basis for the supposition that the machine can carry its guaranteed overload on account of its thermal capacity. The limitation for the continuous rating is based rather on the limitation on the current-collecting parts; that is, if operated continuously on the overload rating, the commutation limit would be exceeded and the maintenance on both commutator and collector rings would be unnecessarily high. With our present state of information on the rectifier, it does not appear to have these two kinds of limitations to the same extent, so that its application may not be made to the best advantage by directly following converter practise.

In regard to telephone interference, I believe that Mr. McCurdy has brought out a number of interesting points. As he mentioned, when rectifiers are connected to a highly inductive load, such as presented by street-car motors, the harmonic currents are reduced to a point where they do not cause any appreciable trouble; but as is usual practise, where low-impedance feeders connect different substations, the differential voltage between two pieces of apparatus in different substations will produce much larger harmonics over the connecting feeder. An exposure of much less than 10 ampere-miles of such harmonic currents has been found to cause trouble in telephone circuits. It has been demonstrated both in the investigation referred to in my paper, and also in later work that telephone interference can be eliminated by installing special apparatus either in the telephone circuits or in the rectifier circuit. The practicability of the elimination of telephone interference comes down, therefore, to a question of economics, both in the first cost of apparatus, and, where installed with the rectifier, in the additional losses involved.

The comments of Mr. McCurdy on the relative advantages of 6-phase and 12-phase rectifiers are not borne out in the experimental values of telephone-interference-factor which he has obtained from these two types of apparatus. It may be noted that the wave shapes of rectifiers under load are such that the advantage of the 12-phase connection will be very much reduced on account of the effect of overlap which produces further variations of voltage fluctuation but which do not occur at no load.

C. A. Butcher: It is seldom required that converters of different frequencies be operated in parallel although this is being done very satisfactorily. On the Edison system in Chicago, 25-cycle and 60-cycle converters are operated in parallel on the d-c. bus with little or no apparent difficulty.

There is something to be said about rectifier development

apparently having been on a more rapid scale in Europe than in America. A reason for this probably lies principally with the rates of development of the central-station industries in the two countries.

The central station industry had its birth in this country in the three-wire d-c. system. This was quickly followed by the a-c. system, which discouraged the installation of numerous small isolated plants. Following later, the development of the central station in Europe was principally at 50 cycles, whereas 25 cycles was the predominating frequency in this country. The 25-cycle converter was, therefore, not in the same demand in Europe as in America and, perhaps, has never reached the same stage of perfection. In the substitution of central-station service for the isolated plant, the rectifier in Europe has been the competitor of the motor generator and the motor converter rather than the synchronous converter.

The development of the 60-cycle converter followed later and those familiar with it know that its early troubles were many. However, these have been quite successfully overcome. In spite of the remarks made about flashovers, the 60-cycle converter is a satisfactory piece of conversion apparatus. The development of the high-speed breaker, and the high-reluctance commutating pole has done much to assist in its proper performance. The operators can do well to study those features in the application of a synchronous converter which will contribute to its more satisfactory performance. Perhaps 50 per cent or more of the responsibility for the flashovers of synchronous converters is with matters of application and operation and not in the limitations of design.

The increase of voltage above 600 brings in many other problems in the way of design of traction motors, control, and distribution insulation, also the problem of using efficiently the higher voltages in congested metropolitan areas. The automatic substation, since attendance is not required, probably lowers the scale of voltages on which d-c. railways may be operated economically. There are probably any number of installations which years ago would have been made at higher voltages had not the automatic substation been perfected to the point where a greater number of substations with smaller spacing might be used without excessive operating cost.

The transformer design, which enables a rectifier designer to gain low efficiency at light loads, is also possible with synchronous converters since it is merely a matter of proper ratio of iron to copper losses.

Power-factor correction by operating rectifiers and converters in parallel in the same station,—a question was brought up by Mr. Blasser—is probably something that has not been given a great deal of consideration. When one stops to think that the power factor of the rectifier, 93 per cent, is much better than that of the average industrial load, and that generators in our power stations are designed for 80 per cent power factor, I doubt if he will find very much to be gained by the parallel operation of converters and transformers in the same station for that purpose.

The question of reverse current at light loads merely means that the designs for interurban substations or metropolitan substations must be considered in conjunction with the a-c. supply in order to gain stability of synchronous apparatus and the system as a whole.

Operating third-rail systems with 60-cycle synchronous converters does not render the problem of flashovers more serious. If the installation is properly made, the flashovers are probably not so severe, on a third-rail system as on overhead, for the reason that the magnetic induction on the third rail on the average fault, causes the current to rise very slowly, and thus it may be interrupted by a breaker of ordinary speed before the load on the converter is such as to cause flashover.

Electricity in the Drilling of Oil Wells

BY L. J. MURPHY[1]

Non-Member

Synopsis. *As in other industries, electricity has taken the lead in the petroleum industry in putting the drilling of oil wells on an engineering basis and as a result of numerous installations it can be said that oil companies in general at the present time have a very receptive attitude toward electric drilling. Satisfied drillers, easy operation, low maintenance, low power bills, fewer shut downs, perfect motion, faster drilling, heavier pulling, no stand-by losses all these factors have contributed to make electricity the coming accepted standard by which all other forms of oil-well drilling will be judged.*

* * * * *

Cable-Tool Drilling

THERE are two forms of drilling practise in common use in the United States today, *i. e.,* cable-tool and rotary. The cable-tool or percussion system was the original method and is the one most extensively employed at the present time. It is used exclusively in the Pennsylvania, Ohio, Illinois, and Kentucky fields and to a very large extent in the mid-continent and western fields.

In drilling with this system, the drilling tools are suspended from a steel cable or manila rope and moved in an up-and-down motion with the speed of the walking beam, which supports the tools, corresponding to the natural period of the string of tools. Naturally this period becomes greater as the depth of the hole increases and, in order to obtain maximum drilling speed, the motor driving the rig must be capable of very delicate adjustment over quite a wide range of speed. It can be seen readily that this method is better adapted to hard solid formations than to soft formations on account of the fact that repeated jarring of the earth will loosen soft structures and cause cave-ins which necessitate fishing jobs and no end of trouble.

There are four principal operations in the drilling of oil wells by the cable-tool system, namely, spudding-in, drilling, hoisting tools, and bailing, each operation necessitating distinct requirements of the electrical equipment operating the rig.

The "spudding" operation consists of raising the drilling tools through a vertical distance of three or four ft. and allowing them to fall. The operation is accomplished by means of a jerk line one end of which is attached to the crank on the band wheel and the other end through a sliding shoe to the cable which supports the drilling tools. The tools are supported usually by a steel or manila cable which passes over a sheave wheel on top of the derrick and then is spooled on a hoisting drum or bull wheel. The tools are fed downward by releasing the brake on the bull wheel. Near the top of the hole the band wheel is operated at a speed of 42 to 45 rev. per min. to give most satisfactory operation and the speed must be very closely controllable. This operation requires approximately 30 to 40 hp.

1. General Engineering Department, Westinghouse Electric and Mfg. Company, East Pittsburgh, Pa.

Presented at the Regional Meeting of District No. 7 of the A. I. E. E., Kansas City, Mo., March 17 and 18, 1927.

After a 200- to 400-ft. length of hole has been drilled by the spudding operation the remainder of the drilling is done on the beam. Drilling on the beam requires that the speed of the driving motor or motors be very closely regulated and that the motors have relatively small fly-wheel effect in order to permit rapid variation in speed in response to variations in torque throughout the drilling cycle. The range of speed throughout the drilling of a well runs from 40 to 45 strokes per min. at the top of the hole down to as low as 14 to 20 strokes per min. at the bottom.

The average speed of the drilling equipment must be adjustable at all times to correspond exactly to the

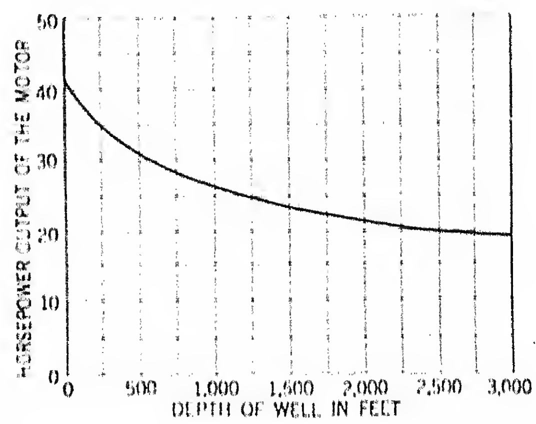

Fig. 1 Power Requirements for Oil Well Drilling by the Cable-Tool Method

natural period of the drilling tools and drilling line, if maximum progress is to be obtained. If the speed of the drilling tool is set too low, the bit does not strike a sharp blow and the progress is slow, while if the speed is set too fast, excessively high stresses are set up in the drilling cable, drilling is slow, and fishing jobs are to be expected.

The horse power required will be found to vary but in general it can be said to decrease somewhat as the depth increases. If the hole is free of water, the horse power required to swing the tools will be comparatively light, the beam will operate at a larger number of strokes, and the drilling will progress faster than if water in appreciable quantity is encountered in the hole.

Fig. 1 is a curve showing how the horsepower output of the motor varies with the depth of the well. As no two wells are exactly alike and as conditions will vary

considerably throughout different parts of the country, the above mentioned curve can be considered as representative only of the general trend of the power requirements with increase in depth.

After every six-foot length of hole has been drilled, it is necessary to remove the cuttings from the hole and before this can be done the drilling tools must be hoisted. In this operation heavy ropes are slipped into a large grooved pulley on the bull wheel and into similar grooves on a tug rim bolted to the band wheel. Thus, the same motor equipment that is used for drilling is used for hoisting also. The pulley ratios between the motor equipment and the band wheel are such that a maximum speed of 80 to 90 rev. per min. is possible at the band wheel and approximately 90 to 100 rev. per min. at the bull wheel. The tools are accordingly hoisted out of the well at a rate of 350 to 700 ft. per min., the speed increasing as the bit nears the surface, due to the increasingly larger effective drum diameter. As the effective drum diameter is increasing, however, the weight to be lifted is decreasing, so that for a given condition the horsepower remains practically constant from bottom to top. At the start of the drilling, the hoisting of the tools is not exceptionally heavy duty, but as the hole becomes deeper this load is likely to become as high as 150 hp., especially if the rig is not very efficient.

As soon as the drilling tools have been hoisted out of the hole, the bailer is lowered several times to remove the cuttings. The bailer, which consists of a piece of pipe with a dart valve at the bottom, is operated by a sand reel, friction-driven from the band wheel. The speed of hoisting the bailer is approximately 2 to 2½ times as fast as the speed of hoisting tools, but because of the lighter weight of the bailer the load on this operation is practically the same as that of hoisting tools.

Fig. 2 represents a section of a drilling chart, showing the various operations when drilling at a depth of approximately 600 ft., using a 15-in. bit. It will be noted that for a considerable portion of the drilling cycle, the load is approximately 16 kw. but that at the peak the meter registered 53 kw. with an average probably around 25 to 30 kw. The operation of hoisting the tools shows that considerable power is required to accelerate the load to full speed but that as soon as the motor has come up to full speed the load remains practically constant. Since the motor is already up to full speed at the time the bailing operation commences, the peaks at the start of this operation can be attributed to pulling the bailer loose from the mud at the bottom of the hole and accelerating it to full speed. It will be noted that the first bailer was evidently more fully loaded than the second.

In order to take care of all the operations incident to the drilling of an oil well by the cable-tool method, there are two equipments in common use in the United States at the present time, one involving two two-speed motors and the other involving one larger single-speed motor. The former method employs two standard two-speed, 15/35-hp., oil-well pumping motors belted to a common counter shaft whereby the drilling is accomplished on the low-speed, low-horsepower connections and the hoisting taken care of on the high-speed, high-horsepower connections. Each motor has nine points of speed control on each speed connection and by operating one controller on one point and the other on any one of its nine points, a total of 45 speeds on each speed connection is available. The latter method employs a standard 75-hp., single-speed motor in which the low drilling speeds are obtained by the insertion of slip resistance in the secondary circuit of the motor. A main controller takes care of acceleration and reversing and an auxiliary controller gives fine speed adjustment by subdividing one of the steps of resistance into a number of smaller steps.

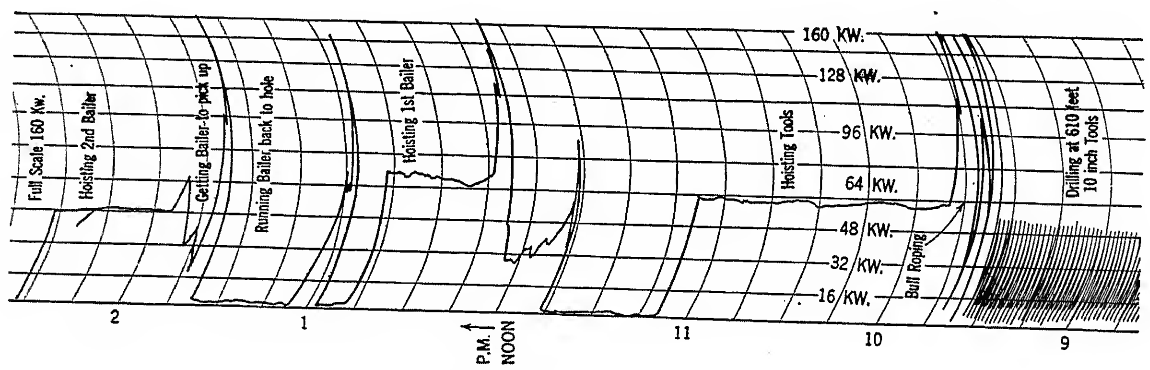

Fig. 2—Typical Graphic Chart Showing Various Operations in Cable-Tool Drilling

In regard to power consumption, the kilowatt-hours per foot will vary considerably with the location and formation but in general it can be said to vary from 4 to 10 kw-hr. per ft. for a 2000-ft. well with an average of 7 and from 5 to 12 kw.-hr. per ft. for a 3000-ft. well with the average correspondingly increased. The two-motor scheme will be found, as a rule, to be the more economical of the two, due to the fact that during the major part of the drilling operation the two motors are operating at more nearly their synchronous speed and

therefore little power is lost in secondary resistance. Fig. 3 shows an installation of this kind.

Fig. 4 shows a typical power curve for cable-tool drilling in the mid-continent field and indicates that the total power consumed tends to increase slightly faster than the increase in depth, due, no doubt, to the greater power consumption in the hoisting and bailing operations.

Rotary Drilling

In certain sections of the country where the formations are, for the most part, of unconsolidated material

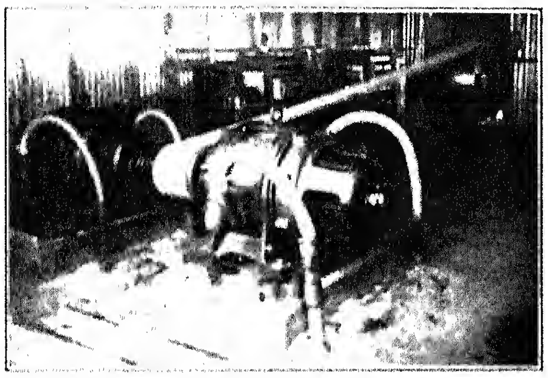

Fig. 3 Installation of two 15/35-Hp. Pumping Motors for Cable-Tool Drilling

such as sand, gravel, and boulders, considerable difficulty was encountered in endeavoring to apply the cable-tool system as the jarring of the tools would loosen the earth and cause cave-ins with resulting fishing jobs. To handle these formations successfully, the rotary system of drilling was developed.

In this system a hollow drill pipe with a suitable bit, usually shaped like a fish tail, fastened to the bottom of it, is rotated at a speed of 60 to 90 rev. per min. and gradually fed downward. At the same time plunger pumps force mud down through the drill pipe, through two small holes or eyes in the bit, and up on the outside of the drill pipe. The combination of the scraping action of the bit with the jetting action of the mud through the holes, actually drills the well, but in addition to assisting in drilling the mud functions also to carry the cuttings continuously to the surface. The high hydrostatic head forces this mud into the soft formations and the rotating pipe trowels it into place and thus the walls of the hole are built up rather solidly. The amount of casing required with this system is thereby reduced to a minimum.

The equipment involved in an electrically-driven rotary drilling rig consists essentially of a motor, a suitable single reduction gear unit, a draw works, a rotary table, and two motor-driven mud pumps. The draw works comprises a line shaft chain-driven from the gear unit and a drum shaft on which is mounted a hoisting drum so arranged with a number of sprockets and jaw clutches, chain-driven from the line shaft, that two or three hoisting speeds can be obtained. The rotary table is also chain-driven from the line shaft with a jaw clutch on the latter whereby the rotary table can be disengaged at any time.

The operation to be performed in rotary drilling may be segregated into three distinct classes: drilling, hoisting and lowering drill pipe, and circulating, each requiring certain fundamental features in the design of the electrical equipment. The drilling operation requires from 30 to 100 kw., depending on the depth, size of hole, and the formation, and as mentioned previously, the table speed ranges normally from 60 to 90 rev. per min., although under some conditions this speed may be as low as 30 rev. per min. Certain formations require as high as 100 kw. at a speed of 70 rev. per min. which is probably the worst condition encountered, while in other formations the most satisfactory progress of the bit will occur at 90 rev. per min. with loads as light as 30 kw. When special types of rock bits are employed, the speed of rotation of the drill pipe will be as low as 30 rev. per min. and the power drawn from the line will seldom exceed 30 kw. Thus it can be seen readily that the ranges of power and speed for satisfactory penetration of the bit vary considerably with the formations and the location.

There is still another feature to take into consideration and that is the ultimate torsional strength of the drill pipe. With the necessity for excessively high torques in hoisting, as will be described later, it is found

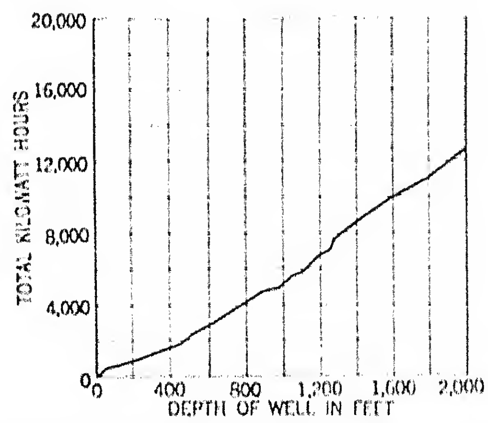

Fig. 4 Typical Curve of Power Consumption of a Well Drilled in Kansas by the Cable-Tool System

highly desirable when drilling to insert a certain amount of permanent resistance in the secondary circuit of the motor which will not only limit the maximum strain that can be applied to the drill pipe but which will also give the motor a drooping speed-torque characteristic. This drooping characteristic offers a cushioning effect between the motor and the drill pipe, a feature particularly desirable when drilling through boulders or hard shells where the equipment is frequently subjected to very severe shocks.

After drilling has progressed for four or five hours, the bit has usually become dull and out of gage and it is therefore necessary to replace it with a fresh bit. To

do so means removing all the drill pipe from the hole and standing it up in the derrick in "fourbels" or approximately 85-ft. lengths. As the well becomes deeper this operation requires an ever increasing percentage of the total time and as a result it is highly desirable to have equipment which will take care of extremely high overloads for short periods of time in order that as much of the drill pipe as possible can be hoisted in high gear. Records show that when handling

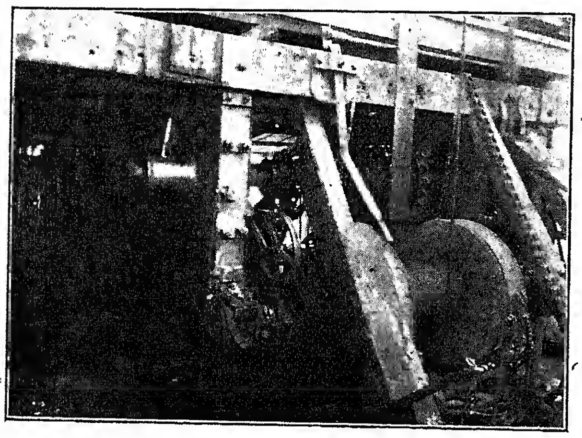

Fig. 5—Installation of 100-Hp. Rotary Drilling Equipment Showing Relative Location of Motor, Control, Gear Unit and Draw Works

3500 ft. of 6-in. diameter drill pipe, representing approximately 42 tons, the hoisting loads are as high as 300 hp. but inasmuch as the load lasts only for a period of 40 to 50 sec., this load can be handled very conveniently by a 100-hp. motor, providing the motor has been designed with ample pull-out torque. After hoisting the entire string of drill pipe approximately

required by friction, the weight of the blocks, and one stand of pipe.

After the worn bit has been replaced, the pipe is put back in the hole, and during this operation very little work is required of the motor other than lifting the 85-ft. sections into place for coupling together and running the blocks up light to the top of the derrick.

Circulating is an operation in which the drill pipe is held off bottom and rotated very slowly at a speed seldom exceeding 15 rev. per min. The purpose of circulating is to allow the pump to force mud through the drill pipe and build up the walls of the hole. Since the load is exceptionally light and the speed extremely low, a considerable amount of secondary resistance is required to accomplish the desired results. Rotating the drill pipe at too high a speed in this operation will cause the bit to become out of gage.

For extremely shallow wells it has been found that a 15/35-hp., two-speed pumping motor has sufficient capacity to do the work, but for the average wells a 100-hp. or 125-hp. motor is required, with the possibility of utilizing a 75-hp. motor on moderately light wells in some territories where oil is reached at a depth not in excess of 3000 ft. It is interesting to note that the deepest well in the world, 8046 ft. deep, was recently completed in California and electric motors were used throughout, both for driving the drilling machinery and for operating the mud pumps.

Fig. 6 is a typical graphic chart showing the load on a 100-hp. drilling motor for the various operations.

The power consumption per foot of hole will vary considerably with the location, with the ultimate depth, and with the diameter of the hole. In the Gulf Coast district for wells around 850 to 950 ft. deep, the kw-hr.-per-ft. range from 1.5 to 4 with an average around 2.5.

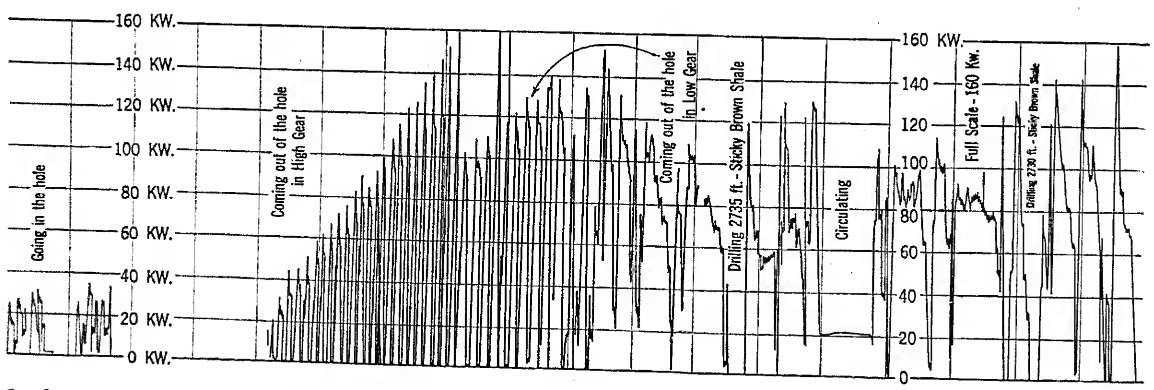

Fig. 6—Graphic Wattmeter Chart of 100-Hp. Rotary Drilling Equipment Operating at a Depth of 2730 Ft.

85 ft., one stand or fourbel is uncoupled and stood in the derrick, the elevators are lowered, a new hold taken on the drill pipe, and the hoisting operation repeated. Thus there is an interval of about one minute when the motor is required to do little or no work. Each succeeding hoisting operation means less load on the motor until, when the last length of pipe is drawn out of the hole, the load is a minimum, amounting only to that

Deeper wells in this same territory require from 8 to 14 kw-hr. per ft. with an average of 9.5, the great increase over the shallower wells being due primarily to the larger diameter hole, the harder formations at the greater depths, the high power consumption during hoisting, and the extra horse power to maintain mud circulation at the greater depths. In the California fields, for 3500- to 4000-ft. wells, the power consump-

tion runs as high as 25 kw-hr. per ft., although, with the general adoption of more efficient bits, this figure has been reduced considerably. It is therefore apparent that no definite figures can be given as to the power consumption for various depths of hole as conditions vary in different fields and even in the same field the formation varies to a great extent.

Automatic Rotary Drilling

A large proportion of the difficulties in rotary drilling are fundamentally caused by improper feed of the drill.

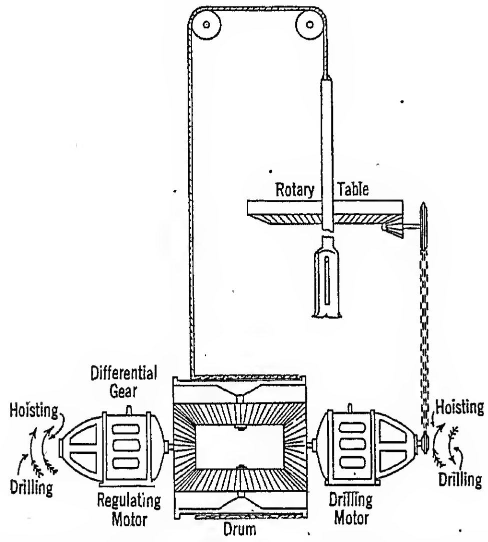

Fig. 7—Schematic Diagram Showing Principle of Operation of the Hild Differential Drive for Automatic Rotary Drilling

SPEED (REV. PER MIN.) OF DIFFERENT PARTS OF AUTOMATIC DRILLER

Operation	Reg. motor	Differential	Drilling motor
Drilling, no progress..........	1000 Forward	0	1000 Forward
Drilling progress.	990 Forward	5 Down	1000 Forward
Drilling progress.	990 Forward	2 Down	996 Forward
Retrieval........	990 Forward	45 Up	900 Forward
Hoisting........	1000 Forward	1000 Up	1000 Reverse

The feed is in the hands of an individual operator and the regulation of proper feed depends upon the personal equation of this individual, his judgment, his experience, his desire to do good work, etc. Errors of the individual are responsible for many such accidents as twist-offs; balled bits, and crooked holes. If the feed of the bit could be made scientifically proportional to the resistance it encounters, and if this feed could be cared for automatically and independent of any personal equation, many of the accidents and errors due to incorrect drill feed would be eliminated, the speed of drilling would be increased, delays would be decreased, and costs would be reduced. The Hild Differential Drive was developed with this idea of providing a scientifically regulated feed for the drill bit in the place of haphazard manual feed dictated by personal judgment and inclination.

The fundamental principle of the Hild Differential Drive is that the downward feed of the drill pipe is varied according to the power required to revolve the bit on bottom. This relationship between the feed and the power required for drilling is not only adjustable but is fixed for any given adjustment due to the inherent characteristics of induction motors and the principle of the differential gear drive. In operation, if the formation changes so that the load on the drill pipe increases, the downward progress of the drill pipe is automatically retarded. Thus the device not only tends to keep the load on the drill pipe constant for any given setting but also tends to hold the pipe on bottom at all times and at a constant pressure. Furthermore, if the load on the drill pipe suddenly becomes excessive, as would be the case in encountering boulders, the drill pipe is raised until the bit is free of the obstruction, after which downward progress is again resumed.

Briefly, the equipment makes use of a differential gear unit and two motors. The drilling motor drives one-half of the differential, and also the rotary table, direct through gears and chains; while the regulating motor is connected to the other half of the differential. The hoist drum is connected to the central portion or floating part of the differential gear unit.

Referring to Fig. 7, it will be seen that if the two motors are rotating in opposite directions as indicated by the arrows, with the drilling motor having the slightly higher speed, there will be a slight downward feed of the bit. Now if the load on the drill pipe increases, the increase is reflected in a slowing down of

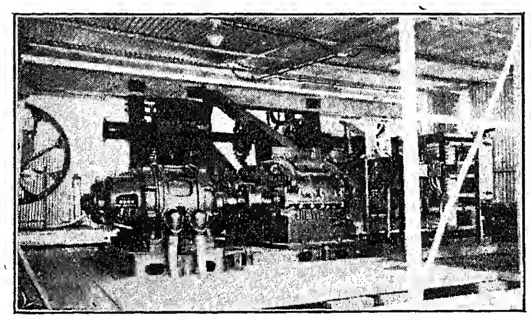

Fig. 8—Installation of Hild Differential Drive for Automatic Rotary Drilling

the drilling motor and a resultant decrease in the rate of feed. If the speed of the drilling motor is reduced below the speed of the regulating motor, the feed reverses and the bit is raised off bottom. Thus the device tends to maintain a constant predetermined pressure of the bit on bottom, at the same time limiting the torsional stresses in the drill pipe. By reversing the drilling motor, the equipment is used for hoisting with the maximum power of both motors available. Fig. 8 shows an installation of this type of drive.

In the operation of this equipment, the drilling, the hoisting, and the other minor operations are all per-

formed in the same manner as with the hand-fed equipment.

In Fig. 9 are shown two typical parallel graphic wattmeter charts representing the loads on the drilling and regulating motors when drilling at depths of 1460 to 1490 ft., using 6-in. diameter drill pipe and 14½-in. fish-tail bits. The total drilling load is represented by the sum of the loads on the two motors. During hoisting both motors are pulling together and the total hoisting load is divided evenly between the two machines. A comparison of the charts in Fig. 9 with those in Fig. 6 demonstrates conclusively the advantages of the automatic feeding of the bit over the hand-fed method, both from an economic and from an engineering standpoint. The absence of peaks during the drilling operation with the automatic feed lessens the strains in the equipment as well as in the drill pipe and the steady uniform load insures that the bit is on bottom the maximum possible portion of the time, resulting naturally in much faster drilling.

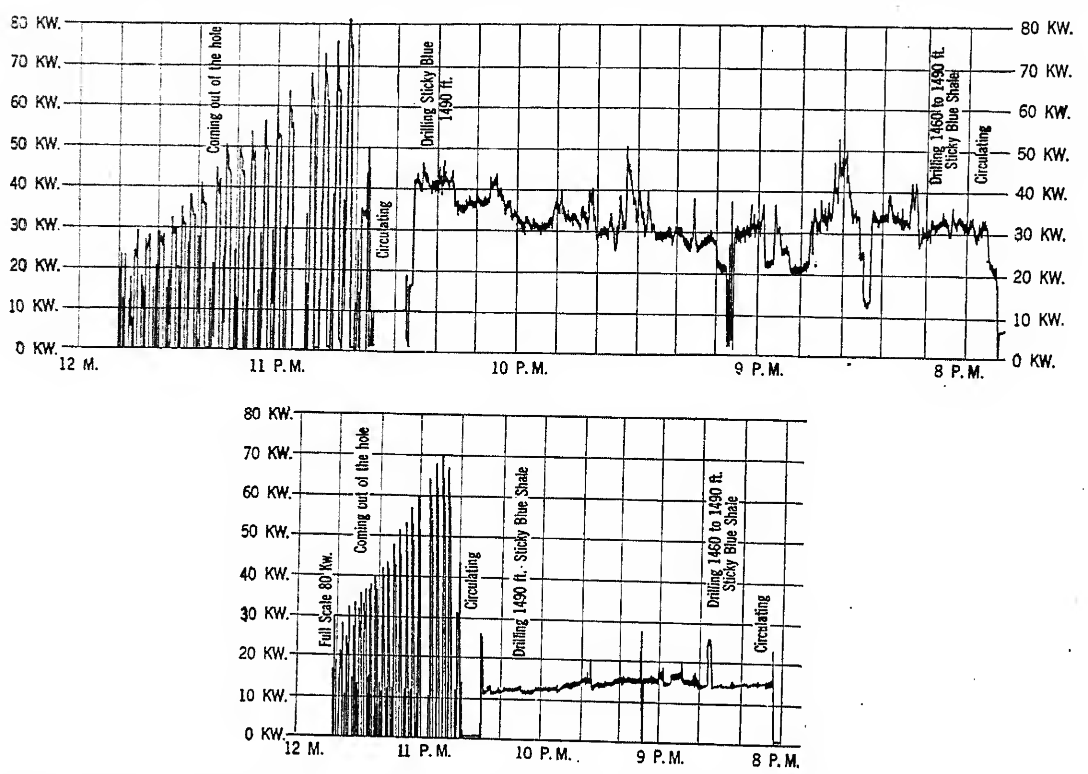

Fig. 9—Parallel Graphic Wattmeter Charts of Load on Drilling and Regulating Motors

Upper—Drilling motor

Lower—Regulating motor

Note the comparison between the loads for automatic drilling and hand fed drilling as shown in Fig. 6

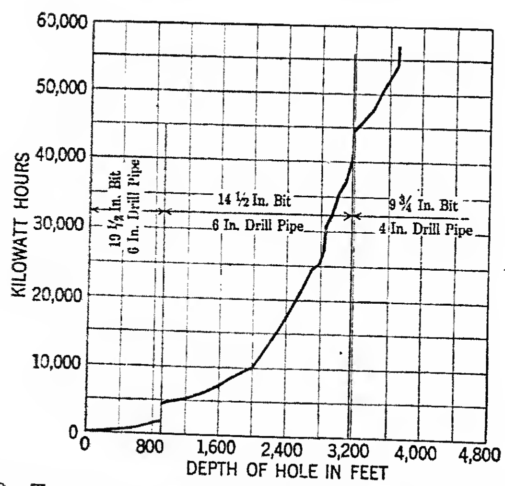

Fig. 10—Typical Curve of Power Consumption for a Well Drilled by the Hild Differential Drive in California

Fig. 10 shows how the total power consumption varies with the depth of the hole in the drilling of a 3700-ft. well in the California fields with the Hild Differential Drive. It will be noticed that in this particular case the power consumption amounted to 15.5 kw-hr. per ft., while for other wells in the same field using the same drive the consumption has run as low as 6.6 kw-hr. per ft. The general shape of the curve appears to be a slight modification of a parabola which differs from the shape of the curve for wells drilled by the cable-tool method as shown in Fig. 4.

The past three years have demonstrated the success of the automatic drive and, in the opinion of quite a few operating men, this drive constitutes the greatest advance in the art of oil-well drilling since the advent of the rotary system.

Everywhere in the oil fields, the operator is in a very receptive mood towards electrification as a result of the success of the pumping and drilling drives. The possibilities are unlimited, especially when it is considered that the industry is at the present time less than 10 per cent electrified and the central stations have only just recently realized the desirability of the oil field load. The drilling load in itself is not so desirable but wherever a well is drilled electrically, it is pumped by the same power and the pumping load with practically a 100 per cent load factors represents the ideal load for any central station.

Discussion

W. G. Taylor: Both cable-tool and rotary drilling impose extremely heavy duty on the power equipment, as is indicated to some extent by the graphic charts submitted in Mr. Murphy's paper. It would be even more interesting if he had shown some records of the work required to handle and set the casing which lines the well. In fact, it is this work which really determines the size of motor necessary for cable-tool drilling. The work is fully as heavy as handling drill pipe in rotary drilling.

The exacting requirements of oil-well drilling by either method have resulted in the development of the special equipments and schemes of control which Mr. Murphy has described. In the case of cable-tool drilling, the relative success of the twin-motor and single-motor schemes has been determined by the practical rather than by the economic aspects, and some of these may well be mentioned here.

Experience has shown that the twin-motor equipment requires more than ordinary attention from the driller to avoid serious overloading of one motor, and that the average driller in the fields cannot be depended upon to handle this type of equipment without burning out a motor now and then. Belt maintenance has proved excessive, and it has been found difficult to keep the motors and countershaft in alinement. On the other hand, the single-motor equipment has been relatively free from troubles. These things explain why oil companies, especially those which have tried out both kinds of equipments on a large scale under similar field conditions and have thus obtained a fair comparison, have a decided preference for the single-motor cable-tool equipment.

It is of interest that a 75-hp. single-motor cable-tool rig very successfully drilled a well in Colorado to a depth of 7300 ft., with every indication that the motor could continue the drilling work indefinitely to greater depths without the least distress.

Automatic feed of the bit in rotary drilling as exemplified by the Hild differential drive is a recent and very interesting development. Two devices of this kind are on the market, both operating on the fundamental principle of the differential gear. One of these is the Hild drive described by Mr. Murphy, and the other is the Halliburton drive. Both accomplish similar results, but the latter is driven by a single motor, or it may be driven by an engine of almost any type. The motor or engine drives the ring gear of the differential, as an engine drives the differential on an automobile. The two shafts, corresponding to the rear-wheel axles of the automobile, drive the drilling bit and the draw-works hoisting drum through suitable chain or gear reductions. Thus the feed of the bit is balanced against the torque of the load and varies inversely as the load, and the bit is automatically retrieved when the load exceeds a certain amount. A number of the Halliburton drives are in successful operation, with both motor and steam-engine drive, and the future will very probably see many more of both types installed, but it seems likely that their application will be limited to deep drilling as long as their present high prices prevail.

B. T. McCormick: Fig. 4 in Mr. Murphy's paper shows that for a well of about 2000 ft. in depth 12,000 kw-hr. is required, which means about an average of 6 kw-hr. per ft.

Some of our recent experience in Pennsylvania field wells of about 2000-ft. depth drilled with gear units and also the old fashioned jack-shaft drive by Star Delta drilling motors indicates that we get an average of about 3 kw-hr. per ft. I do not know whether that difference is due to the difference in formation or not. I should imagine that difference might account for the very much lower kilowatt-hour draw in the Pennsylvania field.

I would like to ask just why the depth of the well influences the power requirements in the way it seems to. There seems to be a marked reduction in horse-power required as the well becomes deeper. That point has not been made entirely clear.

L. J. Murphy: In answer to the latter question, it might be stated that this reduction is due to several different causes—first, the decrease in diameter of the hole as the depth increases, second, a decrease in the size of drill stem used and, third, the slower motion.

Mr. McCormick mentioned that in the Pennsylvania fields they have records which show that drilling could be accomplished to 2000 ft. with a power consumption as low as 3 kw-hr. per ft. In this connection I might state that I have seen installations in the Bradford territory where drilling was accomplished to a similar depth with a 30-hp. motor with a power consumption of 2.4 kw-hr. per ft. However, this equipment is such that high hoisting speeds are not possible, and I believe the same holds true of the equipment which Mr. McCormick mentions. In other words, the band-wheel speeds are not in excess of 50 rev. per min., and, hence, little power is used in the secondary resistance. This accounts for the low power consumption, but, in obtaining low power costs, the motor, during drilling, is operating at more nearly synchronous speed with the result that it has a rather stiff speed-torque characteristic not conducive to satisfactory drilling motion except with a manilla drilling line. The Bradford field is one of the few territories using this type of cable.

Application of Electricity in Cement Mills

BY W. E. NORTH[1]

Associate, A. I. E. E.

Synopsis.—The advantages of electric drive for cement mills are enumerated in this paper and general pointers on installing electrical equipment are given. The electrical installation recently made in a modern cement plant is described.

NO single factor has contributed more to the present design and efficient operation of a modern cement mill than the application of electricity as its motive power.

The older cement plants were designed to operate on steam power and since this necessitated the use of long line shafts to accommodate the numerous pulleys required to drive the many small manufacturing units then in use, these plants were practically built around an engine room. For this reason it was not possible to arrange the machinery used for the manufacture of cement in such a way as to insure maximum efficiency, nor could the elevating and conveying systems be installed so as to give the best flow of materials through the mill.

The first application of electric motors in cement mills was the use of d-c. motors to drive auxiliary machinery requiring from 1 to 50 hp. It was, for example, most inconvenient to transmit power from the line shafts to elevator heads and overhead conveyors, and tests showed that from 50 to 90 per cent of the power was lost in transmission, due to speed reductions usually accomplished with long chain and sprocket drives. Electric motors in such places proved an immediate success. They not only cut the transmission losses but it was soon found possible to install an astonishing amount of connected load in motor horsepower, on a generator set of much less rated capacity. This was due to the fact that such drives are usually over-motored due to the high ratio of the maximum to the average power required by the individual motors. In one case known to the writer a total of 375 hp. in rated motor capacity was carried by generators rated at 150 kw. with only occasional interruptions in service due to opening of circuit breakers. This constituted such a radical and valuable change from the old line transmission practise that small generator units driven by special high-speed engines of from 100 to 500 hp. became a feature of every cement plant.

The electrification of the cement plants in the Lehigh Valley was started on a larger scale when the Lehigh Navigation Electric Company built its plant at Hauto and offered attractive power rates to the cement manufacturers, most of whom were operating with steam power plants that were either in poor condition or badly overloaded due to increased production demands. The work of changing over these mills consisted primarily of replacing the old line shaft drives by individual motors, and in most cases the general layout of the cement machinery was not changed to any great extent to get greater advantages of the use of electric motors. One of the plants installed 2200-volt and 220-volt induction motors, two plants used 550-volt induction motors, and one plant installed d-c. motors.

The advantages of the electrification were realized very soon. At the Coplay Cement Manufacturing Company's plant the production was increased from 2600 barrels per day to over 3000 barrels per day without the addition of a single grinding unit and since the meters on the various feeder circuits gave accurate records of power consumption, causes of trouble and faulty operation could be detected easily and the unit cost of manufacture was decreased.

The use of electrical machinery in a modern cement mill is necessary for the following reasons:

1. It makes it possible to design a plant to meet manufacturing conditions without being restricted by conditions imposed when using other forms of power.

2. Increasing cost of labor necessitates the use of labor saving devices that are not practical except when driven by electric motors.

3. Saving in operating efficiency on account of not running idle machinery.

4. Necessity of keeping accurate daily cost data which is greatly aided by proper use of electric meters.

5. Greater flexibility in making repairs and adjustments to various parts of mill without interfering with other operations.

6. General trend toward larger manufacturing units.

One of the most important points to consider in the operation of a cement mill is the continuous operation of the various departments according to a prearranged schedule. The schedule of operation depends mostly upon local conditions, for, although it is necessary to run the kilns without shut-down, it is sometimes advisable to shut down certain departments over the week-ends. The quarrying and packing operations are in many cases discontinued on Sundays except during periods of maximum shipping requirements.

The manufacturing departments of a dry process cement mill may be divided as follows:

1. Coplay Cement Mfg. Co., Coplay, Pa.

Presented at the Regional Meeting of District No. 2 of the A. I. E. E., Bethlehem, Pa., April 21-23, 1927.

Quarrying,
Stone Crushing and Drying,
Raw Material Grinding,
Kilns,
Coal Crushing and Grinding,
Clinker Grinding,
Stocking and Packing.

It is seen easily that if a mill is designed with sufficient storage capacities between these departments, any department except the kilns and possibly the coal department may be shut down for repairs or other reasons without interfering with the other operations.

In a cement plant as outlined above, the electrical feeders should be so arranged as to supply one department only. If this rule is followed, repairs and adjustments to electrical apparatus and mill machinery can be made without interfering seriously with the operation of the mill. Such a feeder layout will not always meet with approval from an electrical point of view since the power requirements of the various departments vary within wide limits, which means that the feeder panels and the distribution feeders will not be the same size, but the advantages gained from a manufacturing standpoint offset its disadvantages when considered simply as an electrical installation.

The advantage of flexibility of operation and the readiness with which repairs and adjustments may be made without interference have been explained. Another advantage is derived from a cost accounting standpoint. Compared with other industries, the ratio of the cost of power to the total value of the product manufactured is great, varying from 15 to 20 per cent of the total cost, depending upon cost of power and efficiency of operation. To keep accurate and reliable account of the power costs is therefore of utmost importance and if each manufacturing department is provided with its own feeder panel and necessary metering devices, accurate data as to power cost can be obtained daily. Since the power consumption is an indication of the efficiency of general operating conditions, other troubles are easily located and corrected before serious trouble is caused or costs increased. The safety factor is also improved as any department not in operation can be cut off entirely from the feeder system.

The plans under way for the installation of new 60-cycle motors and for remodeling the mills of the Coplay Cement Manufacturing Company at Coplay, Pa. are based on the above principles; that is, the electrical equipment simply supplies a means to drive the machinery and in no way influences the layout of the mill.

When the improvements in the mill are completed, sufficient storages will be supplied between all departments to allow for flexible and economical operation and the electrical system has been installed so as to meet all of the requirements of operation of the mill.

The power for the electrical machinery is purchased from the Pennsylvania Power and Light Company, 60 cycles at 66,000 volts. Due to dusty conditions, and to insure as far as possible freedom from interruptions in power service, all of the 66,000-volt equipment was installed indoors, and the installation was designed to combine the greatest possible protection affording safe and continuous operation with the greatest simplicity of arrangement of equipment.

The transformer house is built of concrete with a cement tile roof supported on steel trusses. The concrete work was erected by the use of sliding forms. The pitched roof (six in. per ft.) with ventilators was used to secure the maximum amount of ventilation for the self-cooled transformers without the use of fans. A tunnel extends through the building under the switchboard and contains cable racks, steam, water, and compressed air service pipes and a concrete tank of sufficient capacity to hold the transformer oil in case it is necessary to empty the transformer tanks for any reason.

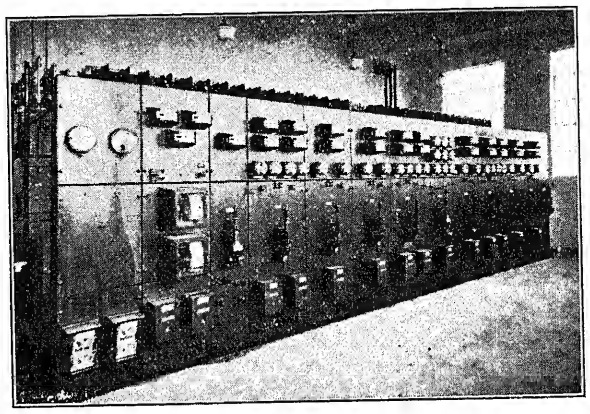

FIG. 1—DISTRIBUTION SWITCHBOARD

The building was erected and all of the equipment installed by the construction forces of the company.

The transformer house and arrangement of the electrical machinery is shown in Figs. 1, 2, and 3, and the schematic wiring diagram of the whole system in Fig. 4.

The incoming feeders enter the building through 110,000-volt wall entrance bushings and the equipment is protected by oxide film lightning arresters. The main line oil circuit breakers have manually operated closing mechanism and are equipped with bushing type current transformers and have d-c. trip coils operated by induction type overload and reverse power relays.

The rupturing capacity of these switches is sufficient to interrupt the current due to a short circuit on any part of the system. The transformers are self-cooled, three-phase, 66,000-2200 volts, 5000-kv-a. capacity with four 2½-per cent taps below 66,000 and are equipped with conservator tanks, thermometers, and temperature indicators connected to coils in the windings. They are mounted on trucks and provision is made for a hoist beam for repairs.

The disconnecting switches between the oil circuit breakers and the bus are three-pole, gang-operated and

are mechanically interlocked so that it is impossible to operate them when the oil breaker is closed. The bus tie switch and the transformer bank switches are three-pole, gang-operated air break switches and are used for breaking the parallel operation and the magnetizing current of the transformers.

It will be noted, Figs. 2-4, that when operating on one transformer bank, one side of the station can be entirely disconnected, making safe repairs and adjustments possible.

The operating switchboard is in a separate room, and

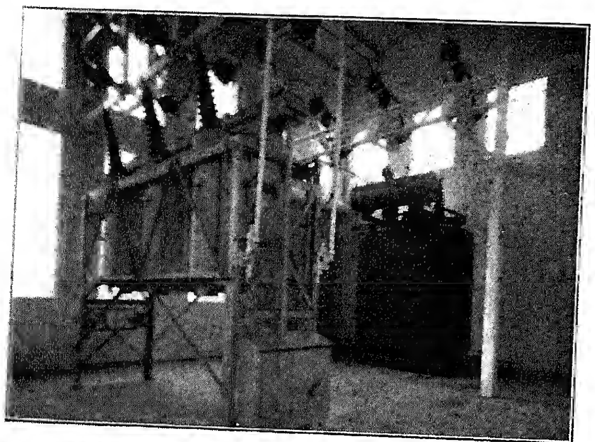

FIG. 2—5000-Kv-A., 66,000, 2200-VOLT, THREE-PHASE TRANSFORMER WITH AIR BRAKE SWITCH AND MAIN LINE OIL SWITCH

consists of two transformer panels, two totalizing meter panels, feeder panels, and a bus tie panel.

The bus-tie switch is operated by an instantaneous overload relay and is used to sectionalize the bus in case of a dead short circuit on one of the feeders to reduce the rupturing capacity required by the feeder circuit

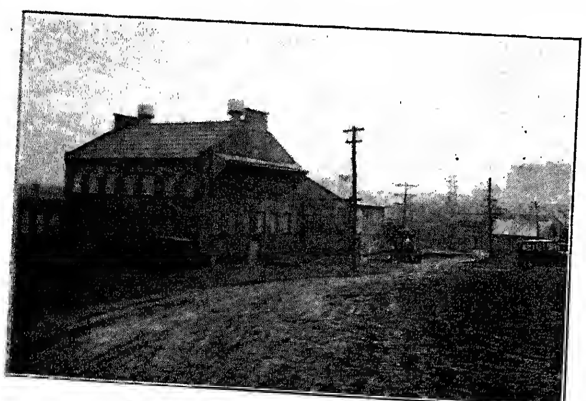

FIG. 3—TRANSFORMER HOUSE

breakers which have d-c. trip coils operated by inverse time limit relays. This combination operated successfully on two occasions when short circuits occurred on feeder cables during the construction period.

The totalizing panel is equipped with watthour meters, printometers, ammeter, voltmeter, curve drawing wattmeter, power-factor indicator, and wattless component indicator to be used with watthour meter in computing the average power factor.

The feeder panels are equipped with oil circuit breakers, disconnecting switches, ammeter, wattmeter and watthour meters, and with a complete set of testing

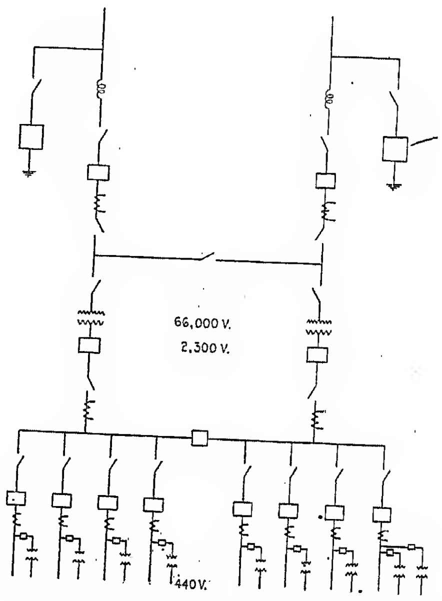

FIG. 4—SCHEMATIC WIRING DIAGRAM OF SYSTEM

studs on the front of the board for testing meters and relays.

All of the feeder circuits to the various departments are of armored lead-covered varnish-cambric-insulated cable. These cables are run underground to the various departments and when located out of doors are buried about three ft. underground and spaced several inches

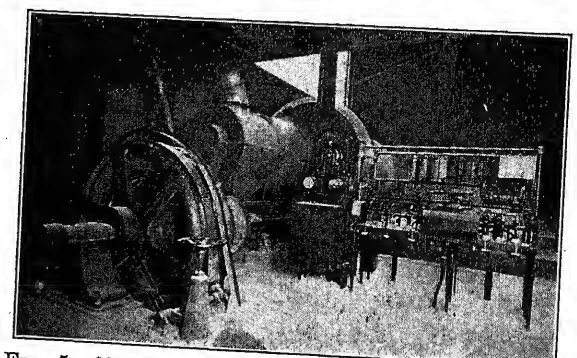

FIG. 5—600-HP., THREE-PHASE, 2200-VOLT SUPER-SYNCHRONOUS MOTOR DRIVING TUBE MILL

apart. Boards are placed about six in. above the cables as a protection against injury by workmen making excavations.

Where the cables are located in buildings having concrete floors, the ditches in which the cables are laid are filled with earth and covered with a 2-in. concrete slab marked to show location of cables and to allow the concrete to be broken out easily, if necessary.

The starting equipment for the various motors con-

nected to a feeder circuit is in most cases arranged in a group at the termination of the feeder. Since 440-volt motors are used for all sizes under 50 horsepower, small distribution transformers are connected to each feeder to take care of these motors.

The 2300-volt induction motors with few exceptions are controlled by manually operated starting compensators and the 440-volt induction motors are controlled by magnetic starters except in case of variable speed motors that have drum controllers and resistors. These starting switches are mounted on panels containing disconnecting switches, fuse blocks, and testing jacks all mounted in a single sheet steel box with safety catches.

The motors for the main grinding units are 600- and 200-hp. super-synchronous motors controlled by automatic panels; see Fig. 5. Where necessary, all motors driving different units of an elevating and conveying system serving a main grinding machine are interlocked to prevent choking of materials in case of stoppage of one of the units. All automatic starters are equipped with but one starting station but many have several stop stations.

With the exception of gasoline locomotives operating in the quarries and on the railroad and two gasoline-engine-operated well drills used for prospecting at points distant from our feeder circuits, all power applications in the mill are motor driven.

The distribution of the motor load may be classified as follows:

Pumps	260 hp.
Air Compressors	170 hp.
Blowers	315 hp.
Well Drills	50 hp.
Electric Shovels (M G Sets)	240 hp.
Quarry Hoists	125 hp.
Bridge Crane (M-G Sets)	200 hp.
Elevators and Conveyors	1055 hp.
Crushers	615 hp.
Dryers	110 hp.
Kilns	240 hp.
Grinding Machinery	4950 hp.
Packing Machinery	140 hp.
Machine Tools and Miscellaneous Applications	288 hp.
Total	8758 hp.

The types of motors used are as follows:

D-c. Motors, 220-volt (Electric Shovels, Cranes, Etc.)	374 hp.
Squirrel-Cage Induction Motors, 440-volt	1886 hp.
Variable-Speed Induction Motors, 440-volt	280 hp.
Squirrel-Cage Induction Motors, 2300-volt	3100 hp.
Hoist Duty Induction Motors, 2300-volt	125 hp.
Synchronous Motors, 2300-volt	3340 hp.
Total	9105 hp.

With the exception of comparatively few motors with characteristics suitable for the operation of electric shovels, cranes, and other labor saving machinery, most of the motors used in the cement industry are of standard design and construction and since the general practise in the installation of this equipment is to make the starting operation as automatic as practicable, specialized mechanics are not required for the operation of the motors and few skilled men are required for their maintenance.

An installation such as described above would be expected to operate 24 hr. a day for 360 days per year, and would have a yearly load factor (ratio of average demand to maximum demand) of 80 per cent and a monthly load factor of 88 per cent with an average power factor of 90 per cent, making it a desirable load from a power generating standpoint.

The tendency in cement mill work is toward larger grinding units and the most efficient electrical apparatus obtainable, standardization in sizes and speeds of the general purpose motors, and distribution of the motor load into circuit so as to best meet the manufacturing requirements of the mill so as to be an aid to more efficient operation.

The recent development of synchronous motors of high starting torque, with either mechanical or magnetic clutches, has caused the installation of more direct-connected units, eliminating many expensive belts and pulleys and resulting in great saving in space and in efficiency and safety of operation.

In many instances, ball and roller bearings have been used in extremely dusty places with good results, but a modern cement mill can be made to be so free from dust that when proper attention is paid to the condition of the equipment, motors with standard babbited bearings can be operated with as little trouble as when installed on similar machinery in other industries.

The use of belts and chains on countershafts for speed reduction necessary to drive elevators and conveyors has been almost universally replaced by the use of gear reduction units direct connected to motors through flexible couplings mounted on common bases. Reducers of these types can be built for speed reductions ranging from 4 to 1 up to 8000 to 1 when power does not exceed 500 hp. and therefore cover the entire range of cement making machinery except in case of the larger grinding units. Rock crushers and heavy machinery subject to severe shock are still usually belt driven to provide flexibility and reduce the strains on the motor bearings and coils.

In addition to the above described motor applications, electricity is used in cement mills for magnetic separators, rivet heaters, arc and spot welders, pyrometers, and various other application of electricity, all of which have become most satisfactory features in operating cement plants, and as is the case in other industries, electric power has become one of the greatest factors in production, and from raw material to the finished product the responsibility of uninterrupted manufacture rests primarily upon the electric motor.

Discussion

E. B. Wagner: Mr. North mentions that the main substation was enclosed in a brick building in order to protect the equipment from dust. I should like to ask how he was able to keep the dust out of the building.

He told us that he had provided the super-synchronous motor with an automatic starter. I should like to know if this is a full automatic starter; that is, does it take care of automatically applying the brake on the revolving stator so as to slow that down and bring the rotor up to speed?

W. E. North: The high-tension transformers and switching equipment were housed in a building because the combination of cement dust and water causes a lot of trouble on 110,000-volt insulators that were used for the 66,000-volt service, and although it might have been satisfactory to build an entirely outdoor station with a little less money, we didn't believe that it was wise to take that chance since the main thing we wanted was absolutely continuous operation.

A small amount of dust gets into the building but the dry dust doesn't have nearly the same disastrous effect on insulators as cement dust coked up with water.

The automatic starters we have on the synchronous motors do not automatically put on the brakes. That has been a later development. The motors are not thrown directly across the line but are started with an autotransformer with reduced-voltage taps. I don't know on which taps they were working at present but about 40 per cent increase over the normal operating current is required for starting and the brake is put on by hand after the starter automatically throws on the field. The men operating these motors have become fairly skillful in the operation of the brake, and we can't see any rise in the power curve when the mill is brought up to speed. We allow from 15 to 20 seconds for the acceleration of the motors and it is entirely possible to operate the brake by hand to get these results.

F. C. Caldwell: I want to ask if high-tension electric precipitation devices for abstracting the dust from the air are in use at all in cement mills; also, whether the general tendency to extend the use of roller and ball bearings that is going on these days is likely to result in their general adoption in the case of the cement-mill motors. Mr. Findlay of the Giant Portland Cement Company told me that his company has used nothing but ball or roller bearings for the last five years and they are thoroughly "sold" on the use of that type of bearing for cement-mill work; that they have had no necessity for the replacement of the roller or ball bearings, and that they would use no other kind.

W. E. North: From 1917 to 1919 we had a precipitation apparatus at our plant. It will collect the dust. The principal reason that we abandoned it is that in our particular case the gain we made was far offset by the cost of operating it. In some cases, in a new plant possibly, where the dust collector is built with the plant and designed to operate with that particular plant, you would probably have much better operating conditions. The mill in which we installed an electric precipitation dust collector was an old one and we had to put this dust collector where we had available space and it was not as efficient as it would have been if we had sufficient space to install a system of greater capacity.

In regard to the bearings, the best way, I believe, to protect motor bearings, or any other kind of bearings or any other machinery around a cement mill is not first to try to make the bearings dust-tight but to provide dust-collecting apparatus to remove the cause of the trouble. However, if that cannot be done without enormous expense, the next step is to protect the bearings. With regard to that, however, our mill is not a dustless mill and we have just installed some new 60-cycle motors there. The original installation was made in 1913 and 1914, and it was taken out the first of January this year, which is 13 years of operation.

As to the life of the bearings in these motors we would sometimes lose a bearing in 2 weeks at first but we soon remedied that. We have, for instance, one 75-hp. motor that ran 12 years without a change of bearings. Our tube mills were driven by 150-hp. squirrel-cage motors mounted in rather dusty places on the second floor because of lack of space on the first floor, and they were running with excessive belt tension. The bearings on these motors averaged 2 years. The average life of the smaller motor bearings; that is 25-, 15-, and 10-hp. motors driving elevators and conveyors which are usually mounted in fairly dusty places, was 1½ years. As to the vertical motors with ball and roller bearings driving Fuller mills in a coal mill, one of those never had the bearings changed. Our vertical motors with ball bearings averaged 4 years.

As to the effect of dust on the coils, we have 80 motors whose coils were never repaired, 70 motors were patched, and 10 of them were completely rewound in 13 years' service.

As to the ball and roller bearing applications on motors, I have personally no data on their life in the cement industry.

In a properly laid out plant, as a rule, the time required to replace babbitted bearings does not often hold up production very much because such repairs can be foreseen and may be made during regular repair periods.

D. M. Petty: There seems to be doubt in the minds of some people, particularly those who have not been in the steel industry to any great extent, as to why some of us in the steel industry are particularly interested in ball bearings. We know from experience in the steel industry that the babbitted bearings will be cheaper than ball bearings, so far as the cost of bearings is concerned. The reason we put ball bearings in our motors, however, is to eliminate the loss of windings due to the lubricating oil getting out of the bearings and into the windings. We found by keeping a very careful record in our own plant and by questionnaires sent out among all of the other larger steel plants where proper records were kept, that at least 75 per cent of all motor failures were due to the oil getting out of the bearings into the windings, and that is the big reason why I, personally, and the committee on which I served came to the conclusion that ball and roller bearings would be a good proposition in the steel industry. In the cement industry, motor windings are not subjected to all the hazards that we have in the steel industry. Cement itself is a fair insulator. If we could only get our motors filled with cement instead of smoke and gasses and carbons and other such things, I don't believe we would have to worry about ball bearings in steel mills. I don't see why ball bearings wouldn't work out in the cement industry, but as in the steel industry more for the sake of saving windings than for the bearings themselves.

G. M. Kennedy: I understand Mr. North to say that the 2300-volt squirrel-cage motors are manually operated and the 440-volt squirrel-cage motors are automatically controlled. I should like to ask why that is the case.

W. E. North: The 440-volt motors are thrown directly across the line simply by means of an automatic magnetic switch. The reason we have manual operation on the 2300-volt squirrel-cage motors is that quite a few of these motors were put on machines which would probably be replaced soon after we finished the reconstruction of the mill and we did not spend any more money than necessary on them.

A. J. Standing: I should like to ask Mr. North, if in the layout of a new mill today he would use 440 volts or would it be possible to go to 2200? What I am getting at is the safety of the men around the plant.

W. E. North: I believe I would put in 440 volts. That, of course, is a matter of personal opinion. I believe that 440-volt equipment with the proper apparatus can be made safe enough not to interfere with safe operation. For 14 years we operated at Coplay with 550 volts and we did not have any serious accidents to our operating force due to the voltage. We have had

a few slight accidents due to flashover on opening switches. On the 440-volt apparatus that we have now, the starting equipment is totally enclosed; there is nothing exposed whatever on the whole layout. I think I would use 440 volts in preference to 220 volts for small motors on account of the feeder conditions, and 2200 volts for larger motors.

John Grotzinger: I am particularly interested in the application of the super-synchronous motor to tube-mill drives as the application of synchronous motors to heavy mill drives in the rubber industry, with which I am connected, has been a feature of the past two years.

Can Mr. North give us the torque characteristics of his super-synchronous motor, particularly the pull-out torque?

Is excitation furnished from a belted exciter or an external d-c. system and what method is used to apply the field at the proper time during the starting operation? Is a frequency relay used for this purpose or current lockout in combination with a definite time relay?

W. E. North: These 600-hp. super-synchronous motors I was speaking about drive tube mills which require a running load of about 425 to 450 kw. We have never made any tests on the starting torque or the pull-out torque on those mills. Since the load is applied by means of a brake the principal starting consideration seems to be the period of acceleration. After the motor is up to speed we begin to apply a manually operated brake and it is possible to hold the current constant at full-load running value, if sufficient care is exercised in tightening the brake. We never have had any trouble with starting and therefore have never made any tests on the starting torque of those motors.

The excitation is supplied for three of these motors by a motor generator or exciter set. I cannot give the exact details of the relays used but to the best of my recollection, current-lockout in combination with time-limit relays are used.

F. E. Fairman: In connection with the operation of these super-synchronous motors and also the other 2300-volt switching equipment, I should like to know just what experience was had with the operation of auxiliary devices and auxiliary contacts for the field contacts on the synchronous motors, first, with dust in the substations, and just what steps were found necessary to be taken in maintenance, cleaning, and the like.

H. H. Leh: We have noticed that when surges occur on the line feeding our plant the undervoltage release on our super-synchronous motor opens quite frequently, throwing the motor off the line, whereas the induction motor in the plant keeps in continuous operation without the undervoltage release opening. I should like to know, if possible, whether this is an inherent characteristic of the motor or if it is only due to the design of the undervoltage releases.

Aubrey Smith: Relays are available which can be used to prevent the disconnection of a synchronous motor from its source of power by voltage dips which are not too great in magnitude nor too long in duration. Ordinarily the lower the voltage dip, the shorter the time during which synchronous operation of the motor may be maintained and vice versa. The degree of continuity of service which can be secured in any given case by use of such relay equipment depends more upon the characteristics of the synchronous apparatus than anything else. General-purpose synchronous motors, for instance, are available which will carry their load operating as induction motors for several minutes, without over-heating, at a slightly reduced speed. On the return of voltage to its normal value, these machines can be made to come up again to synchronous speed and operate as synchronous motors. Of course, in such cases control equipment must be provided which will attend to the removal and re-application of the field when the proper rotating speed of the machine is reached.

Installations making use of the control principles and equipments mentioned have been made in various places and in various industries. Such relay equipment is effective in increasing the continuity of service, especially if line disturbances are not too violent in character. If it is known at the time of planning the new installation that the source of power will be subject to momentary voltage dips, plans should be made at the outset to equip the apparatus with relays designed to sustain synchronous operation as long as possible.

W. H. Lesser: I can give some experience about that, too. We have in operation at one of our collieries a new system of preparing coal known as the sand-flotation process. Each time there is a surge in the voltage or an interruption in the power, this apparatus stops and it takes about half an hour to agitate the sand again. We have sixteen motors there and the control boards are all in one room, and every time we have a surge on the line the whole plant shuts down. Mr. Lloyd looked over the proposition and we ordered a master control panel for this installation, with a time relay on it. We set the relay for 4 sec. which holds the motors on the line during the surges.

There is another point I should like to ask Mr. North about. Do you have any trouble in the operation of the super-synchronous motor; that is, with flashovers and things similar to that?

W. E. North: No, these motors have been running continuously since they have been put in. The only trouble we have had, has been on account of misalinement of a flexible coupling. That was not the fault of the motor and it was remedied within a few hours.

W. E. Lloyd: A few years ago when the interconnection system in this territory was being built and surges were comparatively new to the customers now on this system, the tripping off of apparatus, either synchronous or induction, due to the low-voltage release was very common. We advocated either a time delay on the low-voltage trip or removing the low-voltage trip entirely, that being dependent upon the particular operation. We went through the same conditions in our power stations; fans and pumps, and other auxiliary apparatus would trip off during these surges, which we could not afford because it meant an extended interruption of many minutes rather than one minute. So we have taken off the low-voltage releases in our power stations; many of our customers have taken them off.

I feel that the super-synchronous motor is a new piece of equipment. We, as well as the customers, are feeling our way, but actually I think the time will come when we shall treat the super-synchronous motor from a low-voltage-release standpoint just as we now treat the induction motor; that is, put on an adequate time delay to hold that motor on the line during surges, allowing it to trip clear if the voltage goes entirely off for, say, half a minute or a minute, or else take it off entirely in case the power fails and rely upon the operators to clear the switch and have it cleared before the power comes back on.

In connection with the dust problem Mr. North told how he housed his equipment in a building. We can't very well house our incoming transmission line in a building and we have to fight a problem of dust on the insulators. Of course, we might run the incoming line for the last half mile in a 60 kv-a. cable, but it has not been done to date. It was our practise several years ago to wipe off the insulators every week on the last few towers adjacent to each cement mill. This worked only fairly well. We had no definite plan for changing these insulators and after a protracted dry spell followed by a light rain or a fog, we invariably had a number of insulator failures caused by leakage over the surface of the insulator due to cement dust and collection of the moisture. If we were fortunate enough to get a real heavy rain following a dry period, that heavy rain usually washed off the insulator dust sufficiently so that no trouble was encountered. Our recent experience has been to change these insulators on the last three or four towers of the line going into the cement mill every six months. The insulators further back on that line will be changed probably in periods from two to five years, depending upon just how much precipitation of dust there is on the insulator. These insulators were taken down every six months,

scraped, and then finally scrubbed with a weak solution of hydrochloric acid and water, after which they were tested and if good were put into service again. It was a rather expensive proposition to scrub and clean those insulators. In the last two or three years we have been taking hot paraffin and painting the insulators with a brush. It does not affect the insulating quality at all, and when they are taken down we simply dip them into a bucket of boiling water and it melts off the paraffin and along with it comes the cement dust, and the insulator is ready to go back into service again.

Mr. North speaks about the 66,000-volt transformers which he has installed at his mill. I want to mention the reliability of that transformer. We have at least 250,000 kv-a. of this type transformer in service on the system, either our own transformer or customers', and to date we have not experienced a single failure. When I say that, I want to qualify it in this way: We have had bushings fail, but that is an attachment which can be replaced promptly and stock units are always available. We have had winding failures, where a short circuit occurred on the low-voltage side and the switching equipment did not clear the trouble, but we don't consider that an inherent defect in the transformer. So that I believe Mr. North and every one using this particular transformer at this particular voltage is going to get excellent service from the unit.

Mr. North, in speaking of his load factor of 88 per cent, reminded me of a cement mill which is using rotary converters of 4000-kv-a. capacity. They run a load factor for the month as high as 96.8 per cent at unity power factor. It was very interesting to see the operators in that substation regulate their load. They would go to the lighting switchboard and open and close a knife-switch and by a series of flashes they would signal to a motor tender out in the mill and he would merely drop off one motor or two motors, and they would thus maintain a constant load of 4000 kv-a. hour after hour.

O. S. Clark: I shonder if Mr. North has found it to be an economical proposition to install lead distribution feeder cables underground rather than in conduit. Of course, it is cheaper to install a cable underground without the conduit, but it is also much more expensive to make repairs, and there must be a balance some place, depending upon the extent of the distribution system. I should like to hear from Mr. North on that.

W. E. North: Before putting in the armored lead cables, we got complete prices and cost data on what the cost would be for the installation of lead cables in conduit. Ours is an old mill and if we put in conduit we would have a great number of bends and in many places we would not have room to put in the conduit.

To reduce repairs we have been liberal in our selection of cables. We use cables with 5000-volt insulation for 2300-volt service and the capacities are ample. On lead cables buried in the ground we use 70 per cent of the underwriters' rating in calculating the capacity of the cable, because we believe that many failures in varnished-cambric-covered cable come from a gradual baking out of the varnish which settles to the lower part of the cable, and if the cable is never heated failures are not so frequent. I don't know what the economy would be in a plant where you had plenty of room to put in the cable ducts but in our particular case it would have been rather expensive to attempt to put in any kind of a duct system on account of the numerous manholes we would have to put in. We would have had 6 bends in one run of 400 ft.

Regarding lead cables and open or closed ditches, our experience has been just the reverse of the one mentioned, about overheating of the cables. Of course, we were fortunate enough not to have to run the main feeder lead cables near the kilns. All of the cables in the ditches are separated about 6 in. apart and clay or sand is put in to keep a cable, if it flashes over, from passing the trouble to the other ones. During our construction work some workmen doing concrete work near the cables built a fire to thaw a frozen water pipe, not knowing the cables were near. The fire was about 2 in. from a cable. In very short time the cable burned through and although there was another cable 6 in. away it was not damaged. This, I believe, justifies the use of sand between the cables.

J. T. Waugh: In discussing Mr. North's paper, I might say that the electrical distribution systems in a wet-process mill and in a dry-process, are identical.

One type of construction, for a low-tension transformer station, that has successfully coped with the dust problem is based on the elimination of exposed leakage surfaces.

Where radiant heat is exceptionally high, the use of ventilated cable trenches with the omission of sand has been found satisfactory.

Both air-break and oil-immersed starters have been used and the results are still open to controversy. In a coal mill, however, it is important to eliminate all air contacts due to the ever prevalent inflammable pulverized coal dust and its potential explosive properties, if the proper amount of oxygen is supplied by a sudden gust of wind, and proper care has not been exercised in keeping the place clean.

In further answer to the question of the gentlemen who asks how to take care of dust in a high-tension transformer station already built, I believe the permanent sealing of all windows and the use of louvers covered with muslin will greatly tend to minimize the dust menace. In such a transformer station in the heart of a cement mill, where the above ventilation is used, shut downs for the purpose of cleaning insulators have been practically eliminated.

F. A. Scheffler: I should like to disabuse the minds of some in regard to the statement that there is a possibility of frequent explosions in cement plants. That is altogether up to the cement operating force and is a question of house cleaning. If the cement companies keep their coal mills clean and do not abuse the pulverizing equipment, they will have no trouble whatever from explosions.

Recent Developments in Electric Drives for Rolling Mills

BY L. A. UMANSKY[1]

Associate, A. I. E. E.

Synopsis. The application of electric power in the steel industry introduced many radical changes and improvements in rolling-mill layout and practice. The electric drives, of capacities larger than encountered elsewhere, are usually designed to fit individual cases. Special machines or special combinations of them are frequently used.

Several representative cases are outlined, and some methods of solving the encountered problems are analyzed.

INTRODUCTION

THE iron and steel industry is the largest single consumer of electric power. In 1924 this industry used more than 6,000,000,000 kw-hr., which is about 20 per cent of the total power consumed by all industries in the United States. It is of interest to note that the combined output of all central stations in the country equalled 54,413,403,000 kw-hr. during the same year.

A modern steel plant, starting with an iron ore as a raw product, produces at its blast and open hearth furnaces and at the coke ovens a large amount of waste gas or heat. Electricity gives means of conveniently converting and transmitting this potential power to the centers of its consumption. This explains the rapid growth of power generating plants in the steel mills; one steel plant has an installed capacity of over 100,000 kw.; a number of plants have a demand in excess of 50,000 kw. In 1926 alone the steel industry purchased for its use a 30,000-kw. turbo generator and three others each rated at 20,000 kw., not counting many other units of 15,000-kw. capacity and less.

So great is the demand for power in the steel industry that even plants having their own blast furnaces often purchase additional power from public utilities. Many other plants, deprived of the use of blast furnace gas, run almost exclusively on purchased power. The latter amounted in 1924 to 39 per cent of the total power consumed.

The bulk of this vast amount of energy goes for the work of shaping the steel; the rolling mill drives are the principal outlets of the generated power. Here the electric drive predominates. Hardly any new mills are being equipped with anything but electric motors; older steam driven mills are being gradually electrified, for purely economic reasons.

Many electrical engineers, not connected directly with the steel industry, may not fully realize the profound, almost revolutionary changes which the electric drive brought about in the rolling mills. It is not merely the question of performing the operations in a better, more efficient, or more reliable manner than otherwise possible; but the point, which is sometimes lost sight of, is that many operations and processes, now in wide use, are practically impossible without the agency of electric power. Rolling mill designers have taken advantage of the possibilities of electric drives and have built mills on radically new principles, exceptionally advantageous for steel plants, but not practical, were it not for the presence of electrical motors. On the other hand, the electrical engineers have developed new machines, or new combinations of machines, primarily, if not exclusively, for rolling mill application. Thus the new rolling mill has become closely tied to its drive and is unthinkable without it; the influence between the electrical and mechanical equipments is now not only great. it is also mutual. Many new problems were brought up and were solved more or less successfully.

There will be outlined in this paper, in a necessarily short space, those solutions offered by electrical engineers for a few of these problems. A brief sketch of the types of new rolling mills will give the necessary background.

CONTINUOUS ROLLING AND CONTINUOUS MILLS

It has been generally recognized that for a large tonnage output a continuous rolling mill possesses decided advantages. Such a mill, see Fig. 1, consists of a number of two-high stands, arranged in tandem and conventionally driven through a line shaft and gears by a single motor or engine. The hot bloom or bar passes in succession through all stands, as indicated by the arrow. Each pair of rolls reduces the cross-section of the bar until the latter leaves the last stand as a finished product of the desired shape. The layout is compact; little heat is lost between stands; the metal is rolled at a high temperature and with a relatively low power consumption; the steel requires little, if any, handling; the labor costs per ton are reduced to a minimum.

The bulk of the country's steel output passes through a continuous mill of one kind or another.

To maintain the high tonnages and to keep the cost of handling down, the rolled bars are usually of considerable length; a finished length of several hundred feet is quite common. In order to save floor space the stands are located close to each other. This means that

1. Industrial Engg. Dept., General Electric Co., Schenectady, N. Y.

Presented at the Regional Meeting of District No. 2 of the A. I. E. E., Bethlehem, Pa., April [illegible].

the metal is in several stands at the same time. It is obvious that with such an arrangement the speed of each consecutive pair of rolls is increased in proportion to the reduction of the cross-section area. For a given mill the speed relation between stands is fixed and is determined by ratio of the several gears; hence the reductions per pass, or the so-called drafts, are also more or less fixed. Thus, a continuous mill of the outlined type, capable of producing large tonnages of a

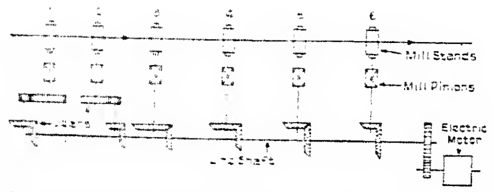

FIG. 1—ELEMENTARY DIAGRAM OF A CONTINUOUS MILL WITH A SINGLE DRIVE

certain class of sections, is not quite flexible when it comes to rolling of a diversified line of products.

Individual drives for several stands of a continuous mill give it the necessary flexibility, at the same time maintaining its inherent advantages.

For instance, the mill, Fig. 2, has its first three roughing stands driven by one motor, the next two stands by another motor, and the last three, or finishing, stands are each provided with a separate drive. If all motors, or several of them, are of the adjustable

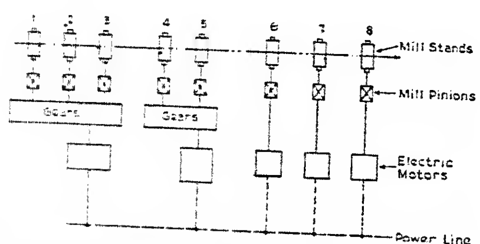

FIG. 2—ELEMENTARY DIAGRAM OF A MULTI-DRIVE CONTINUOUS MILL

speed type, then the speed ratio between the stands may be readily changed. A wide variety of products may be then successfully rolled, each at its proper speed, each with the most suitable reductions at the several stands.

Mills, designed and built on this principle, are springing up all over the country. Hot strip, rods, merchant, and certain structural shapes are being rolled on such mills. They are believed to be economical, flexible and tonnage producing. In many cases one mill of this type takes the place of two or three less modern mills.

Such layouts would be hardly feasible were it not for the application of the electric motor. We are usually accepting it as a matter of fact, and are apt to forget that there is no other device which can concentrate a large bulk of power in a limited space, which is efficient even in small units and which is capable of speed adjustment, yet will closely maintain its speed, once it has been adjusted.

It is outside the scope of the present paper and outside the competence of the writer to offer a thorough analysis of mill layouts from the standpoint of rolling mill operations. It was not intended to convey the idea that, for instance, a continuous mill with individual drives is the best combination or layout for all applications; such a mill was merely discussed in order to illustrate the profound influence of electricity on rolling mill engineering and practise.

TYPES OF ELECTRIC DRIVES

It will be shown presently how the electrical engineers are providing suitable drives for mills of the kind just described. While no radically new machine was

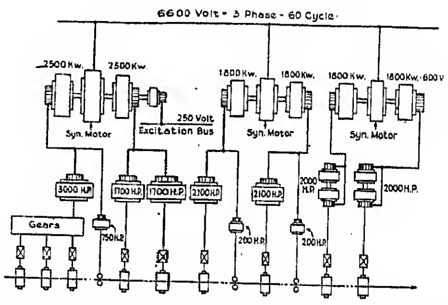

FIG. 3—LAYOUT OF A LARGE CONTINUOUS MILL DRIVEN BY D-C. MOTORS. THE GENERAL VIEW OF THE MOTOR ROOM IS SHOWN ON FIG. 4

invented nor introduced, some new combinations of machines were conceived and were successfully applied.

D-c. Drives. When a mill requires a number of adjustable speed drives it is the simplest and, in many

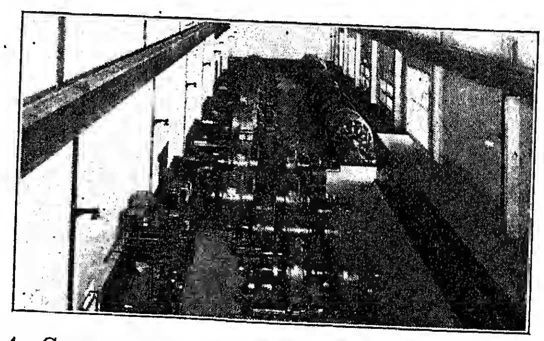

FIG. 4—GENERAL VIEW OF THE MOTOR ROOM AT THE 14-IN. MERCHANT MILL OF THE JONES AND LAUGHLIN STEEL CORPORATION, WOODLAWN, PA.

The elementary diagram of connection is shown on Fig. 3

cases, the best way to make each drive a d-c. motor and to furnish power to them from motor-generator sets or from synchronous converters.

Figs. 3 and 4 give the schematic layout and the general view of the motor room of one of the most modern mills of this type.

A 3000-hp., 200/360-rev. per min. motor drives

the roughing train of three stands; two 1700-hp., 90/204-rev. per min. motors and two 2100-hp., 150/-460-rev. per min. motors are individually driving the next four stands; the two finishing stands are each driven by double-unit, 2000 hp. motors, consisting of two 1000-h. p. armatures which can be connected either in series or in multiple, and operating up to 800 rev. per min. Three smaller edging roll stands are also electrically driven.

All motors are 600-volt, d-c. machines and the power to them is furnished from three large synchronous motor-generator sets, aggregating 12,200 kw. (40 deg. cent. continuous capacity). Practically each motor has a corresponding generator, as is shown on the diagram. Ward-Leonard control is used for starting, and the combination of generator voltage and motor field control gives a very wide speed range (as wide as 4:1 and 5:1) to each drive.

Another interesting example of a modern mill with

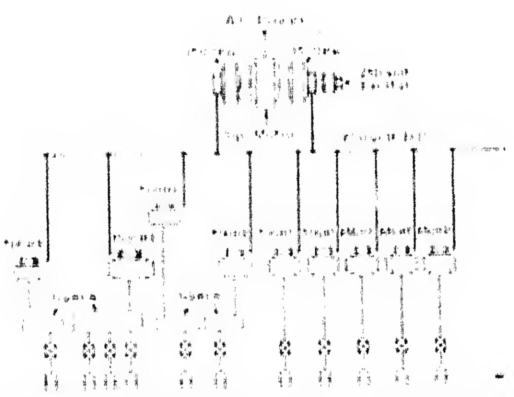

FIG. 5 TYPICAL ARRANGEMENT OF A MODERATE SIZED CONTINUOUS MILL DRIVEN BY D-C. MOTORS

stands individually driven by d-c. motors is represented by the layout in Fig. 5. The capacity of each drive is indicated on the diagram. The power to the motors is supplied from a 3000-kw., 600-volt, three-unit motor-generator set. Ward-Leonard control is used for starting, and motor field control for speed adjustment.

D-c. Versus A-c. Drives. When a mill requires a number of adjustable speed drives, especially of the average or of less than the average capacity, then it is usually more economical to make them of the d-c. type, as just described. When a speed range larger than 2:1 is necessary, the use of direct current becomes almost imperative. The speed regulating control is quite simple, usually consisting of one or several field rheostats. The use of direct current may also reduce the cost of the high voltage switching equipment.

On the other hand, the necessity of converting the full amount of electrical power three times from the available a-c. line to the mill coupling, greatly reduces the over-all efficiency of the drive and increases the running light losses. Assuming an efficiency of a d-c. motor at 92 per cent and that of a motor-generator set at 88 per cent, the over-all efficiency of the drive at full load is only 81 per cent. When the d-c. machines are operating at reduced voltage (*i. e.*, when part of the speed range is covered by Ward-Leonard control) their efficiency goes down quite appreciably. The actual over-all efficiency and the power consumption (in terms of kilowatt-hours used per ton of rolled material) are still further unfavorably affected by the fact that the average mill load is usually much less than the rating of the drives.

Thus, much as a straight d-c. system may seem attractive, in many cases, from the operating standpoint, it would be a fallacy to consider it as a standard for any multi-drive mill.

With alternating current universally adopted in all steel mills for power generation and distribution, the engineers should always analyze whether the available a-c. power could not be more directly used for driving the mills. When large amounts of energy and large tonnages are involved, the possible improvement of 5 or 6 per cent, or more, in over-all efficiency, presents an attractive goal worth striving for. Say, a mill rolls 50,000 tons of steel per month, consuming approximately 40 kw-hr. per ton, or 2,000,000 kw-hr. per month; a saving of 5 per cent at, say, 0.9 cent per kw-hr. will net over $10,000 per year. Such economy alone would justify an additional investment as high as $50,000 if it were required. But, if it is obtainable without any additional outlay, or even with a lower first cost than with a d-c. drive, then the application of a-c. drives becomes vital and their possibilities should be most carefully studied.

A-c. Drives. The art of engineering thus far knows of but one way to build adjustable speed, a-c. drives, of such capacities as are involved in steel mill work. This is to use a slip-ring induction motor and to regulate its speed by acting on its secondary circuit in one or another well known manner. These methods were described in great detail, at various times, before this Institute or before other engineering societies, and the most representative of them are diagrammatically shown on Fig. 6.

Broadly speaking, all these methods have one thing in common. An induction motor, running at a sub-synchronous speed, delivers at its shaft, as mechanical energy, only that portion of the power transmitted to the rotor which is proportional to the speed; the balance of this power, proportional to the slip, is available at the slip-rings and is usually called the slip energy; it is of a frequency and voltage proportional to the slip. This energy is either converted into mechanical power and is returned to the main motor shaft, see 6B, 6D, 6F, or is converted into electric power of the line frequency and voltage and is returned to the a-c. system; see Figs. 6A, 6C, 6E. In the first case the drive is of a "constant horse power" type, as approximately the same amount of power (neglecting conversion losses) is available at the motor coupling at all operating speeds; in other words, larger torque is

available at the reduced speed. In the second case the drive is of "constant torque" type, *i. e.*, the power available at the coupling varies in proportion to the speed.

Figs. 6A and 6B represent the Scherbius system employing an a-c. polyphase commutator motor R to convert the slip energy into mechanical power at *its* shaft; then it is either returned electrically to the line through an induction or synchronous generator K, or is utilized directly on the drive shaft. The regulating machine R is shunt wound and is excited from the slip-rings of the main motor; by controlling the amount of excitation the speed of the drive may be adjusted suitably.

In the Kraemer system the slip energy is converted into d-c. power by means of a synchronous converter C. This d-c. power (of variable voltage) may be also either pumped back to the line through a motor-generator set D-K, Fig. 6C, or returned mechanically to the main motor shaft, Fig. 6D. In either case the speed of the drive is adjusted by controlling the excitation of the motor D.

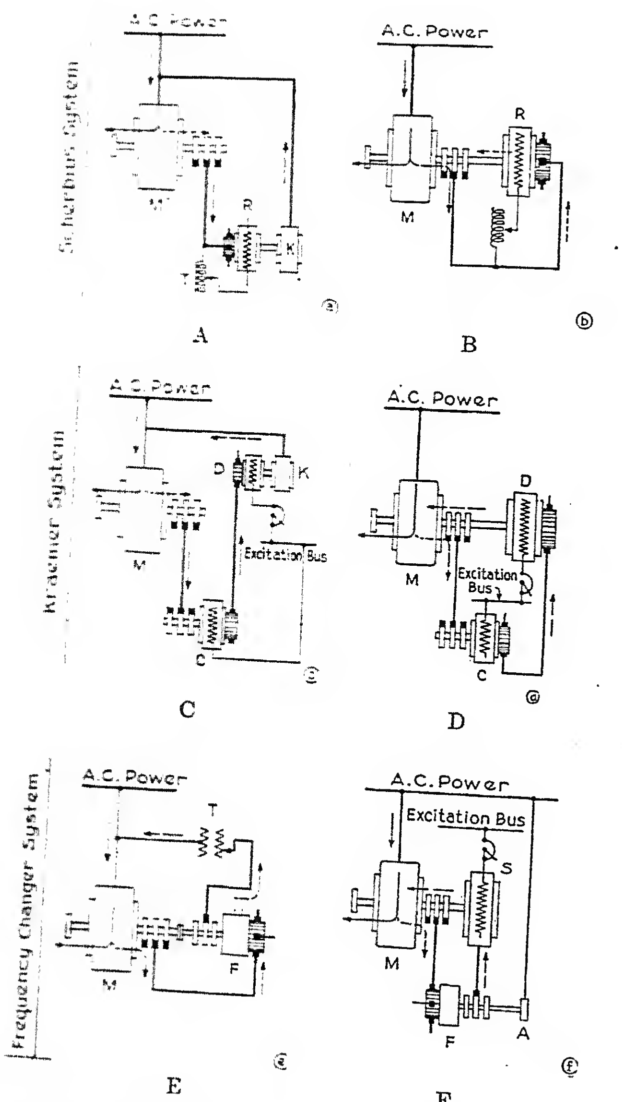

FIG. 6—ELEMENTARY DIAGRAMS OF SEVERAL A-C. ADJUSTABLE SPEED DRIVES

Or, the slip energy may be transformed by means of a frequency converter, F, running at the motor speed, and a regulating transformer, T, Fig. 6E, into line frequency and voltage. Finally, it may be converted suitably by a frequency converter, F, Fig. 6F, separately driven by a small synchronous motor, A, and is then returned as mechanical power to the main shaft by means of a synchronous motor, S; its excitation provides the speed regulating means. Several other schemes, employing a frequency converter, are also conceivable.

Either scheme is capable of regulating the speed of the main motor not only below but also above synchronism, forming a so-called double range drive. Obviously the slip energy is then of a reverse direction; it flows from the regulating machines to the slip-rings, and not from them; the arrows, see Fig. 6, indicating, by dotted lines, the flow of power will have to be reversed. The Scherbius and the frequency converter systems are usually of the double range type; on account of certain difficulties of operating the Kraemer drives close to synchronism (*i. e.* at a very low frequency at the synchronous converter C) and of inability to go through synchronism under load, these drives are usually built as single range equipments, for sub-synchronous operation only.

It will be observed that with all of these schemes the main part of the a-c. power is converted but once until it reaches the mill coupling; only the balance of power or the slip energy goes through more than one transformation before it is utilized. Naturally, the over-all efficiency is higher than with the d-c. drives and is usually around 90 per cent at full load. The machines used for speed regulation should have a capacity depending on the size of the main motor and on the amount of speed range. Therefore, the greater the speed range, the more expensive becomes the a-c. speed regulating equipment, and the less becomes its advantage over a d-c. drive, both from the standpoint of first cost and efficiency. Obviously, with a double-range drive, the same speed regulating equipment is utilized to a greater extent than with a single range drive.

New Combination Drives. While some of the outlined a-c. systems were widely used during the last 10 or 15 years, their application for multi-drive mills, discussed in this paper, gives the engineers an occasional opportunity to get off the beaten track, and to group the well known machines in some new and more advantageous arrangement. The underlying principle of several new combination drives is this:

If the slip energy, contingent on speed regulation of one or several a-c. drives, need not be returned to the shafts of these drives, it may be made use of for furnishing, completely or in part, the power required to drive some other sections of the same mill, or some other mills.

This principle was applied for the first time in 1925 in connection with the equipment shown on Fig. 7, and, to the best of the author's knowledge, it had not been suggested nor applied previously.

This sketch represents a single line diagram of a large continuous rolling mill equipment recently put in operation in the Chicago district. For the sake of simplicity, the switching and control apparatus are not shown. The mill consists of several stands arranged in tandem. The roughing stands were to be driven by one motor *I M*-1 developing 3600 hp. at 290 rev. per min. and 1960 hp. at 156 rev. per min.; the intermediate train was to be driven by another motor, *IM*-2, developing 7500 hp. at 250 rev. per min. and 4040 hp. at 136 rev. per min. The three finishing stands were to be each driven by a 2000-hp. motor, developing this capacity at any speed from 85 to 165 rev. per min. A set of edging rolls required a 250-hp. drive. The electric power was available at 2200 volts, three-phase, 60-cycle.

The electrical engineers have solved the problem

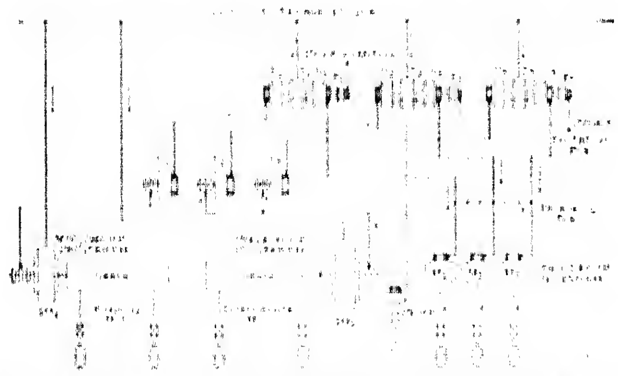

FIG. 7—ELECTRICAL ARRANGEMENT OF COMBINATION A-C. AND D-C. DRIVES FOR A LARGE CONTINUOUS MILL

The total continuous capacity of the equipment is 17,350 hp.

of selecting the drives for this mill in the following manner.

The 3600-hp. and 7500-hp. drives, being large units running at reasonably high speeds, could be economically designed as induction motors, with speed adjusted by the Kraemer method. The finishing mill drives, smaller in capacity and much lower in speed, could be more advantageously and more compactly built as 600-volt, d-c. motors, with speed adjustment by motor field control. The power to these motors is furnished from three 1700-kw. 600-rev. per min., d-c. generators, *G*1, *G*2, and *G*3, driven by synchronous motors, *S*1, *S*2, and *S*3. Low-speed, 60-cycle induction motors for driving the three finishing mills would be expensive machines with a rather poor power factor; the use of reduction gears would not be very advantageous, nor feasible, due to certain local conditions.

It will be observed that the 3600-hp. induction motor, *IM*-1, when running at 156 rev. per min. (*i. e.*, at 52 per cent synchronous speed), is required to develop only 1960 hp. as mechanical power at its shaft; the other 48 per cent or 1640 hp. are available as slip energy. The latter is converted by means of the synchronous converter, *C*1, into d-c. power and drives a d-c. machine, *D*1, as a motor. The excitation of the latter determines its voltage and, therefore, the speed of the drive *IM*-1.

Likewise, the 7500-hp. motor, running at 136 rev. per min. or 52 per cent synchronous speed, delivers to the mill 4040 hp., while the available slip energy amounts to 3460 hp. It is converted to direct current by means of two synchronous converters, *C*2 and *C*3, duplicates of *C*1, and is used for driving the d-c. machines, *D*2 and *D*3, as motors; by changing simultaneously the excitation of *D*2 and *D*3 the speed of the drive *IM*-2 is adjusted.

As the maximum amount of the slip energy to be handled by each of the machines *D*1, *D*2, and *D*3 is approximately 1750 hp., they are made exact duplicates of the 1700-kw. generators, *G*1, *G*2, and *G*3.

Arrows on Fig. 7 indicate the flow of power when the entire mill is in operation. It will be seen that the machines, *D*, are running as motors and are assisting the synchronous motors, *S*, in driving the generators, *G*. This assistance is the greater, of course, the lower the speed of the drives *I M*-1 and *I M*-2; if this speed is close to synchronism, or if the load on the drives *I M*-1 and *I M*-2 is relatively light, then the synchronous motors are more heavily loaded. In the extreme case they should be capable of furnishing the total power required by the generators and cover the friction and windage of the machines, *D*. In other words, the synchronous motors need be only 50 per cent of the capacity required for a three-unit motor-generator set of the same d-c. rating.

Ordinarily, the motors, *S*, would be running underloaded, providing an additional amount of leading kilovolt-amperes, and compensating for the reactive kilovolt-amperes of the large induction motors. The power factor of the whole installation is approximately 97 per cent leading at full load.

Thus the slip energy of the constant torque drives *I M*-1 and *I M*-2 is not returned mechanically to the shaft of these drives where it was not required in this case, nor is it returned electrically to the power bus. Instead of this, it is made use of in a more direct manner; namely, for driving the finishing mills. The over-all efficiency is improved and the required capacity of the regulating apparatus is reduced to a minimum.

The drive just described possesses a number of secondary advantageous points, although these are not directly connected with the new principle of utilizing the slip energy. For instance, in case of light loads, it is possible to operate the drive *I M*-2 with only one synchronous converter and one d-c. motor, say with *C* 2 and *D* 2, and to operate the three d-c. motors *M* 1, *M* 2, and *M* 3 from only two generators, say *G* 1 and *G* 2, by using the paralleling bus. This will

permit the shutting down of one motor-generator set, thereby reducing the running light losses. Although it is hard to estimate with any degree of accuracy the resultant saving in power, it is evident that any such saving is a net gain. It may be truly said in this connection that in steel mill drives, which are usually liberally motored to take care of the maximum load conditions, the low running light losses are just as big a factor in conservation of power as the high efficiency.

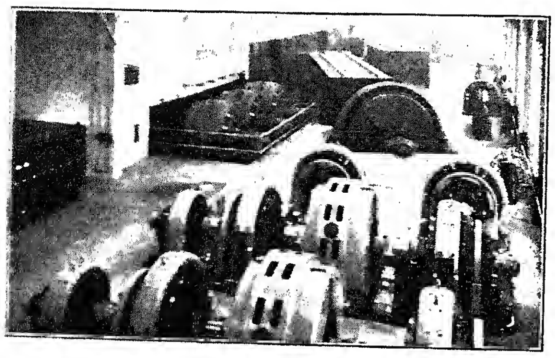

FIG. 8—GENERAL VIEW OF THE MILL MOTOR ROOM CONTAINING THE ELECTRICAL EQUIPMENT ARRANGED AS SHOWN ON FIG. 7

Two out of three synchronous motor generator sets and two synchronous converters are seen in the foreground; three 2000-hp., d-c. motors are located next to the wall, with the 7500-hp. Kraemer drive seen to the right of them. The 3600-hp. Kraemer drive is located back of the gear cases and is not shown on the photograph

The motor room of the mill just described is illustrated by Figs. 8 and 9.

Another continuous mill, now being built for a large eastern steel manufacturer, will be equipped with electric drives embodying to a smaller extent the same

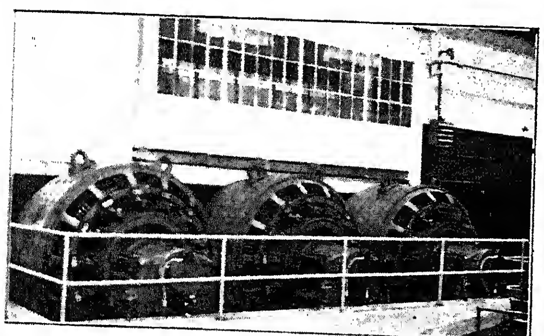

FIG. 9—CLOSE-UP VIEW SHOWING THREE 2000-HP., D-C. MOTORS, EACH DRIVING A FINISHING STAND OF A CONTINUOUS MILL

See Figs. 7 and 8

principle; several new features of a different nature will make a brief review of this equipment rather interesting.

In this case the mill will have a number of stands arranged in tandem, as shown diagrammatically on Fig. 10. The rolling requirements being different, the first several stands will be driven by constant speed motors. The power supply is 6600-volt, 25-cycle.

The roughing train will take a 4000-hp., 83.3-rev. per min. motor, *A*, the intermediate train will be driven by a 6500-hp., 187.5-rev. per min. motor, *B*. The following group of stands will be jointly driven through a train of gears by an adjustable speed equipment, *C*, developing 6700 hp. at 500 rev. per min. and 3350 hp. at 250 rev. per min.

The last finishing stand will take a separate direct-connected drive, *D*, with an output of 2600 hp. at a speed of 275 rev. per min.; constant horsepower output will be maintained for speeds above 275 rev. per min., and reduced output on constant torque basis, for speeds below this value.

These drives will never be required to start their respective mills with metal in the rolls. Mill friction on a cold winter day, after a prolonged shut-down, would be the most severe starting condition. Several tests have shown that a torque of about 25 or 30 per

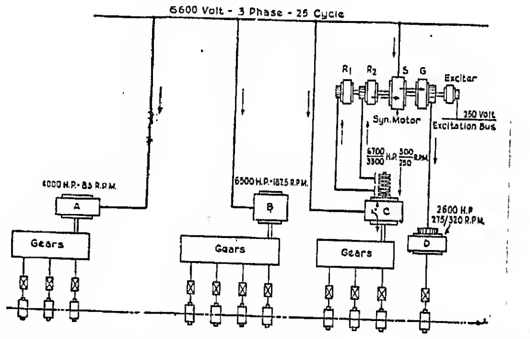

FIG. 10—ARRANGEMENT OF ELECTRIC DRIVES FOR A LARGE CONTINUOUS MILL

Two synchronous motors, one Scherbius equipment and one d-c. motor aggregating approximately 20,000 hp. continuous capacity will be used for driving this mill

cent normal will start a continuous mill under most adverse conditions.

Actual experience with a 9000-hp., 107- rev. per min., synchronous motor, driving since the summer of 1926 a large continuous rolling mill at the McKinney Steel Company, Cleveland, Ohio, has proved conclusively that a synchronous drive is quite applicable for mills of this nature. This synchronous motor, shown on Fig. 11, is capable of developing a starting torque of 265 per cent normal if started on full voltage; it is usually started on a low voltage tap of an auto-transformer, developing the starting torque actually required with considerably less than normal line kilo-volt-ampere input.

Under circumstances it has been decided to build the drives *A* and *B* as synchronous motors and to take advantage of their leading kilovolt-amperes for power factor correction of the steel plant.

The large adjustable speed drive, *C*, will consist of a 5000-hp., 375-rev. per min. slip-ring induction motor, the speed of which will be adjusted up to 33 per cent above, and up to 33 per cent below, synchronism

(*i. e.*, from 500 rev. per min. to 250 rev. per min.) by means of the two Scherbius regulating machines *R* 1 and *R* 2. With this constant torque layout, the capacity of the drive will be 6700 hp. at 500 rev. per min. and 3300 hp. at 250 rev. per min. An a-c. drive of such capacity and speed can be built more economically and with a much higher efficiency than any combination of d-c. machines. The fact that the power supply was 25-cycle gave the Scherbius system an advantage over the Kraemer drive.

The last finishing mill drive, *D*, will have a wider speed range, is of smaller capacity, and runs at a lower speed than the drive *C*. While a Scherbius equipment for the drive, *D*, would be fully competitive in first

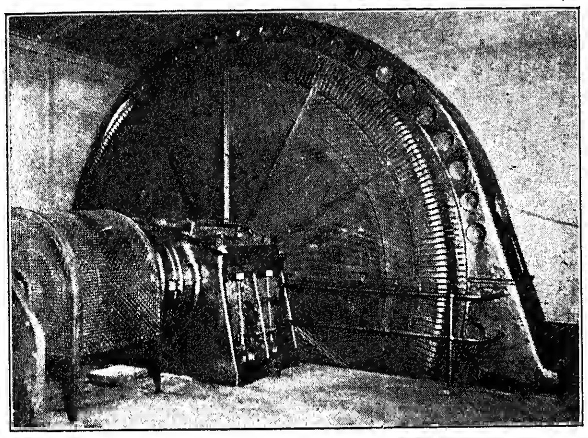

Fig. 11—9000-Hp.-107, Rev. Per Min. 6600-Volt, 25-Cycle, Synchronous Motor Driving a Large Continuous Rolling Mill

cost, the difference between it and that of a d-c. drive was not as wide as in the case of the drive *C*. For the sake of greater flexibility of control it was decided to make the drive *D* of the d-c. type.

A 500-rev. per min. synchronous motor, *S*, will drive a 2300-kw., d-c. generator *G* (furnishing power to the motor *D*) and the two 650-kv-a. Scherbius speed regulating machines *R* 1 and *R* 2 used for adjusting the speed of the induction motor *C*. When the motor *C* runs below its synchronous speed, the slip energy flows to the machines *R* 1 and *R* 2; the latter run as motors and assist the synchronous motor *S* in driving the generator *G*. In other words, the slip energy does not have to be returned as electric power to the incoming line; instead of this, it may be used for driving, wholly or in part, the finishing mill *D*. The flow of power is indicated by arrows. This is another application of the same principle which was illustrated on Fig. 7.

When the drive *C* is running above synchronism, the slip energy becomes negative and arrows shown by the dotted lines, see Fig. 11, will be reversed. The machines *R* 1 and *R* 2 act then as generators, and derive their power from the synchronous motor *S*.

A direct-connected exciter provides the necessary 250-volt excitation to the synchronous motors *A*, *B*, and *S*, and to the d-c. machines *G* and *D*.

The use of two regulating machines *R* 1 and *R* 2 for controlling the speed of the motor *C* presents some interesting features. The maximum amount of the slip energy to be handled by the speed regulating equipment is 1700-hp.; it is not practicable to build an a-c. commutator machine of such capacity and to run at 500 rev. per min.; a lower speed like 375 rev. per min. or 300 rev. per min. would be required. With the proposed layout such reduced speed would considerably increase the cost of the d-c. generator *G* and of the motor *S*. It would be still more expensive to provide a separate low speed drive for the regulating machines *R* 1 and *R* 2, and to drive the generator *G* by another 500-rev. per min. motor. It was quite advantageous, therefore, to split the capacity of the regulating equipment in two units and to run them at 500 rev. per min.

The connections of the regulating machines to the secondary winding of the induction motor are shown on the Fig. 12. The 5000-hp. motor is equipped with six slip-rings, with both ends of each phase of the rotor

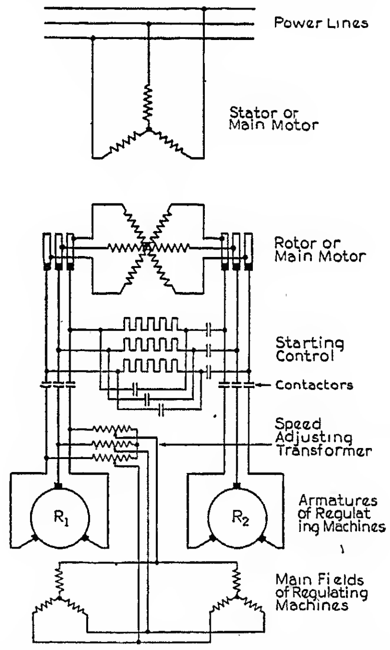

Fig. 12—Elementary Diagram of Electrical Connections of a Scherbius Adjustable Speed Drive with Two Regulating Machines Connected in Series

brought out. Each set of three slip-rings is connected electrically to the commutator of the regulating machines *R* 1 and *R* 2, which thus forms the two Y-points of the secondary circuit. In other words, the two machines *R* 1 and *R* 2 act as if they were connected in series with each other, their e. m. fs. added together. The shunt fields *F* 1 and *F* 2 are adjusted simultaneously by a common speed control apparatus.

By disconnecting one regulating machine and by short-circuiting the corresponding set of slip-rings, it is still possible to operate the drive with the other regulating machine; full torque of the drive will be obtainable, but the speed range will be cut in half;

i. e., it will be in this case approximately 312/437 rev. per min.

Conclusion

None of the several electrical layouts described on the preceding pages should be considered as anything more than what they were originally intended for:—a good combination of electrical machines to fit a set of given requirements. Certain principles may be used again in some future drives; the whole combination may never be repeated. Electric drives for modern large rolling mills can hardly be standardized. They rather are and may rightly be called "custom made."

Many single mills require up to, or over, 20,000 hp. in electric drives; investment runs into several hundred thousands of dollars; the cost of power consumed in a year may approach the same figure. This alone justifies a thorough engineering study and a preparation of an individual layout for each case. Machines of special design need not necessarily be built for any new drive, but there is usually a broad field for working up a good new combination of apparatus.

It was the author's intention to point out, by means of the several illustrated schemes, that such an opportunity is present in most cases and that the electrical engineers seldom let such opportunities slip by.

Discussion

D. M. Petty: In reading the introduction to this paper, I noted that there was just one rather important point which Mr. Umansky did not cover. I think it is a rather vital point and is becoming more vital every day. That is, the relation of the power generated in steel plants to that which is purchased. A number of steel plants are making it a point to buy a certain proportion of their power and with the advent of interconnections of large power companies, I think the interchanging of power between steel companies and power companies becomes increasingly important. The power companies themselves, naturally, having a wider range of load, are now able to absorb waste-gas and waste-heat energy better than they otherwise could have done had their system been limited to a small territory, it being understood, of course, that the steel plant has this power available as a by-product.

Immediately I imagine the problem arises in the minds of a good many of the central station men that most steel plants are 25-cycle and the power companies are 60-cycle. This has for a long time apparently offered an almost insurmountable barrier to an interchange of power agreement, but I find in talking to some of the power engineers, that as these super-power systems grow and their lines extend over greater distances, the use of synchronous condensers becomes a considerable factor in the regulation of voltages at different points.

It has occurred to me that possibly some of these synchronous condensers at different points could have a 25-cycle generator connected to the big, 60-cycle synchronous condensers. It might look, in a good many cases, like an exciter connected to the synchronous condenser. However, it might be big enough to provide a means of interchange of power in sufficient quantities to provide for the needs of the steel plant when it wanted to buy power and also to provide an outlet for a maximum amount of power which the steel plant might have available at any particular time in its operations.

The various rolling-mill layouts which Mr. Umansky showed, I think, are very typical of the modern trend of steel-mill design and rolling-mill design. There is just one thought that I should like to mention in this connection, for fear that possibly some one who is not a steel-mill engineer might be a little misled. The big thing in rolling-mill practise is to obtain tonnage from the mill, and, with the various Kraemer and Scherbius drives as illustrated, it must always be borne in mind that the first consideration is that the particular electrical drive to be hooked to the mill must enable the millman to deliver from the mill the maximum amount of tonnage at the lowest possible cost, and cost in a rolling mill hinges almost always around production more than any other factor. So that when you think of cost in a rolling mill, you are almost saying "reliability," since a drive that is not reliable, either because of complications or anything else, would immediately run the cost up by virtue of the fact that it would reduce the tonnage. The actual dollars and cents expended on labor and material in repairs might be negligible but the reduction in tonnage would be a serious matter. So that while we like to feel that we are going after all the efficiency we can get in mill drives, we should not hesitate to throw out 3 or 4 per cent of efficiency if there was a thought that a d-c. drive might produce more tonnage on a mill than either a Kraemer or a Scherbius or any other system of a-c. drive. In other words, production is the most important factor, especially where the product of the mill is not determined at the time it is laid out.

Of course, if it is known beforehand that the mill is never going to roll anything else but a particular product, it is comparatively easy to make the layout. So that while we want to do everything we can to make the drives more efficient, the big point is always reliability and flexibility, whenever flexibility means more tonnage. That, to my mind, is the big factor in the matter of drives.

I wish also to emphasize further the point that you cannot say that one drive, because it has worked out excellently in one mill, will always work out so well in the next mill. Each mill must necessarily be laid out for itself and for the purposes which the product of the mill demands. In some cases two mills may look alike in the number of stands, but the product may be different and consequently it may be necessary to have an entirely different type of drive. I feel that that particular point is one of the best points brought out by Mr. Umansky.

A. J. Standing: The mills should be so designed that the mill layout may not be the limiting factor; in other words, the mill shall be so laid out from the heating and the furnace end of it that steel can be delivered to the drive as fast as the drive can roll it, and that, at the other end of the drive, steel can be taken care of at the finishing and disposal end fast enough to take care of the drive. The reason I mention this is because oftentimes the mill is laid out for the production of one product, and later we find that the mill has undergone considerable change from the time when original product was got out. So that in

putting a drive on a mill, the past experience has a great deal of weight due to the fact that information has been obtained as to the speed with which we can handle steel both before it enters the drive and especially after it leaves the mill. With that in view, I think the steel manufacturers each year are gaining more experience with various installations so that those who are installing electrical drives from now on will be able to profit by the actual applications and the improvements which have been made in the tonnages, especially from the standpoint of cost per ton.

R. H. Wright: Under present-day business conditions, it is essential that any organization, to be successful, must be quick to adopt new methods and equipment. Steel plant engineers and executives for years have been pioneers in the application of electrical equipment to heavy mechanical operations and, through continual expansion of their electrical power systems, they have effected great economies of operation.

One of the chief advantages of the electric motor drive in the steel industry, in addition to the inherent economy, is the extreme flexibility and the ease with which it can be applied to new processes and labor-saving devices. Through liberal use of electric motors and automatic control in the modern steel plant, the output per man has been increased many times and the accident hazard reduced to a minimum. That the advantages of electrification can be obtained without sacrificing plant production during installation of new equipment is illustrated by a project recently completed in the Philadelphia district. All the steam engines in this plant were replaced by electric drives operating on purchased power in less than three years with no appreciable loss in production during the change-over period. The saving in power cost and operating labor will, in three years, cover the cost of the installation.

To meet the peculiar needs in the industry, the electrical manufacturers have developed complete lines of equipment for steel mill service. One of the first main-roll drives was a reversing motor, installed twenty years ago to drive a plate mill. Since the initial installation reversing motors have been increasing in size until units rated 7000 hp. at 50 rev. per min. are now quite common and one motor has been built for 8000 hp. at 40 rev. per min.

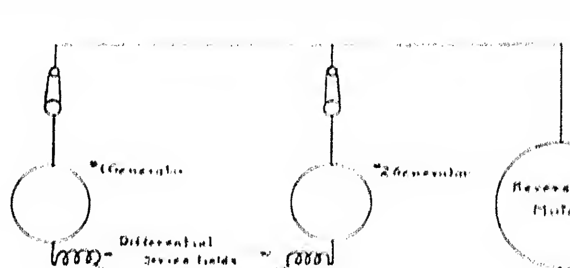
Up to a few years ago all reversing motors above 5000-hp. rating were built with two armatures on a common shaft. Direct current power was supplied to the motor through a motor-generator set having two generators. In order to keep the voltage to ground from exceeding the potential of one generator, a sandwich scheme of electrical connections was employed in the circuit between the generator armatures and the double-armature motor. Motor-generator sets with two generators are used with the more recent equipments, but the double-unit armature construction of the motors has been abandoned, and one 8000-hp. and six 7000 hp. motors have been built with single-unit armatures by the Westinghouse Company.

It will be obvious that the single-unit motor has one-half the armature end windings of a double-unit motor of the same rating and diameter and that the number of cross connections for the commutating pole and compensating windings is also reduced to half that required for a double-unit motor. The copper loss of the single-unit motor is therefore about 25 per cent less than the copper loss of a double-unit motor of the same rating and the efficiency is higher.

When two generators are used in the motor-generator set they are connected in parallel. Equal division of the rapidly varying load to which such generators are subjected is obtained by means of special field connections. As shown in the accompanying figure, each generator has a differential series winding and a cumulative series winding. These windings are identical and under balanced load conditions, they neutralize each other. However, if No. 1 generator, for example, should tend to take more than its share of the load, the differential series field of the No. 1 generator would be stronger than the cumulative series field and the voltage; consequently, the load on the No. 1 generator would be reduced. At the same time, the excess of current from the No. 1 generator would strengthen the cumulative winding of the No. 2 generator, causing it to take more load. Any tendency for unequal division of load is therefore corrected very quickly.

W. E. Lloyd: I should like to include one question. How is it controlled? Do you have a dozen men or one man with a push button?

L. A. Umansky: This paper was not intended to cover the very interesting point just brought up by Mr. Petty; namely, the interchange of power between the steel plants and the public utilities. It is very fortunate, however, that this problem has been mentioned here as it is a very vital one and will undoubtedly grow in importance as time goes on. Whenever the steel plant operates at a frequency of 25 cycles, while the purchased power is available at 60 cycles, the two systems will be undoubtedly tied-in by means of special frequency-changer sets. Their purpose will be not only to convert the 60-cycle to 25-cycle power, or vice versa, but also to *control* the flow of power between the two systems. It means that while one unit, presumably at the 60-cycle end of the set, will be of a synchronous type, the 25-cycle unit is likely to be an induction motor with a speed-regulating equipment attached to it. The latter may be similar



to the Scherbius, Kraemer, or similar systems outlined in this paper. The actual speed of the frequency-changer set is not changed as long as the frequencies remain fixed, but, by controlling the frequency applied to the secondary circuit of the induction machine, the latter may be given a tendency to operate either as a motor or as a generator; in this manner the interchange of power between the two systems may be readily controlled. The synchronous motor of the set, if suitably designed, may also act as a synchronous condenser on the 60-cycle line.

We all agree with Mr. Petty that the question of reliability and flexibility is just as important in selecting electric drives for rolling mills as is the question of efficiency. So many of both a-c. and d-c. drives are in successful operation for many years that their reliability certainly should be considered on a par.

No reversing drives were mentioned in my discussion as there were no radical changes made in this line for the last ten or fifteen years. Many details were undoubtedly improved, as pointed out by Mr. Wright, but the method of operation of the machines remains substantially unchanged. A single-unit armature of a, say, 7000-hp. reversing motor, is an improvement of size rather than of kind. When two generators are supplying power to a single-armature reversing motor, means should be provided, of course, to divide the load automatically and evenly between the two generators. The scheme mentioned by Mr. Wright is very effective for this purpose; as a matter of fact, the same scheme is used for a number of years on the double-unit, d-c. motors shown on Figs. 3 and 4 of my paper. It should be borne in mind, however, that if we equip each of the two machines with two

series fields, one cumulative and one differential, then the load balance is maintained at the expense of crowding the main poles of the machine with a double amount of series field turns; the latter carry the full current but, in the ideal case, do not produce any flux. In other words, the balance is obtained magnetically and not electrically. By causing the current to circulate through two series fields, the copper losses are increased and the efficiency is, therefore, reduced.

The reversing drives usually give an excellent opportunity to apply a simpler but an equally effective scheme which, at the same time, is devoid of the above shortcoming. A relatively small potential winding may be mounted on the main poles of each generator and these auxiliary fields of the two machines are then connected in series with each other. They are so wired that, when one of them acts cumulatively with the main field of its generator, the other auxiliary winding acts differentially with the main field of the second generator. The free ends of the auxiliary fields are connected to terminals of the two generators of the same polarity. The current of each generator is carried separately to the reversing motor, where the two circuits are joined together. When the load is evenly divided between the two generators the IR drop in each circuit is equal and, therefore, no current is flowing through the auxiliary fields. If, for any reason, one generator carries less than its proper share of the load, the IR drops in the two circuits will differ and therefore a current will flow through the auxiliary fields, strengthening the main field of this particular generator and weakening the field of the second generator, thereby re-establishing the balance. It will be seen that the results are obtained directly by means of an electrical balance; in other words, the auxiliary field does not carry any current in case the load is evenly divided. The copper losses are lower than in the scheme described by Mr. Wright and the main poles are less crowded.

This scheme has been in successful operation for a number of years. It will be of interest to note that just a few days ago a large rolling mill was started at the Lackawanna Plant of the Bethlehem Steel Company. This mill includes five reversing drives, of which three are 7000-hp., single-armature motors, each furnished with power from two generators connected in multiple. The division of load is load is maintained in a perfect manner by means of the scheme just described.

Once the reversing drives are discussed, I wish to mention one other point which may eventually change in one respect the conventional form of these equipments. It has been commonly understood that any reversing drive requires a motor-generator set equipped with a heavy flywheel to equalize the load on the incoming line. This is still true for the larger reversing drives, but, as the power systems grow, the question of limiting the instantaneous peak load will acquire relatively less importance. Just recently, a reversing drive which will include a synchronous motor-generator set was ordered. The power in this case was purchased from a public utility and the question was put squarely before the power company: Did it prefer to take on its system a heavier instantaneous peak load, not smoothed out by any flywheel, or to reduce this peak load and contend with the lagging power factor of the induction-motor-driven set. The answer was in favor of the synchronous motor drive. While this particular reversing drive is of a moderate size, (4200-kv-a. synchronous motor), I believe that it is a forerunner of larger equipments provided with synchronous motor-generator sets. Maybe in ten or fifteen years from now, even the 7000-hp., reversing blooming-mill drives will lose one of their typical features,—the flywheel set.

Mr. Lloyd inquired as to how many operators usually control a large continuous mill with individual drives. The motors and the motor-generator sets are usually fully protected by automatic devices, and, strictly speaking, no attendant is required in the motor room. The actual starting speed adjustment and stopping of each drive is controlled by one man in the operating pulpit having within his easy reach the necessary master switches, push buttons, rheostats, etc. One man is usually sufficient to do this work; a second man would be comparatively useless.

Notes on the Use of a Radio Frequency Voltmeter

BY W. N. GOODWIN, Jr.[1]

Fellow, A. I. E. E.

Synopsis. *A thermovoltmeter having a special form of shielding, for use in the accurate measurement of voltage at radio frequencies was described in 1924 in a paper by Mr. Leon T. Wilson. This instrument has since been developed into a commercial form, and this paper describes the technique for using it in a few of its practical applications.*

The voltmeter correctly indicates the voltage at its terminals for any frequency up to about [illegible] kilocycles. For low frequencies the instrument is used exactly as an ordinary voltmeter. For high frequencies, it is necessary to pay especial attention to the external connections, in order that the voltage desired to be measured shall be applied unchanged to the voltmeter binding posts.

Methods are described for measuring the radio frequency resistance and inductance of coils, and for establishing a definite voltage across a circuit such as the input circuit of an amplifier.

* * * * *

AT the Midwinter Convention held in Philadelphia, Feb. 1924, Mr. Leon T. Wilson described a specially shielded voltmeter designed for the measurement of voltages at radio frequencies. A detailed description of the instrument will not be repeated at this time, as this was quite fully covered by Mr. Wilson in his paper, except to state that it is a thermocouple type voltmeter enclosed in a metal shield formed in two halves, insulated from each other. The movement and couple are placed between the two shields, symmetrical with them, and the resistor is divided in two parts, symmetrically disposed, one on each side of the movement. The two terminals are connected directly to the shields, one to each.

The complete voltmeter is illustrated in Fig. 1, and the arrangement of parts in Fig. 2. Briefly, the principle of the shielding is as follows: The thermocouple circuit and d-c. movement, in which it is desired that no alternating current shall flow, are placed exactly midway between the two shields, so that the values of their electrostatic capacities to both shields are equal.

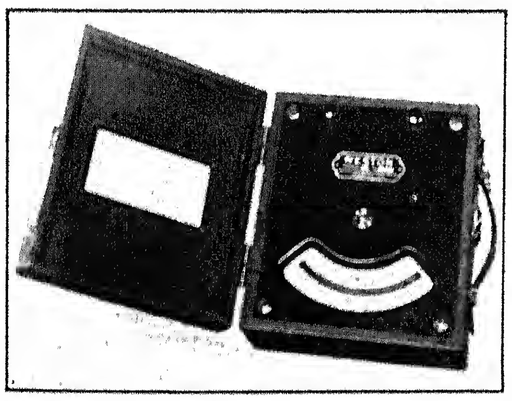


FIG. 1 THERMO-VOLTMETER

The resistors, in two halves, also have equal electrostatic capacities with their corresponding parts of the shield. On account of this symmetry, therefore, there is no tendency for the alternating current to pass from the heating wire through the couple into the movable coil, which is the cause of errors in voltmeters not provided with this form of shield.

This type of voltmeter is used in a manner very similar to the ordinary low-frequency voltmeter, and since it requires current for its operation, is subject to

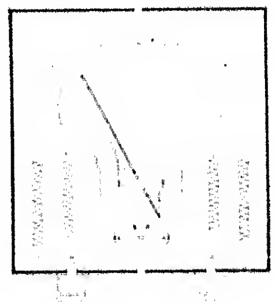

FIG. 2

the same limitations; that is, it will not give correct indications of voltage in a circuit if the current drawn from that circuit for the instrument appreciably affects the voltage to be measured. The current required varies from two to eight milliamperes, depending upon the range of the instrument. In addition to this operating current, there is also the charging current for the shields, which form the plates of a condenser in parallel to the instrument circuit. This current, at a frequency of 1000 kc., is of the same order of magnitude as the current in the instrument circuit, but it is in quadrature with it.

In using the voltmeter for direct current or alternating current of low frequencies, it is used in exactly the same manner as an ordinary voltmeter. For high-frequency measurements, however, while the principle of the measurement is the same as for low frequency, there is a definite technique which must be followed in order that the voltage at the binding posts of the instrument will be the value desired to be measured, and not the resultant of this voltage and those of mutual and self-inductance in the connections and the effects of capacity. A few examples will be given to illustrate the technique.

1. Chief Electrical Engineer, Weston Electrical Instrument Corp., Newark, N. J.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

To Measure the Effective Resistance and Inductance of a Coil

The method used is the usual voltmeter-ammeter method in which the resistance is measured by the drop across it produced by a measured current.

The connections are made as shown in Fig. 3. The coil D, the resistance of which is to be measured, is connected in series with a condenser C_2, having a negligible or known loss and a thermomilliammeter A_2. The circuit thus formed is connected across the non-inductive resistance R at the points $E_1 E_2$. The point E_2 should be carefully grounded and the shielded side of the condenser C_2 connected to the milliammeter, which is in the grounded side. The resistor R and connections should all be short, especially the connection between B_2 and the condenser C_2, as this is the only part of the circuit at relatively high potential. This connection should preferably be suspended, together with the coil, away from all dielectrics except air, in order to prevent any losses being added to those of the coil being measured. The voltmeter V_M must be connected with short leads directly at the points $E_1 E_2$ where the measuring circuit is connected to the resistance R.

Current is supplied at the frequency desired from an

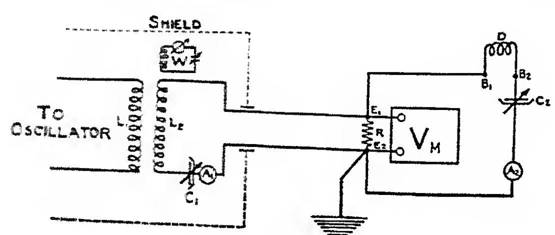

Fig. 3

oscillator, either shielded or placed at a considerable distance from the measuring circuit and connected by leads placed close together, to avoid mutual inductance effects in the measuring circuit. The coil L_2 is loosely coupled to the oscillator coil L_1 and has a tuning condenser C_1 in series with it to adjust the current I_1 in the circuit. The frequency of the oscillator is adjusted by the use of the wavemeter W.

The current I_1 should be 10 or more times greater than I_2, so that the tuning of the two circuits will not materially affect each other. The drop across R then becomes practically equivalent to a non-inductive source of high-frequency voltage for use in the measuring circuit.

To measure the resistance of a coil D, for example, such as is used as a tuning coil for ordinary broadcasting frequencies, the condenser C_2 should have a maximum capacity of about 500 $\mu.\ \mu.$ f., the milliammeter A_2 a range of about 100 milliamperes, the voltmeter V_M a full scale value of about three volts, and the resistor R a resistance of about 1.2 ohms. A very desirable resistor for the purpose may consist of about two inches of manganin, constantan, or other high-resistance wire about 0.0065 in. in diameter.

It is desirable to have a thermoammeter A_1 in the high current circuit, having a range of two or three amperes. An oscillator having two five-watt tubes in parallel will supply sufficient power for this purpose. The oscillator is adjusted to the proper frequency, and then the current I_1 adjusted to one or two amperes by means of the condenser C_1, to give a readable indication on the voltmeter scale. The condenser C_2 is then adjusted until the current I_2, indicated by the milliammeter A_2, is a maximum. It is desirable to use a vernier condenser or vernier attachment on condenser C_2, as the tuning is exceedingly sharp. Under this condition, all self-inductance in the measuring circuit has been neutralized and the resulting current is due solely to the voltage V indicated by the voltmeter and the resistance of the circuit, which is computed in the usual manner by Ohm's law. The coil resistance is then obtained by subtracting from the computed resistance of the entire circuit the known resistance of the milliammeter, and the resistance of the condenser if it is not negligible. It is obvious, of course, that the resistance R is not included in this circuit.

The same setting may be also used to measure the effective inductance of the coil, if the condenser C_2 is a calibrated one. The condenser capacity to give the maximum current I_2 is noted, together with the frequency. Since the inductive and capacity reactances are equal, the inductance is then

$$L = \frac{25.35 \times 10^6}{f^2\, C} \text{ millihenrys,}$$

where f = frequency in kilocycles, and C is the capacity of C_2 in $\mu.\ \mu.$ f.

It has been found, in using the voltmeter for the measurement of resistance, that whereas the voltmeter measures the voltage at its terminals with high accuracy, the final accuracy of the resistance measurement almost wholly depends upon the set-up of the measuring circuit. It must not be concluded that this method or any other method for measuring resistances at radio frequencies is as simple or as accurate as low-frequency measurements, for experience has shown that the best arrangement of circuit is often difficult to determine, and considerable experimental work is necessary to obtain the best results.

The general rules referred to above may be followed but the actual circuit and location of measuring apparatus will depend in each case upon the particular apparatus used. It is advisable to make the "set-up" permanent when the best arrangement has been found. The chief advantage of the voltmeter method is the rapidity with which coils of various types can be compared.

Establishing a Voltage

It is often desired to apply a definite measured high-frequency voltage to the grid circuit of an amplifier or to the primary of a transformer or to some other device. The voltmeter operates very satisfactory for this purpose by simply connecting it across the input circuit between the points where the voltage is to be established.

Limitations of Use and Accuracy

The voltmeter is limited at high frequencies to measurements of voltage in continuous wave circuits and to frequencies up to about 1500 kc., and where the current required to operate the instrument and its electrostatic capacity do not materially alter the value of the voltage to be measured, which is similar to the limitation under which the ordinary low-frequency voltmeter operates.

It cannot be used, for example, to measure voltages from spark generators, or in continuous wave circuits having large harmonics greatly exceeding 1500 kc., nor can it be used to measure the output voltage of a radio frequency transformer, or coupling coil, or, which is often the same thing, the grid input voltage to an interstage tube of an amplifier, on account of the disturbing effects of operating current and the capacity of the instrument.

The error in the voltmeter due to frequency from 60 cycles to 1000 kc. averages about 0.5 per cent, and to 1500 kc., about one per cent.

Discussion

L. T. Wilson: It has been mentioned that this meter takes from 2 to 8 milliamperes, and that a displacement current flows between the shields of the same order of magnitude. It was not specified in that statement that charging current is of the same order of magnitude as this 2 to 8 milliamperes only at 1,000,000 cycles. Of course, at any frequency lower than that, the charging current is proportionately lower, and down at very low frequencies, it is entirely negligible.

P. A. Borden: Mr. Goodwin states that in using the instrument he has described, it becomes necessary to get the voltage at the terminals of the instrument to be the voltage which it is desired to measure; and in this regard its application does not differ from that of any other voltmeter. To obtain this object he suggests what he has styled a "point source" of voltage, which is very nicely worked out on high frequency circuits. Without having had the opportunity to fully study the circuit, my question in this regard is, can that arrangement be applied to commercial frequencies? If so, it would be very useful in measuring small voltages, and potential differences across circuits where a very small amount of power is available. I refer to circuits where the power consumption of the instrument compared with the power available in the circuit is so great that the ordinary instrument would disturb the value of the quantity under measurement. For example, in the determination of the volt-ampere consumption of the voltage coil of a watthour meter, current and voltage being measured simultaneously, it would be very valuable if the "point source" of voltage could be applied in the measurement.

H. M. Turner: Mr. Goodwin mentioned the fact that it is desirable to have a fairly large ratio between the currents I_1 and I_2 of say 10 to 1. The advantages are that the current amplitudes may be easily controlled by adjusting C, (Fig. 3 of the paper) without changing the oscillator coupling and that when tuning the measuring circuit to resonance the reaction on the oscillator is usually negligible.

I have used this method in the laboratory and find it convenient and satisfactory for measuring circuit constants.

W. N. Goodwin, Jr: Mr. Borden asks whether the "point source" of electromotive force could not also be applied advantageously to low-frequency measurements. What I termed a "point source" of electromotive force was provided as a means for obtaining a source of electromotive force which for all practical purposes was free from inductance. To obtain this at radio frequencies, it was found that the voltage drop across a high-resistance wire of very small dimensions gave the desired results.

On low-frequency circuits a somewhat similar method is often used in practise in which a low voltage is obtained from a higher one by means of the well-known voltage divider. In this case, however, there is no advantage in using what I have termed a "point source," since the ratio of reactance to resistance can readily be made negligible without special reduction in dimensions.

The method described, either for low or for radio frequencies is not intended for the measurement of unknown voltages, but for establishing a voltage for use in measurements. The voltage can, of course, be adjusted to a definite value by knowing the value of the resistance and that of the current passing through it.

I wish to thank Mr. Wilson for calling attention to the fact that the value of the charging current given for the shields is for frequencies of the order of 1,000,000 cycles. This was inadvertently omitted from the text.

Substitution Method for the Determination of Resistance of Inductors and Capacitors at Radio Frequencies

BY C. T. BURKE[1]
Associate, A. I. E. E.

Synopsis.—The use of a series resonant circuit for the measurement of the resistance of coils and capacitors at high frequencies is described. The circuit is tuned with the unknown in circuit and with it removed, introducing sufficient resistance to keep the current constant. From the condition of constant current, and the circuit constants, the constants of the unknown are derived. The derivation of the expression for the resistance of a capacitor involves certain assumptions which are shown to be justified for frequencies at which coils and capacitors are now generally used. Sources of error are pointed out and discussed. In the measurement of resistances of the order of two ohms and larger, the precision of the method is of the order of one per cent. A change of circuit resistance of approximately 0.02 ohm can be measured.

* * * * *

THE measurement at radio frequency of the resistance of coils and capacities has presented some difficulty. A number of methods has been proposed, but most of them have been rather elaborate and some have involved quite formidable complications. The method to be described does not involve any new principle, and is, in fact, rather obvious. It possesses a simplicity which makes it compare most favorably with many of the schemes heretofore proposed, and renders it deserving of more attention than it has received. While it does not pretend to hair-splitting exactitude, its precision, if the system is constructed with reasonable care, is equal to the requirements of a vast number of factory and research requirements. It also possesses the advantage that the sources of error are known, and most of them can be reduced to almost any degree required for precision work if the necessary precautions are taken.

The measuring circuit consists of a simple series circuit containing inductance, capacitance, and resistance, and a current indicator. This circuit is coupled to the output coil of a radio frequency oscillator of suitable frequency range. Provision is made for connecting the inductor to be measured in series in this circuit. Capacitors under measurement are connected in parallel with the test capacitor. While the absolute value of the measurement may be questioned, the method is of great value in determining the relative efficiency of coils and condensers, which is in many cases of more interest than the actual resistance. Using the set-up described, changes in circuit resistance of the order of 0.02 ohm can be detected. This permits the measurement of coil resistance of the order of one ohm with fair accuracy, and of resistances of two ohms and over to one per cent.

High Frequency Measurement of Inductors

In the measurement of inductors, the unknown inductor is connected at L_x and the variable resistance set at zero. The measuring circuit is tuned to resonance with the oscillator, adjusting the coupling to give a convenient reading on the current-indicating device. Then

$$I = \frac{j\, \omega\, M\, I_0}{Z}$$

L_x is removed, a short-circuiting plug substituted, and the circuit retuned to resonance. Adjusting R until the current is reduced to its former value, it follows that

$$Z_1 = Z_2$$

This assumes: (1) the current in the oscillator is constant; (2) the coupling between the circuits is not

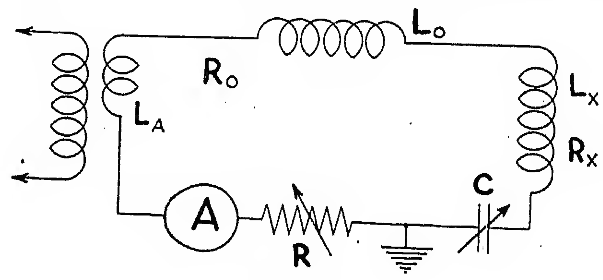

Fig. 1

changed. The first of these conditions is readily obtainable. The realization of the second requires sufficient spacing between the coil under measurement and the oscillator to prevent appreciable coupling between them. Stray coupling between the oscillator and the load coil is of no consequence, as no change is made in this portion of the circuit during the measurement. All question on this point can be removed, where the precision required justifies it, by means of suitable shielding.

$$Z_1 = R_0 + R_x + R_{c1} + j\, \omega \left(L_A + L_0 + L_x - \frac{1}{\omega^2\, C_1} \right)$$

$$Z_2 = R_0 + R + R_{c2} + j\, \omega \left(L_A + L_0 - \frac{1}{\omega^2\, C_2} \right)$$

At resonance

$$L_A + L_0 + L_x - \frac{1}{\omega^2\, C_1} = 0$$

1. General Radio Co., 30 State St., Cambridge, Mass.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

$$L_A + L_0 - \frac{1}{\omega^2 C_2} = 0$$

Hence

$$L_A + L_0 + L_x - \frac{1}{\omega^2 C_1} = L_A + L_0 - \frac{1}{\omega^2 C_2}$$

and

$$L_x = \frac{1}{\omega^2 C_1} - \frac{1}{\omega^2 C_2} = \frac{1}{\omega^2 C_1 C_2}(C_2 - C_1)$$

Likewise

$$R_0 + R_x + R_{c1} = R_0 + R + R_{c2}$$

and

$$R_x = R + R_{c2} - R_{c1}$$

This assumes the variable resistance to be non-reactive.

If the capacitor used for tuning the circuit to resonance has a series resistance which is appreciable in comparison with the coil resistance, a calibration of the equivalent series resistance as a function of the capacitance will be required. A capacitor designed so as to eliminate this complication should be used, however. This is readily accomplished, as the loading coil is so chosen that the capacitor is used near the maximum capacitance where the equivalent series resistance is small. It is possible by means of proper design to reduce the capacitor resistance to the vanishing point. Using a capacitor of such design, it is obvious that the change in resistance disappears.

Therefore:

$$R_x = R$$

Summary of Procedure for Inductance Measurements. With the unknown coil in the circuit, and the loading coil of such inductance as to give a capacitor setting near the maximum capacitance, the circuit is tuned to resonance as indicated by maximum galvanometer reading. The coupling coil is moved so as to give a convenient galvanometer deflection. Removing the unknown coil, the coil mounting is short-circuited and the circuit retuned to resonance and R adjusted until the current equals that obtained on the first reading.

Then

$R_x = R$ (Equivalent series resistance = reading of standard resistance.)

and

$$L_x = \frac{1}{\omega^2 C_1 C_2}(C_2 - C_1)$$

The loading coil should be so chosen as to give a high capacitor reading without the test coil, for two reasons. Not only is the capacitor resistance less at high capacitance settings but the potential of the coil under test with respect to ground is determined principally by the inductance of the loading coil. As the potential of the coil with respect to earth affects its resistance somewhat, it is desirable to have the test coil as near ground potential as possible.

High Frequency Measurement of Capacitors

In the measurement of capacitors, the unknown is connected in parallel with the capacitor of the test set. Sufficient inductance is connected in circuit to give resonance at a rather low value of capacitance. The procedure in measuring is the same as that employed with inductors. The circuit is adjusted to resonance with the unknown connected across the test capacitor, the unknown removed, and the circuit retuned, introducing sufficient resistance after the second tuning to bring the current to its former value.

Again the condition of constant current in the measuring circuit requires constant impedance in the circuit. As all other portions of the circuit are unchanged, it is necessary to consider only the measuring condenser, the unknown condenser, and the variable resistance.

When the test circuit is first adjusted to resonance, this portion of the circuit consists of the standard capacitor, shunted by the capacitor under measurement. After the second adjustment, the impedance consists of the standards capacitor in series with a resistance. Equating the impedances of these two circuits, the

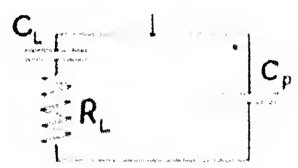

Fig. 2

relation between the resistance added to reduce the current to its first value and the equivalent series resistance of the unknown capacitor may be derived.

In a properly designed capacitor, the dielectric is placed in a constant field, so that the dielectric loss does not vary with setting. It is convenient to represent such a capacitor as a fixed capacitance in series with a fixed resistance, the whole shunted by a perfect variable capacitor; see Fig. 2.

In this circuit, the customary equation for parallel circuits (resultant impedance equals the reciprocal of the sum of the reciprocals) reduces to:

$$Z = \frac{Z_L Z_P}{Z_L + Z_P}$$

where

Z = resultant impedance,
Z_L = impedance of "loss" circuit,
Z_P = impedance of perfect capacitor.

$$Z = \frac{\left(R_L + \frac{1}{j\,\omega\,C_L}\right)\left(\frac{1}{j\,\omega\,C_P}\right)}{R_L + \frac{1}{j\,\omega\,C_L} + \frac{1}{j\,\omega\,C_P}}$$

$$= \frac{-(1 + j\,\omega\,R_L\,C_L)}{R_L\,\omega^2\,C_P\,C_L - j\,\omega\,(C_P + C_L)}$$

Rationalizing and reducing:

$$Z = \frac{R_L\,\omega^2\,C_L^2 - j\,\omega\,[(C_P + C_L) + \omega^2\,R_L^2\,C_P\,C_L^2]}{(R_L\,\omega^2\,C_P\,C_L)^2 + \omega^2\,(C_P + C_L)^2}$$

The order of magnitude of the second term of the reactance under test conditions is 10^{-30}; that of the first term, 10^{-10}. The second term is therefore negligible for values of ω up to 10^{9}.

Taking out ω^2, the first term of the denominator is of the order of $10^{-40}\,\omega^2$, while the second is of the order of 10^{-20}. The first term of the denominator is therefore also negligible for values of ω less than 10^{-9}, and the expression reduces to

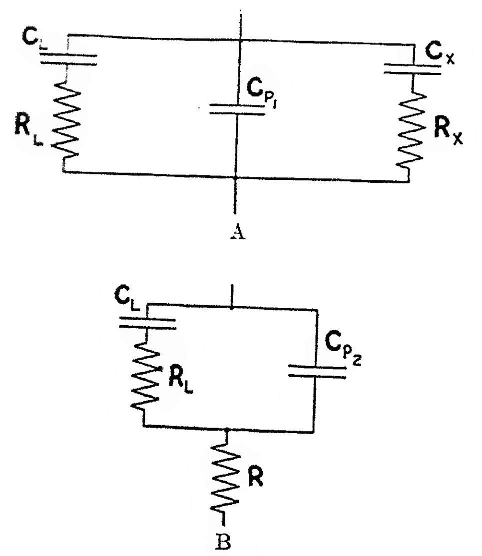

FIG. 3

$$Z = R_L\,\frac{C_L^2}{(C_P + C_L)^2} - \frac{j}{\omega\,(C_P + C_L)}$$

$(C_P + C_L)$ is the total capacitance of the capacitor; therefore, the system is equivalent to a capacitor of capacitance $C = (C_P + C_L)$, and equivalent series resistance $R = R_L\,\dfrac{C_L^2}{C^2}$.

Making use of this convention, Figs. 3A and 3B represent the variable portion of the test circuit at the first and second stages of the measurement. The solution will be simplified by considering the admittances rather than the impedances of these circuits. In the figure:

C_L = imperfect "loss" capacitance of the standard capacitor,
R_L = imperfect "loss" resistance of the standard capacitor,
C_{P1} and C_{P2} = settings of perfect capacitor,
C_x = unknown capacitance,
R_x = equivalent series resistance of the unknown capacitor.

Then

$$Z_L = \sqrt{R_L^2 + \frac{1}{\omega^2\,C_L^2}} \qquad \theta_L = \tan^{-1}\frac{1}{R\,\omega\,C_L}$$

$$Z_P = \frac{1}{\omega^2\,C_P} \qquad \theta_P = \tan^{-1}\infty$$

$$Z_x = \sqrt{R_x^2 + \frac{1}{\omega^2\,C_x^2}} \qquad \theta_x = \tan^{-1}\frac{1}{R\,\omega\,C_x}$$

$$\bar{Z}_L = Z_L\,\epsilon^{j\theta_L} \qquad \bar{Z}_P = Z_P\,\epsilon^{j\theta_P} \qquad \bar{Z}_x = Z_x\,\epsilon^{j\theta_x}$$

The resultant admittance of circuit A is

$$\bar{Y}_A = \frac{1}{Z_L}\,\epsilon^{-j\theta_L} + \frac{1}{Z_P}\,\epsilon^{-j\theta_P} + \frac{1}{Z_x}\,\epsilon^{-j\theta_x}$$

$$= \frac{Z_P\,Z_x\,\epsilon^{-j\theta_L} + Z_L\,Z_x\,\epsilon^{-j\theta_P} + Z_L\,Z_P\,\epsilon^{-j\theta_x}}{Z_L\,Z_P\,Z_x}$$

$$= \frac{1}{Z_L\,Z_P\,Z_x}\,[Z_P\,Z_x\,(\cos\theta_L - j\sin\theta_L) + Z_L\,Z_x\,(\cos\theta_P - j\sin\theta_P) + Z_L\,Z_P\,(\cos\theta_x - j\sin\theta_x)]$$

As the j terms disappear at resonance:

$$\bar{Y}_A = \frac{1}{Z_L\,Z_P\,Z_x}\left[Z_P\,Z_x\,\frac{R_L}{Z_L} + Z_L\,Z_P\,\frac{R_x}{Z_x}\right]$$

$$= \frac{R_L}{Z_L^2} + \frac{R_x}{Z_x^2}$$

$$= \frac{R_L}{R_L^2 + \dfrac{1}{\omega^2\,C_L^2}} + \frac{R_x}{R_x^2 + \dfrac{1}{\omega\,C_x^2}}$$

As the capacitances are of the order of 10^{-10}, and the resistance of the order of unity, the first term of the denominator may be neglected for values of ω up to the order of 10^9.

Therefore:

$$Y_A = R_L\,\omega^2\,C_L^2 + R_x\,\omega^2\,C_x^2$$

In the circuit of Fig. 3B, for the parallel portion as previously developed:

$$Z = R_L\,\frac{C_L^2}{C_{s2}} - \frac{j}{\omega\,C_{s2}}$$

where

$C_{s2} = C_L + C_{P2}$ = total capacitance of standard capacitor.

For the complete circuit:

$$Z_B = R + R_L\,\frac{C_L^2}{C_{s2}^2} - \frac{j}{\omega\,C_{s2}}$$

$$= \frac{\omega\,C_{s2}\left[R + R_L\left(\dfrac{C_L}{C_{s2}}\right)^2\right] - j\,1}{\omega\,C_{s2}}$$

$$Y_n = \frac{1}{Z_n} = \frac{\omega C_{s2}}{\omega C_{s2}\left[R + R_L\left(\frac{C_L}{C_{s2}}\right)^2\right] - j1}$$

$$= \frac{\omega^2 C_{s2}^2\left[R + R_L\left(\frac{C_L}{C_{s2}}\right)^2\right] + j\omega C_{s2}}{\omega^2 C_{s2}^2\left[R + R_L\left(\frac{C_L}{C_{s2}}\right)^2\right]^2 + 1}$$

The first term of the denominator is of the order of 10^{-6}, when ω is less than 10^6.
Therefore:

$$Y_n = \omega^2 C_{s2}^2\left[R + R_L\left(\frac{C_L}{C_{s2}}\right)^2\right] + j\omega C_{s2}$$

At resonance the j term disappears.

For constant current, equal admittances are required.
Therefore

$$R_L \omega^2 C_L^2 + R_x \omega^2 C_x^2 = R\omega^2 C_{s2}^2 + R_L \omega^2 C_L^2$$

or

$$R_x = R\frac{C_{s2}^2}{C_x^2}$$

The capacitance of the unknown is equal, of course, to the change in capacitance, *i. e.*,

$$C_x = C_{s1} - C_{s2}$$

It will be noted that the resistance measurement of capacitors involves the assumption that the field through the solid dielectric does not change with the position of the capacitor plates, a requirement met by any properly designed capacitor for laboratory use, and that the conductive resistance of the capacitor is negligible. The latter requirement may require special construction, especially as the higher frequencies are approached.

As the sensitivity of the measurement depends to a

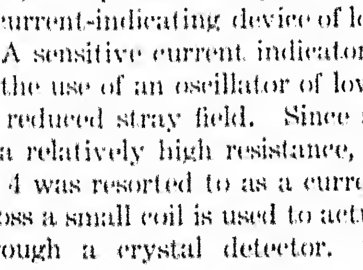

FIG. 4

considerable degree upon the sharpness of resonance of the circuit, a current-indicating device of low resistance is required. A sensitive current indicator is of value as it permits the use of an oscillator of low power, and consequently reduced stray field. Since sensitive a-c. meters have a relatively high resistance, the arrangement on Fig. 4 was resorted to as a current indicator. The drop across a small coil is used to actuate a micro-ammeter through a crystal detector. There is no difficulty in keeping the detector sensitivity constant for the short time required; in fact, the sensitivity of the fixed crystal used is constant over a long period of time.

The actual layout of apparatus used is shown in the reproduction of the photograph. Plug mountings for the loading coil and the unknown inductor were mounted on insulators to reduce the capacitance between the coils and earth. As it is desirable to keep the circuit resistance as low as possible, the jacks were mounted on hard rubber, and the dielectric directly between the jacks was cut away to lengthen the path. The mountings for the two coils were permanently secured about

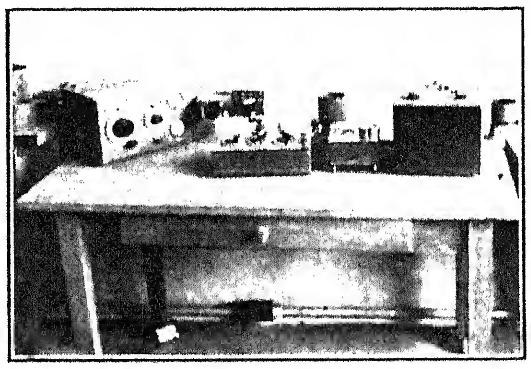

FIG. 5

two feet apart. This distance seems sufficient to eliminate coupling between the coil under measurement and the loading coil or oscillator. The pick-up coil was mounted on a wooden block and connected to the rest of the circuit by means of flexible leads so that the coupling to the oscillator could be conveniently altered. The drop coil and detector were mounted on the side of the galvanometer. The galvanometer used had full scale deflection on 50 microamperes. The pick-up coil was so wound as to have little external field.

The resistance used was one of the standard decade type, using the Ayrtron-Perry type of non-reactive winding. It is probable that this resistance has a slight reactance at the higher radio frequencies and would not be proper for extremely precise work. There is undoubtedly a change in the resistance of these units with frequency. Where the requirements of the work warrant it, the resistance standard should be calibrated at the frequency used.

A special type of capacitor was used. The capacitor was designed so as to permit a very fine adjustment of the capacitance and to have a very low equivalent series resistance.

The main scale in the capacitor is fitted with a vernier, making possible readings to one-tenth of the smallest scale division. A small uncalibrated capacitor is placed across the main capacitor in order to permit setting exactly to resonance. The error of calibration on the main scale due to this capacitor is ordinarily negligible.

A shield was used under the galvanometer and associated apparatus, the resistance, and the standard capacitor. The junction of the standard capacitor and the standard resistor was selected for grounding. It is desirable that one side of the standard and also of the unknown capacitor be grounded. If the junction of the coil and capacitor were grounded, the resistor and meter would be at high potential. As the potential drop through the resistance is small, the junction of the resistor and current indicator could have been grounded with practically identical results. The oscillator is of standard type, using a UV 199 tube and plug-in coils to cover a wide frequency range.

Summary of Procedure for Condenser Measurements. The unknown capacitor is connected in parallel with the standard capacitor, loading coils being used in one or both mountings, and the circuit is tuned to resonance, adjusting the coupling for a convenient galvanometer reading. The unknown capacitor is removed and the circuit is again tuned to resonance, adding resistance to bring the current to its former value.

Then $C_x = C_2 - C_1$

$$R_x = R\frac{C_2^2}{(C_2 - C_1)^2} = R\frac{C_2^2}{C_x^2}$$

Discussion

T. E. Shea: This paper offers an opportunity to call attention to certain equivalent networks, due to Dr. O. J. Zobel, which do not seem to have become generally absorbed into the literature to the extent that they deserve.

In the design of wave filters, of equalizers, or of balancing networks for simulating telephone lines, these equivalents have two values. In the first place, they simplify a great many formulas and give a better picture of what is going on in the circuit. In the second place, more desirable inductance, capacity and resistance values are often obtainable.

Now consider the network represented in Fig. 2 of the present paper. We are all familiar with the various relationships of equivalent T and π networks (for example, those made up of capacities) where there are three terminals for each network. Nobody would ever question, if he had one mesh and it were more convenient to substitute another in a circuit and get a better picture of what was going on or get a more easily calculated circuit, the validity of using the second mesh. If he obtained more desirable capacity values, or a more convenient arrangement of capacities, he might even substitute the one mesh physically in place of the other.

In the case of two-terminal networks, that is, impedances in which there is only one main current path, there is a large number of similar equivalents. In the case of Fig. 2, the corresponding equivalent two-terminal network is in the form of capacity in series with a parallel combination of resistance and capacity. Likewise there are equivalent two-terminal meshes using inductance and resistance, and inductance and capacity, respectively, and for any number of component impedance elements.

If in this present case, for example, one wishes to investigate the matter of selectivity—the change in sensitivity of the device as the frequency is slightly changed—I suggest that it can be done very much more readily by means of equivalent networks, although, of course, the formulas in the paper ultimately simplify down to give the same results.

Two-terminal equivalent networks are discussed in many places in the literature; for example, in Zobel's papers on "Wave Filters," R. S. Hoyt's paper on "Design of Networks to Simulate Smooth Lines," and R. M. Foster's paper on "A Reactance Theorem," and in K. S. Johnson's book "Transmission Circuits for Telephonic Communication."

J. G. Ferguson: I should like to point out the small modification necessary in a circuit of this type to transform it into a bridge network and thus eliminate the necessity of measuring the current in the circuit in order to determine the point of resonance.

In Fig. 1 of the paper, we have a resonant circuit consisting of the three inductances, the variable capacitance, and the variable resistance, all connected in series. In order to measure resistance, as described in the paper, it is necessary to adjust the circuit for resonance. The resistance is determined by adjusting R to give the same current reading with the test coil or condenser in and out of the circuit. The difference in the reading of R then gives the value of resistance required.

Now the e. m. f. applied to this circuit is induced in Coil L_X. If we place across this coil in series, two equal resistances, we do not change the circuit in any way except to introduce a shunt across the generator coil. By connecting a detector from the midpoint of the two added resistances to ground, we transform the circuit into a bridge network, having two equal resistance arms, a third arm containing the resistance R, and a fourth arm containing L_0, L_x, and C in series. If we balance this bridge by adjusting R and C to give zero current through the detector, then L_0 and L_x in series must be in resonance with C, and the total resistance of this arm must be equal to R.

This method is practically identical with the method described, except that it is unnecessary to measure the current, or even to hold it constant. Consequently, we do not have the same requirement of stability in the oscillator.

The general method described is really a substitution one, the assumption being made that the change in the capacitance of C may be made without changing the loss in the circuit. The usual assumption made is that if the dielectric loss is known or negligible, there are no other losses to be considered. However, at radio frequencies this is by no means the case, as in certain designs of capacitors we may have considerable eddy-current loss. Consequently one of the chief limitations of the method is in the determination of the loss in the standard capacitor. Knowing the loss in the standard, the method consists simply of substituting the unknown for the known, keeping other conditions the same and reading the change in the setting of the variable resistor R.

Probably the only absolute way of determining the loss in a standard capacitor is the calorimeter method, and there are so many difficulties to be overcome in a measurement of that type, that a high degree of accuracy can be obtained only by use of extraordinary precautions.

In conclusion, there is just one other point which makes a bridge method preferable to an indicating method. If the detector is a heterodyne type or some type which allows us to discriminate between the frequency at which we wish to make the measurement and other frequencies, it is possible to balance the bridge for one frequency only, that is, for the fundamental. Any indicating method such as described in the paper which is dependent on a current measurement, measures the total current in the circuit including all of the harmonics, and the result obtained becomes a function of wave shape.

A. Nyman: I was rather amused on the question of nomenclature and particularly as applied to condensers. The company I am connected with is making millions of condensers every year, and I believe if we started changing the name to capacitor we would find ourselves in difficulty; people wouldn't know what we were talking about.

In connection with the measurement of condensers in Mr. Burke's paper, particularly at radio frequency, we worked out a method of measuring condensers at radio frequency which I believe is very accurate and quite simple.

The accompanying figure shows the construction of this test set. It consists of two independent oscillating circuits both with adjustable capacities. By arranging the capacities close to the same values, a beat note is formed between the two oscillating circuits, and this beat note can be brought very close to 1000 cycles by introducing in the circuit a 1000-cycle note from a tuning fork. Thus, on the left-hand side of the diagram, a standard condenser is adjusted alone until the 1000-cycle beat note tunes in with the 1000-cycle note from the tuning fork. Then a condenser to be measured is inserted in parallel with the standard and the standard readjusted to get the same condition.

It is of course necessary to watch that this beat note is always on the same side of the resonance curve. This will be the condition if the resonance is always approached from the same side, say, reducing the condenser in each case. Since the frequency of the circuit is now the same as it was before, the total capacity is the same as it was originally.

It has been found that it is possible to gage the frequency of the beat between the two 1000-cycle notes to within one cycle every two or three sec. With a million cycles on each oscillating circuit, this would give an accuracy of comparison of condensers of one in a million. Of course, this accuracy is a good deal higher than is required under any practical circumstances. Moreover, the actual accuracy is limited by the construction of the standard

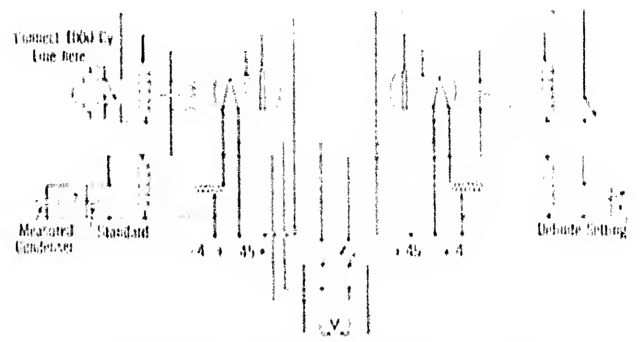

FIG. 1 PRECISION CAPACITY MEASUREMENT

condenser. With a General Radio type 222 standard condenser, this accuracy is not more than one in 25,000.

This method of measurement has been found quite reliable and is not affected by any outside circumstances. Since the two measurements are made on the same oscillating circuit, and the measured condenser is generally considerably smaller than the standard, the load conditions on each tube are practically identical and there is no tendency to upset the frequency relations of the two circuits. Moreover, the coupling between these two circuits is so loose that any change in one circuit does not affect the oscillation in the other circuit until approximate resonance (beat note of about 25 to 60 cycles) is reached. Thus, at the 1000-cycle beat note, the effect of one circuit on the other is entirely negligible.

C. T. Burke: In regard to the points raised by Mr. Ferguson, the condenser is the weakest link in the circuit. We have found in fact that on very high frequencies of the order of 50,000 kilocycles or thereabouts, the use of a condenser of the soldered-plate type does show a noticeable improvement over the usual stacked-plate type.

In connection with the other question as to the effect of harmonics, since this circuit is tuned to the fundamental of the oscillator, the magnitude of harmonics in the circuit should be rather small, and as the actual value of current is not used in the computation but is only used to reset the circuit, harmonics in the circuit should not affect the accuracy of the method unless the magnitude of the harmonic differs between the two tunings, and there does not seem to be any reason for expecting this to occur.

As to the other point raised in the matter of nomenclature, the terms "capacitor" and "condenser" do refer to the same thing.

Condenser Shunt for Measurement
of High-Frequency Currents of Large Magnitude

BY ALEXANDER NYMAN[1]
Member, A. I. E. E.

Synopsis.—*The necessity for an accurate ammeter for large high-frequency currents is pointed out. A new device consisting of a large condenser in parallel with a small condenser, and the latter carrying the current to a small thermocouple ammeter, is described.*

A device of this nature can be made very accurate; in fact, comparable in accuracy to any available standards.

The construction of the device includes provisions for restricting the electrostatic and electromagnetic field, due to large current, the reduction of distributed inductance and capacity, and a provision to prevent the resonance effect of high harmonics of the operating current. Provisions are also made for locating the measuring instrument at a distance from the circuit. Large ratings are possible by connecting a number of condenser blocks in parallel.

THE use of large broadcasting stations and other continuous-wave, high-power installations has created a demand for accurate means of measuring high-frequency current of large magnitude.

The methods so far in use are all limited in one particular or another. The use of the hot-wire expansion type instruments is not feasible for values above 10 amperes, as the size of heating element becomes excessively large and the skin effect does not allow the subdivision of hot wire into parallel elements.

The direct thermocouple type has been used with

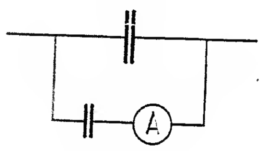

Fig. 1

satisfactory results up to currents over 100 amperes, but the heating element of the higher ranges becomes bulky and expensive to build on account of the large-sized conductors and careful workmanship required. Also the skin effect becomes appreciable at the higher frequencies.

An iron core transformer for reducing the high-frequency current so that it can be applied directly to a small instrument gives satisfactory results for frequencies up to 500 kc. For higher frequencies, the heating of the iron parts of the transformer becomes quite appreciable and is the greatest drawback. At 2000 kc. and above, it is difficult to use such a transformer; the heating of parts, the influence of stray fields, and the distributed capacity of windings become quite objectionable.

This article describes a novel arrangement which will permit the limits of operation to be extended as far as the present art of radio transmission requires.

The advantage of the new condenser type of ammeter for large currents lies in its accuracy and simplicity, combined with its comparatively low cost, even for the highest of frequencies.

Fig. 1 illustrates the method by which currents of large magnitude and high frequency can be satisfactorily measured. It consists in general of two condensers in parallel: a large one which carries the greater portion of the current to be measured, without appreciable voltage drop, and so constructed that it can pass large current at high frequency without appreciable losses; and one considerably smaller, designed to shunt off a predetermined fraction of the total current through a small ammeter, either of the hot-wire or the thermocouple type. In the latter case, the meter may be located at a distance from the main circuit, as illustrated in Fig. 2.

A device of this nature, if properly designed, will give satisfactory measurements of current at frequencies as high as 60,000 kc., which is practically the limit of the present-day operations of radio stations. It can be designed for higher frequencies. The error due to the resistance of the thermocouple element is practically negligible, even at the highest frequencies used. Thus,

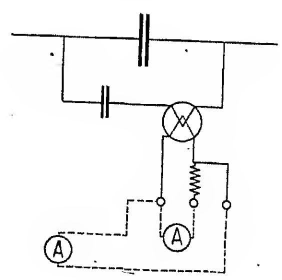

Fig. 2

if the condenser has a capacity of 0.001 μ f. and the thermocouple element has a resistance of 2.6 ohms, the error becomes one-half of one per cent at 6000 kc. (50-meter wavelength). For shorter waves, smaller capacity would be used.

The only source of error actually found in operation is due to the fact that the two condensers and the thermocouple form a closed circuit which has a resonant frequency that sometimes comes within the range of some harmonic of the frequency of operation of the

1. Consulting Engineer, Dubilier Condenser Corporation, New York, N. Y.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

instrument. The presence of such a condition becomes apparent in an obvious irregularity of the meter reading. Fig. 3 shows a very evident method to avoid this error at the resonant frequency. An auxiliary circuit which is tuned to the resonant frequency of the closed circuit referred to is connected to some point of the condenser shunt and actually absorbs the power of the harmonic from this circuit and in this way eliminates this error.

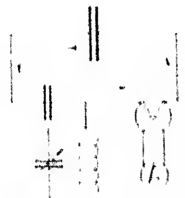

FIG. 3

Since this tuned circuit is connected only at one point, its effect at all other frequencies is entirely negligible.

It is worthy of notice that the accuracy of this instrument cannot really be checked by any available standards of high-frequency current. Probably the most accurate fundamental method of measuring high-frequency current is by means of the calorimeter ammeter in which the heating due to the current registers the value of that current in terms of the resistance of the heating element. Even this method, however, is subject to two errors which are difficult to eliminate. One is the actual value of resistance at the high frequency and the second is the distributed

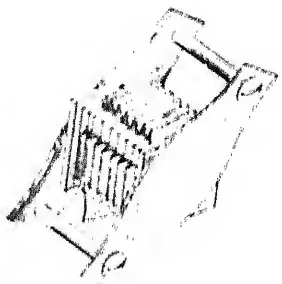

FIG. 4

capacity of the heating elements and the calorimeter apparatus.

If it is remembered that the capacity values used in condenser shunt are considerably in excess of any distributed capacity, and moreover, with a properly constructed mica condenser, these values are constant at all frequencies, and if it is further realized that the distributed inductance and resistance of leads are really negligible, the accuracy of this method becomes self-evident; it establishes a standard of large high-frequency current determined only by the accuracy of the meter element in series with the small condenser.

Fig. 4 illustrates the construction of the condenser element suitable for this apparatus. It shows a unitary structure with a powerful clamp and two capacity elements, both within this clamp. One element consisting of a number of metal foils in parallel gives the large capacity, while one extra foil brought out as a separate lead gives the small capacity. It is evident that the construction is made so symmetrical that there is no chance of one capacity changing relatively to the other. It will also be seen that the incoming and the outgoing leads of this condenser are on the same side of the clamp. There is no magnetic loop around the condenser element, therefore, and the losses are reduced to a minimum.

It is a well-known fact that for high-frequency operation, the presence of iron near the conductors results in considerable losses and consequent heating which may become prohibitive. In the improved construction of this element, although a steel clamp is used to hold together the condenser under a high pressure, the

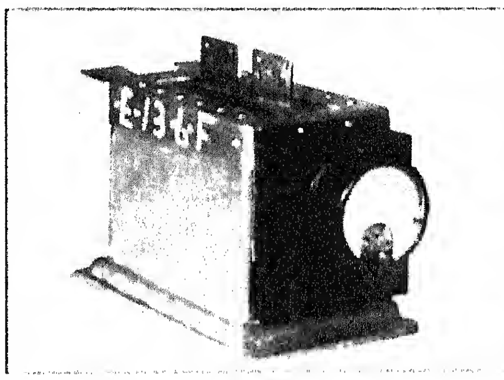

FIG. 5

arrangement of conductors is such that with a current of 50 amperes the losses are negligible.

A typical example for a condenser to operate at 50 amperes is as follows: The shunt element is 0.199 μ f. and the part constituting the small condenser is 0.001 μ f. The shunt element consists of a large number of metal foils, and therefore each foil will carry only a fraction of an ampere; also each one of these foils will be of a very short length. For this reason, the resistance losses in the foils will be quite small and it will carry a total current of 50 amperes, without appreciable heating.

At 6000 kc., the potential across this condenser would be only 6.6 volts. Although the clamp is of the same potential as the condenser, it is separated from it by a space of almost half an inch, which is sufficient to avoid the losses in the steel clamp due to the spreading electromagnetic and electrostatic field of the condenser element.

Fig. 5 is an illustration of a meter of this type constructed for operating with a current of 100 amperes. It will be seen that there are two leads coming out through the cover which can be connected in parallel or individually, depending on the current to be measured. There are two condenser elements corresponding to these leads. Only one of these condenser

elements contains a small capacity in series with the meter, that is, the element closest to the meter end. If this element alone is used, the reading is 50 amperes. If the second element is also connected, the reading becomes 100 amperes, and the meter readings must be multiplied by 2 without affecting the calibration of the instrument.

Fig. 6 shows this condenser viewed from the bottom, with the base removed. The two condenser elements will be seen inside a perforated aluminum container with the thermocouple and instrument mounted on one side. A small adjustable condenser and spool

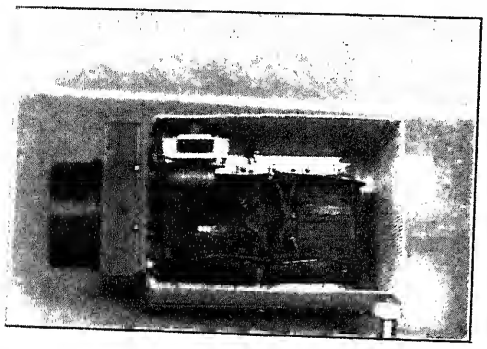

Fig. 6

next to the meter are for the purpose described in connection with Fig. 3, to eliminate the effect of the higher harmonics.

Fig. 7 illustrates the arrangement of parts in this instrument. It shows a small resistance element R connected in the output leads of the thermocouple. This is a small spool of resistance wire which is equivalent in resistance to a certain length of lead so that when it is desirable to use the meter at a distance from

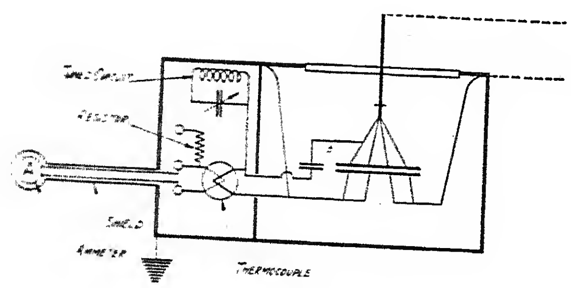

Fig. 7

the circuit this can be done without any change in the calibration by leaving out the spool and substituting the resistance of a standard length of leads. Fig. 7 also shows that the leads from the condenser element to the heater are arranged to have the minimum effect from stray fields and a minimum induction. These leads are seen to be made of two twisted wires, see Fig. 6, placed together closely, and brought to the thermocouple. Fig. 7 shows the terminals located at the end opposite to the meter, and when connected to the circuit, the leads would be going in a direction away from the meter.

If the meter is used at a distance from the thermocouple, the leads from the latter to the meter are brought through a metal shield casing which is grounded to prevent any radio frequency from affecting the circuit.

Fig. 8 shows the mounting of the condenser element inside the casing. It is seen to be held by two metal plates which act as ground leads of the condenser element. Thus the two ground leads are parallel to each other and almost completely enclose the condenser element and the incoming lead. It will be observed from Fig. 6 that the condenser element is connected to these metal plates by means of several thin, wide metal leads. It can be seen readily, by observing Fig. 8, that the electrostatic field is confined within the ground leads and its influence on the meter and the thermal element is thereby minimized.

For high current ratings, the principle of block additions of condenser elements is utilized. Thus for 50 amperes, one block is used; for 100 amperes, two

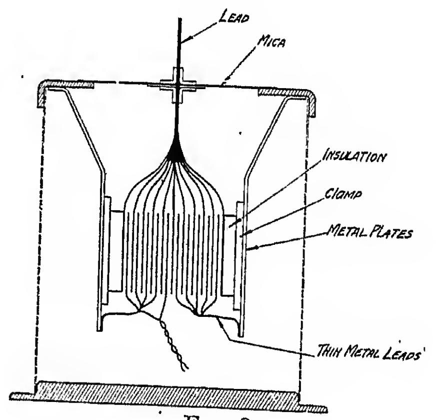

Fig. 8

are used; for 150 amperes, three blocks are used; etc. The same thermocouple and meter are used in each case and the scale need only be multiplied by the number of blocks connected.

With the arrangement described, the ratio of capacity is 200 to 1; therefore, the thermocouple will carry only a quarter of an ampere while 50 amperes are flowing in the radio frequency circuit. A quarter of an ampere is quite practical for a sensitive and accurate thermal instrument. With 100, 150, or 200 amperes, the thermocouple will receive the same current, but the ratio will have changed in accordance with the capacity, that is, the number of blocks.

A meter as described above has been in continual use for over two years on a testing set where the frequencies have ranged from 100 kc. to 6000 kc., and the current values have ranged up to 120 amperes. It has been found that the meter indications are consistent and reliable at all these values. In fact, its accuracy has

been such that it was possible to measure the voltage in a circuit by connecting such an ammeter in series with a known condenser, and determining the voltage drop in the condenser by calculation.

For developing a special thermocouple ammeter used in connection with the condenser shunt, an acknowledgment is due the Weston Electrical Instrument Corporation of Newark, N. J.

Discussion

B. E. Lenehan: It is not apparent why the capacity of a condenser can be assumed to be constant up to frequencies as high as 6000 kilocycles. Two conductors spaced approximately 10 times their diameter will have an inductive drop at 50 amperes 6000 kc. of about 345 volts per ft. The mutual inductance between the meter and shunt circuit can hardly be disregarded as only 1 per cent coupling would introduce errors of around 50 per cent.

The method is a very good practical way of making high-frequency measurements after its accuracy has been established, but it can hardly be classed as a standard. The well known difficulties of shielding high frequency circuits are evidently due to the high resistance of all materials. This effect accounts for the use of only moderately high frequencies in induction furnaces.

We must remember that no method of demonstrated accuracy exists for measurement of currents above 1000 kc. Resistances and inductances are all affected by the proximity of the return conductor of a circuit if any exists and the usual effects by which one makes measurements are complicated by the fact that the usual "constants" of a circuit are not constant.

Alexander Nyman: Concerning the statements of Mr. Lenehan, with regard to the voltage drop on leads at 6000 kc. and 50 amperes, it is not clear what size of lead he is contemplating, as of course the bigger the lead the less would be the drop per unit length. It is of course also true that the leads to condenser shunt are short from the junction point of the small condenser and these leads are so arranged as to confine the magnetic field to a small space and for this season the voltage drop is practically negligible.

The inductive effect of these leads is again reduced by their mutual shielding arrangement, and by the fact that the leads to the thermo-couple are very short. This inductive effect can of course be determined by connecting the small condenser element to the large, in which case it will be found that no current passes through the thermo-couple. In other words, the mutual inductance which Mr. Lenehan mentions is much less than 1 percent and probably could not be readily determined.

With regard to the second paragraph, the writer is fully aware of the difficulties of shielding as this factor had been carefully studied in the design of the condenser shunt. The shortness of leads, the construction which encloses the incoming lead by outgoing leads, and a complete separation in a metallic container are the essential features which were found necessary for shielding. In other words, if the construction is such that there is no external field except in close proximity to the conductors, then the magnetic effect evidently is much easier to shield than than for an exposed conductor.

Methods for the Measurement of Radio Field Strengths

BY C. R. ENGLUND[1] and H. T. FRIIS[1]
Non-member Member, A. I. E. E.

***Synopsis.**—This paper presents a review of successful methods of measuring several classes of radio waves, (a) sinusoidal waves of frequencies below 1000 kilocycles and (b) sinusoidal waves of frequencies above 1000 kilocycles, (c) telegraph dots and dashes and (d) static.*

* * * * * *

FOR several reasons the radio art was well advanced before the most fundamental measurements, those of the signal strength in free space, were undertaken. Chief among these reasons, perhaps, was the fact that the damped spark transmitter was the most common generator. Such a radiator has so many variables that accuracy in measurement is difficult. The simultaneous advent of the vacuum tube generator and amplifier furnished the sinusoidal radiation and the sensitive receiving set, so that an exact knowledge of the field strength became a matter of greater engineering moment and at the same time more accurate and sensitive means of measurement became available.

The earliest transmission measurements were made by inserting sensitive a-c. ammeters in the receiving antenna. Later the coupled circuit with crystal rectifier and d-c. instrument was used. Here the coupling allowed a matching of circuits and the high sensitivity of the d-c. instrument made it a moderately sensitive method. Still later the telephone and audibility meter were added, increasing the sensitivity and making the measurement one differing only slightly from the normal operating technique, a desirable feature. The advent of the vacuum tube amplifier and detector enormously increased the intensity range of the signal which could be received and estimated as a unit of audibility.

There were serious deficiencies, however. The measuring unit was too far away electrically from the antenna, the step from free space to antenna was not bridged, and the threshold of audibility which furnished the basis of measurement was not an accurately reproducible standard. One of us, therefore, in 1917[2] proposed the idea of introducing a local measurable signal into the antenna and turning the measurement setting into a comparison between local and distant signals. The advantages would be that the type of receiving set would become immaterial, since this set serves merely as a comparator, and the comparison would become one of equal voltages impressed in the antenna, the only antenna constant required being the so called effective height. This method has now become standard for frequencies below 10^6 cycles,[3] (300 meters,) and while it has been found inapplicable at higher frequencies, due to technical difficulties,[4] some of its features are retained. Its chief disadvantages are the physical difficulties of generating and controlling the local signal and the increased cost of apparatus. The limiting signal which can be measured, in the absence of static, is fixed by the leakage through the comparison oscillator shielding and it is the control of this that has made the method feasible.

From the theoretical viewpoint, there is no question as to what should be measured, and granting that technical troubles do not intervene, the same holds for the practical viewpoint. This is to measure the electromagnetic condition at the receiving antenna, or rather the condition as it would be if the antenna were not there. Whether the unit should be that of energy density, electric field, or magnetic displacement may be debatable; it has been chosen as a practical matter, and by common consent, as the electric field expressed in microvolts per meter. This gives a convenient unit, the range of from 0.1 to 500,000 microvolts per meter representing the present reception levels. Since the energy density in free space of an electromagnetic disturbance is

$$W = \frac{E^2 + H^2}{8\pi}$$

and for pure radiation fields $|E| = |H|$, in absolute electrostatic and electromagnetic units respectively, it is immaterial which is chosen. For very short transmission distances, the second equation does not obtain as the fields are not pure radiation fields[5].

When a fine wire conductor, where eddy currents may be neglected, is exposed to an electromagnetic radiation,

a total electromotive force is developed along the wire length which is equal to

$$\int_a^b E_c \, d\, l$$

where E_c is the component of electric field parallel to the wire and a and b are the coordinates of the wire ends. If $a \neq b$ we have the ordinary "open" or "marconi" antenna; if $a = b$ we have the closed or "loop" antenna. In the latter case, the line integral around the closed curve always gives the same value as the surface integral of the rate of change of magnetic displacement through the closed curve. This is the origin of the inexact notion that the open antenna operates from the electric field and the closed antenna from the magnetic field.

When either of the antennas mentioned is exposed to electromagnetic fields, currents flow in it. In the general case the relation between current and driving field at any point on the conductor is a very complicated one and while an equivalent lumped electromotive force can always be found to replace the distributed electromotive force in a single given connection of input and indicating apparatus, the most desirable state of affairs is that when the integral of the wire component of the electric field can be replaced by an equal total lumped electromotive force. This condition can be met for an open antenna by making it short and adding large capacity areas at the end; for a loop antenna we need only make the dimensions small and wind to such an inductance that the tuning capacity greatly exceeds the natural or "shunt" capacity of the conductor. A comparison in the antenna itself of a locally generated electromotive force and the signal electromotive force, both of the same frequency, does not require an antenna tune. It is advisable to tune, however, because of the sensitivity and selectivity resulting. The free space field can then be determined in terms of what may be termed the "effective height" of the receiving antenna. For the open antenna, the effective height is the physical length and the resultant voltage in the antenna V_0 is related to the electric field E by the condition $V_0 = h_0 E$. For the closed antenna of N turns, the resultant voltage is

$$V_L = -\frac{N}{c} \frac{\partial}{\partial t} \int \int B_n \, d\, s$$

which is to be evaluated for any given field and loop area. If the loop is in free space and is so small that the field is sensibly constant over its area A and if the field is sinusoidal of frequency $\frac{\omega}{2\pi}$ then

$$V_L = \frac{\omega N A H}{c}.$$

Now for pure radiation $|H| = |E|$ and accordingly an effective height or height of equivalent open antenna h_L can be defined as

$$V_L = E\, h_L = \frac{\omega N A E}{c} \text{ or } h_L = \frac{\omega A N}{c}$$

and is convenient as long as the transmission distance is great enough to assure only a radiation field. The tacit assumption is of course made that the fields are rectilinear and the antennas oriented for maximum pick-up.

As a practical fact, we have had little success in using an open antenna as an antenna for which the effective height is determined from physical dimensions. We have always had to rely on the loop as the absolute antenna type. In the last analysis, then, all transmission measurements and formulas are based on a computed loop effective height which it is impossible to check by direct measurement. We have had no

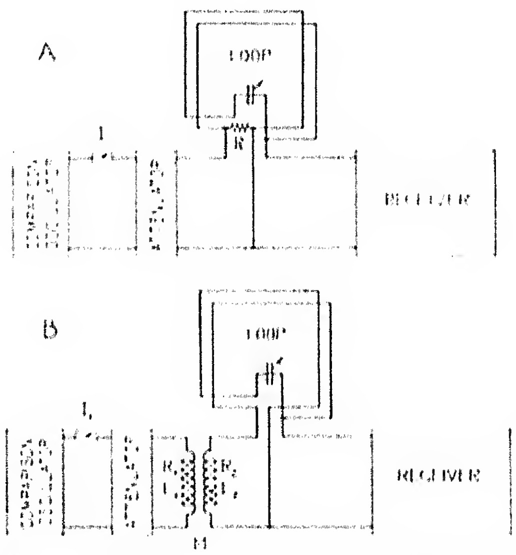

FIG. 1 MEASURING METHODS OF LONG WAVE FIELD STRENGTH

indirect evidence to date showing that the effective height computed in this manner is incorrect.

The method of introducing the sinusoidal comparison voltage into the antenna is at the disposal of the operator. Two which have been commonly used are the resistance drop and the mutual inductance voltage[6]. Figs. 1-A and 1-B are schematic of these.

If K be the current attenuation ratio, $(K > 1)$, then the voltage introduced into the antenna is, in the two cases,

$$\frac{R\, I_1}{K}, \quad \frac{i\, \omega\, M\, I_1}{K}$$

and the currents resulting in the antennas, (we actually indirectly compare voltages through the resulting currents), are

6. Vallauri, *Proc. I. R. E.*, **8**, p. 286, 1920; Lunnon, *Inst. El. Eng. Jl.*, **59**, 1921, p. 685; Beverage and Peterson, *Proc. I. R. E.*, **11**, 1923, p. 661; Hollingsworth, *Inst. El. Eng. Jl.*, **61**, 1923, p. 501.

$$\frac{R\, I_1}{K\,(R + Z)}, \quad \frac{i\,\omega\, M\, I_1}{K\,(i\,\omega\, L_2 + R_2 + Z)}$$

where Z is the antenna impedance beyond the local input terminals. Now the currents produced in the antennas by the radiation fields are

$$\frac{h\,E}{\frac{R\,r}{r + R} + Z}, \text{ and}$$

$$\frac{h\,E}{R_2 + i\,\omega\, L_2 + \frac{\omega^2\, M^2}{r + R_1 + i\,\omega\, L_1} + Z}$$

where r is the impedance of the attenuator looking backwards into it. The condition of equality means that

$$\frac{R\, I_1}{K\,(R + Z)} = \frac{h\,E}{\frac{R\,r}{r + R} + Z}$$

$$\frac{i\,\omega\, M\, I_1}{K\,[R_2 + i\,\omega\, L_2 + Z]} = \frac{h\,E}{R_2 + i\,\omega\, L_2 + \frac{\omega^2\, M^2}{R_1 + i\,\omega\, L_1 + r} + Z}$$

in the two cases. Now it is very easy to make $r >> R_1$ and, this done, $R\, I_1 = K\, h\, E$ or $E = \frac{R\, I_1}{K\, h}$ for the first equation. For the second, it is equally simple to make

$$\left| \frac{\omega^2\, M^2}{R_1 + i\,\omega\, L_1 + r} \right| << \left| R_2 + i\,\omega\, L_2 + Z \right|$$

and, this achieved,

$$K\, h\, E = i\,\omega\, M\, I_1 \text{ or } E = \frac{i\,\omega\, M\, I_1}{K\, h}$$

In case a loop is used, the last equation further simplifies. For substituting the effective height of the loop gives

$$|\,E\,| = \frac{\omega\, M\, |\,I_1\,|}{K\, h_L} = \frac{M\, c}{K\, A\, N}\, |\,I_1\,|$$

and the frequency has cancelled out which is an advantage. The relative availability of these two methods will depend somewhat on the occasion. A workable mutual inductance unit may be purchased in the open market while a resistance unit cannot be so bought. On the other hand, it is our experience that a resistance can be made without a-c. calibration which will function more accurately than a small mutual inductance can be calibrated, particularly when shielding is necessary to prevent antenna pick-up. Another point in favor of the resistance input is that the reactance of the unit can be as much as 14 per cent of the resistance before the impedance drop across it increases 1 per cent. Moreover, the constant impedance attenuation network of resistances is the first that comes to mind because of its independence of frequency and a resistance termination is then the logical one. No question of efficiency is involved since rejection and not conservation is aimed at.

We have used two types of resistance attenuator[7] and have found that below 1000 kc., safe resistance units can be made and used. Even if reactive units should result, a reasonable agreement of phase angle among them will maintain the high accuracy of the resulting attenuator and the utility of the resulting instrument exceeds that of similar apparatus made up of inductances or capacities. For example, the shielding of a resistance attenuator is very easy, a statement not valid for an inductance attenuator. At high frequencies, the unavoidable inductance of leads ruins the operation of a capacity attenuator.

The theory of the measurement by means of a comparison signal in the antenna has been sketched above; it was also stated that a different method was forced upon us at the higher frequencies by reason of the impossibility of constructing predeterminate attenuating networks. Several suggestions have been investigated but at these frequencies the dimensions of conductors having negligibly small impedances become unworkable and it is necessary to make a radical move. The resulting method[8], requiring a double detection type of receiver, may be sketched as follows.

The loop signal and beating oscillator voltages are applied to the first detector grid. (The beating oscillator input may also be introduced into the detector plate circuit.) The detector output passes through a controllable attenuation element and a selective intermediate frequency amplifier, the amplified intermediate frequency being applied to the last or low-frequency detector grid. A meter in this detector plate circuit serves as an indicator and by adjusting the attenuation unit a convenient deflection is obtained from the signal, Fig. 2A. Let this attenuation ratio be K_1. The beating oscillator is now disconnected and a comparison oscillator input introduced into the loop and increased until a readable deflection is obtained in a meter in the first detector plate circuit, Fig. 2B. This detector having been calibrated as a vacuum tube voltmeter, the voltage is read directly from the calibration curve, say V. Next the beating oscillator is reconnected and the attenuation increased until the output meter gives the original deflection. The attenuation is now K_2 and it is evident that the original signal voltage applied to the first detector grid was $\frac{K_1}{K_2}\, V$. Finally, the

7. Englund, loc. cit; Jensen, loc. cit.
8. Friis and Bruce, loc. cit.

loop tune is short-circuited so that the unchanged comparison oscillator output is applied directly to the first detector grid. A reduction in the attenuation to a third setting K_3 brings the output up to its original value. The signal voltage picked up by the loop is thus,

$$\frac{K_1 \; K_3}{K_2^2} V$$

and equating this to the product of field strength times loop effective height gives

$$E = \frac{K_1 \; K_3}{K_2^2} \cdot \frac{V}{h_L}.$$

As practical procedure, V is conveniently chosen as one volt. The necessary condition is that the inter-

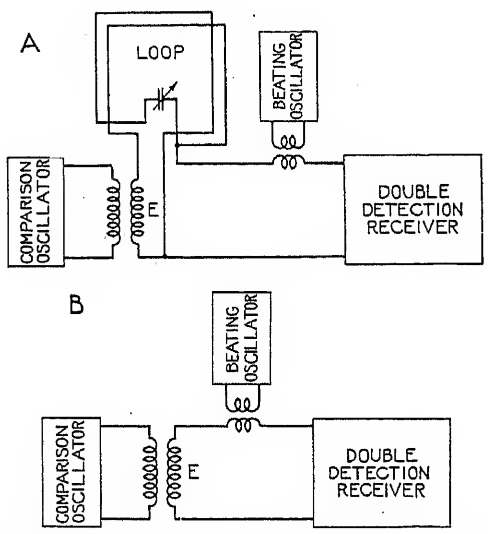

Fig. 2—Measuring Method of Short Wave Field Strength

mediate frequency output of the first detector be proportional to the product of the two inputs over the wide range from signal voltage up to unit voltage, a condition which is found to be satisfied. The attenuation unit, being in the intermediate frequency circuit, operates accurately as in the direct use for lower frequencies. It may be added that when consideration is taken of the extraordinary variability of short wave transmission, both in amplitude and polarization angle, the accuracy of measurement required is not great and is amply met by the apparatus described above. In fact, we believe that the significant type of measurement for short wave signals is a continuous record over extended periods, such as would be obtained by an automatic recorder operating out of a receiving set. It will be necessary, at any rate, to record both the amplitude and the polarization angle.

Another type of signal comparison measurement, very easy of execution, is that of erecting a local transmitting antenna of low effective height and comparing its radiation with that of the signal. It is not possible to make this an accurate method as a little consideration will show. A method of determining the effective height of an antenna by a set of interconnected measurements on three antennas has been proposed[9] but it is difficult to see how it can compare with a loop measurement in accuracy. Naturally, an open antenna has a great effective height compared to that of a usable loop and the problems of comparison oscillator shielding, high current attenuations, and high amplification at a low noise level, in great measure fade out.

The discussion so far has assumed a simple sinusoidal signal but this is not the only type awaiting measurement. The major applications of radio are for communication purposes and such applications require a modulation of the simple sinusoid. To mention only two such, we have the broadcast transmitter and the radio telegraph sender. The former carries a dominant unmodulated carrier and measurements are simply made on this carrier frequency using a meter in the final detector plate circuit for comparison. Normal signal strengths for broadcast purposes make a meter reading simple. To measure the dot and dash amplitudes of telegraphy requires something of the nature of an oscillograph, and the cathode ray oscillograph using a neon tube discharger[10] to spread the beam has proved serviceable as a visual comparator. The signal intensities are here likely to be small and static interference marked. It has been shown that static interference is proportional to the width of the resonance band[11] of the receiver and for telegraph signals a sharp low-frequency tune will reduce the interference so greatly that it has usually been found possible to measure with the cathode ray tube if the signals can be read[12] in the phones.

Static is another signal type awaiting measurement. The rather intangible "noise value" of the static is what it is desired to measure in radio telephony and for rectifying systems such as telegraph recorders and printers the total static energy is of greatest importance. The first static measurements were obtained by measuring the intensity of the telegraph signal which was just masked or rendered unintelligible by the static. Consistent results can be obtained on continuous static by this method. For telephony, the same considerations demand a signal representative of speech and the so called "warbler"[13] was chosen for this. This signal is produced by varying the frequency of a continuous-wave oscillator, over the range covered by the transmission band of the receiver, at a slow rate—5 to 10 times per sec. But the great variability of static, in direction as well as in amplitude and type, makes isolated observations of limited value and an automatic static recorder appears to be the logical

attack upon the static measurement problem. Because of the extreme ranges of received energy which occur, it is necessary to invert such a measurement and instead of recording the static itself, record the gain of

the receiving set necessary to maintain the static output constant; and this has been the method chosen[14]. The particular output metering sytem which seems to have

a. Loop; b. Double detection receiver; c. Attenuator; d. Batteries; e. Output meter; f. Comparison oscillator

the greater number of advantages is one employing a "fluxmeter" or non-restoring type of deflection instrument to add up the energy received for a definite interval. This is not a "lagging" type of average such as a sluggish thermocouple would give and is yet immune from the wild fluctuations of set gain which result when a "rapid" thermocouple is used.

The static measurement desired is naturally a measurement of the interfering effect or signal destructiveness of the static. This is exactly the property of greatest interest since the signal to static ratio thus defined is the engineering factor of safety for continuous transmission of the desired intelligence.

In closing this resume of radio field measurement methods of today, a few observations from the practical side may be welcome. We have had occasion to make

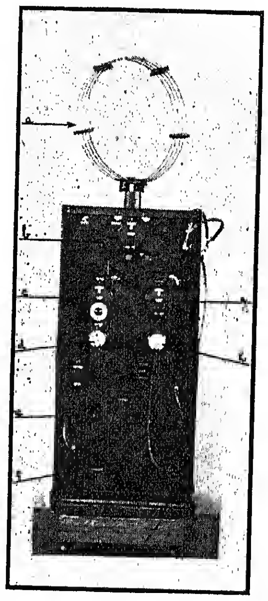

FIG. 5—FIELD STRENGTH MEASUREMENT APPARATUS, 1-40-MEGACYCLES

measurements of field strengths from 15 kc. to 25 megacycles and from 0.1 to 500,000 microvolts per meter. It is a striking fact that for the entire frequency range a measuring set sensitivity of 0.1 microvolt per meter reaches the weakest usable signals. From a radio telephone point of view the most important frequency ranges at present are 40-70 kc., 550-1500 kc., and 3 to 25 megacycles. In Figs. 3, 4, and 5, reproductions of photographs of measuring apparatus for each of these ranges are given. This apparatus possesses enough flexibility to bridge the frequency gaps and cover the 15-kc. to 25-megacycle range already mentioned. The measuring sets of Figs. 3 and 4 measure by means of local comparison signals in the loops; the apparatus of Fig. 5 uses a calibrated intermediate frequency detector with an attenuator in its output circuit as already described. All three sets are double detection receivers and are intended to be portable.

Appendix I

The "Hertzian doublet" is essentially a rectilinear antenna with such large capacity areas at its ends that the current in the linear portion is everywhere the same. If we now assume such an antenna in free space with a capacity area separation of h and carrying a current $I_0 \sin \omega t$, then at a distance d such that $d >> h$, the fields, in cylindrical coordinates, are given by the following expressions, where the center of the antenna has been chosen as the zero of the coordinate system and the antenna along the Z axis:

$$H_\theta = \frac{h I_0 r}{d^2}\left[\frac{\omega}{c}\cos\omega\left(t-\frac{d}{c}\right) + \frac{\sin\omega\left(t-\frac{d}{c}\right)}{d}\right]$$

$$E_r = \frac{h I_0 r z}{d^3}\left[\left(\frac{\omega d}{c}-\frac{3c}{\omega d}\right)\cos\omega\left(t-\frac{d}{c}\right) + 3\sin\omega\left(t-\frac{d}{c}\right)\right]$$

$$E_z = -\frac{h I_0}{d^3}\left[\left(\frac{\omega r^2 d}{c} + c\,\frac{2z^2-r^2}{\omega d}\right)\cos\omega\left(t-\frac{d}{c}\right) + (2z^2-r^2)\sin\omega\left(t-\frac{d}{c}\right)\right]$$

where $d = \sqrt{r^2+z^2}$.

Obviously, the magnetic field lies in circles about the z axis and the electric field in the plane containing d and the z axis. As before, the units are absolute electromagnetic and electrostatic, respectively.

For distances where d is not great compared with h, these formulas must be integrated over the antenna. Thus, for the magnetic field,

$$H_\theta = r\,\omega\int_{-\frac{h}{2}}^{\frac{h}{2}}\frac{I_l\cos\omega\left(t-\frac{\sqrt{r^2+(z'-l)^2}}{c}\right)}{r^2+(z'-l)^2}\,dl + r\int_{-\frac{h}{2}}^{\frac{h}{2}}\frac{I_l\sin\omega\left(t-\frac{\sqrt{r^2+(z'-l)^2}}{c}\right)}{[r^2+(z'-l)^2]^{3/2}}\,dl$$

With similar expressions for the electric field, (r, z') are the coordinates of the point of observation and the symmetry makes a θ coordinate unnecessary. In the formula I_l, the current function is arbitrary and may be any given function of l. Until this is specified, the integrations cannot be carried out.

For the equatorial plane, $z = 0$, the simple doublet equations reduce to

$$H_\theta = h I_0\left[\frac{\omega\cos\omega\left(t-\frac{r}{c}\right)}{c\,r} + \frac{\sin\omega\left(t-\frac{r}{c}\right)}{r^2}\right]$$

$$E_z = -h I_0\left[\frac{\omega\cos\omega\left(t-\frac{r}{c}\right)}{c\,r} + \frac{\sin\omega\left(t-\frac{r}{c}\right)}{r^2} - \frac{c\cos\omega\left(t-\frac{r}{c}\right)}{\omega r^3}\right]$$

Notice that the first two terms in H_θ and E_z are separately equal. At great distances, all but the first terms in H_θ and E_z become negligible, these two terms being the radiation fields. It is easily seen that the radiation components $|E_z|$, $|H_\theta|$, and r form, in the order named, a right hand screw system.

To pass from the antenna in space to a grounded antenna we need only notice that if the grounded antenna is half the length of the free antenna, the fields in free space are the same. We assume, of course, that the ground conductivity is great enough to produce a true antenna image.

In amperes, volts, and meters the electric field in the meridian plane of the doublet becomes, at great distances,

$$|E| = \frac{60\,\pi}{r\,\lambda}\cdot h\,I_0$$

Quantitative Determination of Radio Receiver Performance

BY H. D. OAKLEY[1]

Associate, A. I. E. E.

Synopsis.—The practise of making quantitative measurements on the individual units of radio receivers is quite general, but seldom are such measurements made on receivers as a whole because of certain difficulties encountered in this type of measurement. This paper describes apparatus developed to overcome these difficulties and to make possible a study of the performance of receivers as such. The over-all characteristics of receivers are classified and described, the method of tests for obtaining measurements on them explained, with some curves shown to illustrate the results obtained from these tests.

* * * * *

INTRODUCTION

In the development and design of a device consisting of more than a single unit, it is advantageous to subject it to a series of tests to determine its operating characteristics as a whole, as well as the characteristics of the individual units alone. A radio receiver is comprised of apparatus performing, as a rule, five main functions: (1) Selecting a voltage of a particular radio frequency from among several co-existing voltages, the frequency of each one being different from that of the desired voltage; (2) amplifying the selected voltage; (3) deriving from this amplified voltage an audio-frequency voltage; (4) amplifying the audio-frequency voltage; (5) converting it into sound energy. Present day receivers perform functions (1) and (2) simultaneously in the radio-frequency selector amplifier, function (3) in the detector, (4) in the audio frequency amplifier, and (5) in the loud speaker. Testing the apparatus performing any one of these five functions is relatively easy but to make measurements of the whole assemblage is rather difficult.

It is the purpose of this paper to describe briefly the test apparatus used by the General Electric Company, to explain the quantities measured, and the method of test, and to present some results obtained from over-all tests on receivers.

To obtain satisfactory results from over-all tests, three main conditions must be satisfied. 1. To the input terminals of the receiver must be supplied a radio-frequency voltage of a character and magnitude comparable with normal operating conditions. 2. The testing apparatus must be so constructed and arranged that the receiver is subjected to the signal in a known manner and is not affected by unknown stray signal effects. 3. The test conditions must be so controlled that the receiver is not influenced by electrical disturbances other than the test signal.

DESCRIPTION OF TEST APPARATUS

The apparatus developed to meet these conditions consists of a signal generator, a current-controlling and measuring device, a voltage attenuator, a dummy antenna, and an output voltmeter. The first two units are in a shielded room and in another are the last three, as is also the receiver to be tested. The signal generator is a miniature broadcast transmitter employing the Heising system of modulation, and is composed of five main units: (1) An audio-frequency oscillator with a range of 40 to 10,000 cycles; (2) a radio-frequency oscillator, having a range of from 550 to 1500 kilocycles; (3) a modulator, with its grid controlled by the audio-frequency oscillator and its plate controlling the plate voltage of the modulated radio-frequency amplifier; (4) a modulated radio-frequency amplifier the grid of which is excited by the radio-frequency oscillator and whose output is varied at an audio-frequency rate by the modulator; (5) a power amplifier (provided with a modulation indicator), excited by the radio-frequency amplifier. The power amplifier supplies current to the current controlling and measuring device. This is a variable mutual inductor with its primary connected to the signal generator and in its secondary circuit a tuning condenser, a thermoammeter, and a voltage attenuator. The value of the current flowing in the voltage attenuator is measured by the thermoammeter, and is controlled by varying the mutual inductance. The attenuator is a special form of self inductor, first proposed and used by Dr. N. H. Williams of the University of Michigan. It consists of a coaxial metal shell and rod, which terminate at one end in a metal plate perpendicular to their axes. At the point where the rod meets the plate it is connected to ground. The design of this inductor is such that its inductance per unit length is easily calculated. This particular inductor has three taps providing inductances of approximately 0.001, 0.0055, and 0.02 microhenrys. With these taps and an input current, range of from 0.5 to 350.0 milliamperes, a voltage range of from 1.5 to 22,000 microvolts may be obtained at the lower frequency end of the broadcast range, (550 to 1500 kilocycles), and three times these values at the higher end. The dummy antenna is a circuit so designed that its characteristics are representative of those of the average broadcast receiver antenna. An arbitrary value of ten meters is given as its effective height, because it is believed that this is the average value of antennas commonly used. The output voltmeter

1. General Engg. Laboratory, General Electric Co., Schenectady, N. Y.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

measures the effective value of audio-frequency voltage existing across the output of the receiver. It has a range of 0.2 to 250 volts and its indications are independent of frequency. The impedance (160,000 ohms) of the voltmeter is so great compared with that of the loud speaker that the extra load imposed upon the circuit by the voltmeter is negligible.

This concludes a description of the apparatus used in making the usual over-all characteristic tests. The quantitites measured will be explained now; then the test procedure for obtaining them.

Quantities Measured

The characteristics commonly measured are sensitivity, selectivity, and quality. In some special cases, the radiation from the set is also measured. Sensitivity is defined as the degree to which a radio receiving set responds to signals of the frequency to which it is tuned. The output of a receiver is not directly proportional to the input field strength. Therefore, sensitivity cannot be expressed by a single figure, but takes the form of a curve. Sensitivity can be expressed by an input-output curve; *i. e.*, a curve showing the relation between the potential induced in the antenna circuit and the voltage existing across the loud speaker. It is convenient, however, to express sensitivity as the ratio of output voltage to input field strength at various output voltages. This method is somewhat analogous to transformer practise wherein relations are found between the transformer ratio and the voltage applied to the load at various loads, rather than between impressed primary voltage and voltage supplied to the load. The ratio of output voltage to input field strength, expressed by a dimensional formula, reduces to a length. Since this is so and since the field strength is expressed as a certain potential per meter, the unit of sensitivity has been called the meter. A receiver is said to have a sensitivity of one meter when a field with strength of one volt per meter acting upon the antenna circuit causes a potential of one volt to exist across the loud speaker.

Selectivity is the degree to which a receiving set is capable of differentiating between signals of different frequencies. As measured, selectivity is a curve showing the input field strength required to maintain a constant signal voltage in the output as the frequency of the field is changed. Of course, the field strength is lowest at the frequency of the desired signal, and increases in value as the frequency becomes greater or less than that of the desired signal.

The definition of quality is the degree to which sound is faithfully reproduced. To be strictly in accord with this definition, quality measurements made on receivers should be such that the sound wave modulating the radio wave actuating the receiver can be compared with the sound wave generated by the loudspeaker of the receiver. Then the results of these measurements should be expressed in such a way that the nature and magnitude of the discrepancies between the original and the reproduced sound waves can be shown. The measurements as actually made are not so rigid. The assumption is made that the radio-frequency voltage induced in the antenna circuit is of such a nature that, were the receiver and sound reproducing apparatus perfect, the reproduced sound would be identical with that which acted upon the microphone of the transmitter. The measurements as made furnish data showing the relation between the receiver output voltage and the modulation frequency, as this frequency is varied from 40 to 10,000 cycles, without changing either the voltage induced in the antenna or the degree of modulation. A perfect receiver subjected to this test would maintain a constant value of voltage across its output and therefore its quality curve would be a straight line parallel to the modulation frequency axis. In order to compare the quality of different receivers, it has been the practise to plot these curves as output voltage in percentage of output voltage at some one frequency (usually 1000 cycles), against frequency. The more nearly the output voltage remains constant, the better is the quality.

The last receiver characteristic to be considered is radiation. Radiation is defined as the process of emitting electromagnetic waves into space. Obviously it is impossible to measure a process, so that when radiation measurements are discussed, the act in mind is not that of measuring the process but rather that of measuring the quantities causing the phenomenon of radiation. The relative distances to which transmitters can maintain communication depend upon their antenna height and the current flowing in the antenna. The antenna height is expressed ordinarily in meters and the current in amperes, so that it is customary to express the radiating power of a transmitter in meter amperes—the product of the antenna height and the current. Some receivers contain an oscillating tube and it is possible to so adjust the controls of certain others that one or more tubes will oscillate. In both cases disturbances are sent out which seriously interfere with the operation of neighboring receiver sets. Tests are made to determine both the magnitude and frequency of this disturbance. The results are expressed in meter amperes, since, in this case, the receiver is considered as a transmitter and the strength of its field at various distant points can be determined if the equivalent meter amperes and the distances are known.

Method of Test

Sensitivity, selectivity, and quality are more or less inter-related so that, in general, it is impossible to adjust a receiver to obtain a maximum of one of these quantities without a decrease in one or both of the other two. In making tests on a receiver an attempt is made to so adjust it that a satisfactory compromise among the three is reached. This condition is considered as the average normal operating one. Fig. 1 is

a schematic layout of the test apparatus and an antenna type receiver which is undergoing test. An RCA model-100 loud speaker is used as the output load, and across it is measured the output voltage.

Sensitivity. To determine sensitivity, the signal generator is set to some desired carrier frequency and adjustments are made so that the current is modulated 50 per cent at 1000 cycles. The current flowing through the voltage attenuator is adjusted to some convenient

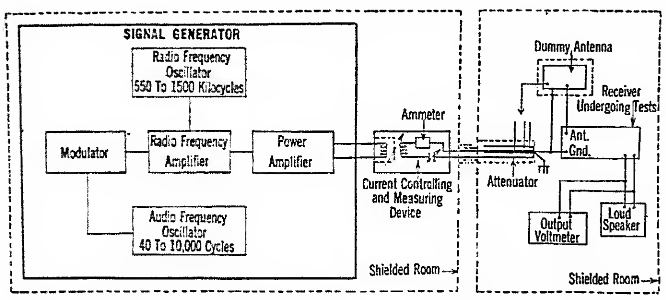

FIG. 1—SCHEMATIC LAYOUT OF RECEIVER TEST APPARATUS

value and the receiver antenna circuit is connected to one of the attenuator taps. The receiver is then tuned to the signal and other adjustments made so that the receiver is operating normally. The test is then begun by adjusting the input to the receiver, (input current to the attenuator or changing taps), so that some low value of output voltage is obtained. The input is increased in steps and at each step the corresponding output voltage is recorded. The test is continued until the grid of one of the receiver tubes becomes positive during a part of the cycle (this usually occurs first in the tube located in the last stage of the audio frequency amplifier). This point is considered the operating limit of the set, since any further increase in input will result in a distorted output. During this test the following data were recorded: carrier frequency, current flowing through attenuator, attenuator tap used, and output voltage. To plot sensitivity curves the field strength for the different output voltages must be known. It is found in this way: knowing the current flowing through the attenuator and its frequency, and the inductance corresponding with the tap used, the voltage induced in the antenna circuit can be calculated. This voltage, divided by the height of the antenna in meters, (in this case 10 meters), is considered as the field strength of the signal. The sensitivity of the receiver in meters is then found by dividing a given output expressed in microvolts by the corresponding field strength expressed in microvolts per meter.

The test just described is made with the receiver tuned to 560 kilocycles. The signal generator is then reset to give the same sort of signal as before except that the frequency is now 1000 kilocycles. The receiver is tuned to this new frequency and the test repeated. A third setting of the generator and retuning of the receiver to 1300 kilocycles completes the sensitivity tests. The complete test then shows not only how the sensitivity varies for different input field strengths but also gives an idea of how it varies for different carrier frequencies. Tests to determine the other receiver characteristics are also made at these same three carrier frequencies so the whole set of curves obtained furnishes a very good picture of the behavior of the receiver over the entire broadcast range.

Selectivity. With the receiver tuned to 560 kilocycles, the frequency of the signal generator is set to a value such that with the receiver connected to the highest tap of the attenuator and the maximum obtainable current flowing through it, no signal exists in the receiver output. The frequency is brought nearer and nearer to the tuning frequency of the receiver until a point is reached where some low value of signal (0.5 volt) exists in the output. From this point on, through resonance and beyond as far as it is possible to go, the frequency is changed in steps, and at each step, the current through the attenuator and the attenuator tap is chosen so that the voltage in the output remains constant. As the frequency of the signal generator is changed, its modulation frequency and degree of modulation remains unchanged. These data are recorded: frequency, value of current flowing through attenuator, attenuator tap used, and the value at which the output voltage was maintained. The field strength corresponding with the several frequencies is then calculated in the manner explained under sensitivity tests. The curve obtained by plotting field strength required to maintain a constant output voltage against carrier frequency is the selectivity curve for this particular tuning point. After this test, another is made with the receiver tuned to 1000 kilocycles and after that a third test is made with the tuning point at 1300 kilocycles.

Quality. A preliminary test is made to determine at what audio frequency the maximum output voltage is obtained. After finding this point the input to the receiver is adjusted so that at this frequency the grid of the last tube does not at any time become positive. The input is then maintained at this value while the modulation frequency is varied from 40 to 10,000 cycles and the degree of modulation is held constant at 50 per cent. At each frequency, the output voltage is recorded. A plot is then made of output voltage in per cent of output voltage at some one frequency (usually 1000 cycles), against modulation frequency and the quality can then be judged by the amount the curve deviates from a horizontal straight line—the greater the deviation, the poorer the quality.

Radiation. These measurements fall into two classes: (1) Measurement of radiation from loop or antenna alone; (2) measurement of radiation from receiver and loop or antenna combined. In the case of sets operating with an antenna, the amount of radiation from the set

itself as compared with that from the antenna is usually small, so that on this type of set measurements are confined to radiation from the antenna itself. But in the case of sets operating with loops, the electrical dimensions of them and of the receiver circuits are comparable, so that quite a large part of the radiation may originate in the receiver. Thus, measurements on this type of set include both loop and set radiation.

The first mentioned type of measurement is made in this manner. The receiver to be tested is set up in the same room with the signal generator and in the other room is another receiver which will be designated as the indicator. The two current leads of the attenuator are disconnected from the current controlling and measuring unit and are connected to the antenna circuit of the receiver. The indicator is connected to the highest tap of the attenuator. Tests are made to be certain the receiver is tuned to some carrier frequency, and then if it is radiating it will be sending current through its antenna circuit, which consists of the dummy antenna and the attenuator. This current flowing through the attenuator will set up a voltage across the input of the indicator resulting in a certain value of output voltage. The current leads of the attenuator are then removed from the antenna circuit and returned to their normal connection. The indicator is connected to the lowest tap on the attenuator and the signal generator supplies current (of the same frequency as that generated by the receiver) the value of which is so adjusted that the output voltage of the indicator is the same as before. This current, multiplied by the ratio of the inductance of the lowest tap to that of the highest, gives the value of current that was in the receiver antenna circuit. This current, in amperes, multiplied by the height of the antenna in meters, (in this case 10 meters), expresses the radiation of the receiver in meter amperes.

To measure the combined radiation from a receiver and a loop, they are set up near the attenuator; and in the same room, but at a distance from them, is another receiver called the indicator. The receiver is properly tuned to receive some carrier frequency. If the receiver is radiating it will cause a voltage to exist in the indicator. The value of this voltage is noted, the receiver and its loop removed, and in their stead is set up a loop circuit whose effective height and resistance are known. With the aid of the attenuator and signal generator a current is set up in the loop circuit, of such a value that the voltage in the indicator is the same as before. Multiplying this current in amperes by the effective height of the loop in meters (not the receiver loop) the combined radiation of the receiver circuits and its loop is expressed in meter amperes.

Effective Height of Receiver Loops

The sensitivity, selectivity, and quality testsd escribed were for the antenna type of receiver. These tests are the same for loop receivers, but the method of determining field strength needs an explanation. When testing this type of receiver, the dummy antenna, of course, is not used but the attenuator is connected directly in the low side of the loop circuit. The connections are as shown in Fig. 2. The voltage induced in the loop circuit is found in exactly the same manner as it was in the case of the antenna circuit. The same dummy antenna is used for all antenna receivers and its height is always considered to be 10 meters; but when testing loop receivers, the loop belonging to the particular set undergoing tests is used. It is therefore necessary to determine the effective height of this loop in order to find the input field strength. The effective height of a loop is simply a figure which, multiplied by the field strength of the electric component of an electromagnetic wave, gives the value of the voltage induced in the loop. In other words, if a loop and an antenna were simultaneously subjected to the influence of a moving electromagnetic field, and the height of the antenna happened to be such that the voltage induced in the antenna was equal to that induced in the loop, then the effective height of the loop would be considered

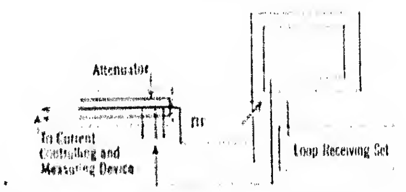

Fig. 2 Diagram of Connections for Testing a Loop Type Receiver

equal to the height of the antenna. It can be shown that the effective height of a loop is dependent upon the frequency of the field, the area of the plane enclosed by the loop winding, and the number of turns in the loop. The relation is:

$$H_m = 0.66\,N\,A\,F\,10^{-9}$$

where

H_m = Loop height in meters
N = Number of turns in loop
A = Area in sq. cm. enclosed by loop winding
F Frequency of the field in kilocycles

Curves Obtained from Test Data

A number of different types and makes of receivers have been tested, but for purposes of illustration, the curves plotted from data obtained from tests on one well-known make of receiver are shown here (see Figs. 3 to 6). These curves are typical of those obtained for other receivers and show up the faults of present day sets. The sensitivity is different at different carrier frequencies within the broadcast range. This is not a desirable characteristic, and receivers are now being designed so that the sensitivity will be more nearly uniform. Another bad feature is that a weak input signal produces an output voltage that is proportionately very much smaller than that produced by a stronger input signal. This condition is due to the type of detector in use today. There exist special

forms of detectors which overcome this difficulty, but they are not generally used because of their lack of simplicity as compared with the usual form.

The selectivity of a receiver should be such that there is very little discrimination among frequencies over a

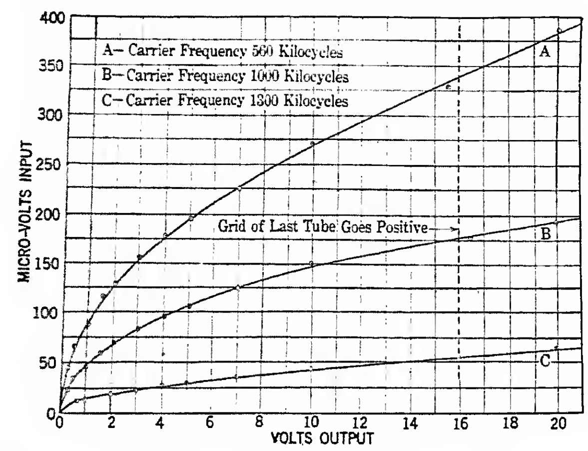

FIG. 3—CURVES SHOWING THE RELATION BETWEEN THE POTENTIAL INDUCED IN THE ANTENNA CIRCUIT AND THE VOLTAGE EXISTING ACROSS THE LOUD SPEAKER OF A RECEIVER

range of from 10 kilocycles below to 10 kilocycles above the resonant frequency and outside the band the receiver should be unresponsive. The first condition is set down so that there will be no impairment in

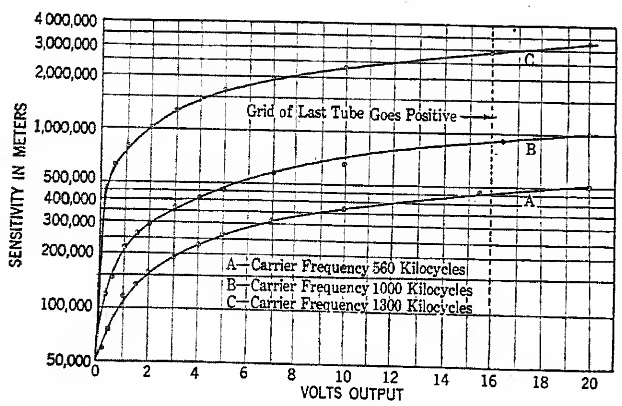

FIG. 4—CURVES SHOWING THE RELATION BETWEEN THE SENSITIVITY OF A RECEIVER AND THE VOLTAGE EXISTING ACROSS ITS LOUD SPEAKER

quality of the audio output of the receiver and the second condition so that undesired signals can not affect the receiver and thus also impair the quality. Fig. 5 shows the selectivity curves. At 560 kilocycles the selectivity is very good with respect to eliminating undesired signals, but is too selective for good quality. At 1000 and 1300 kilocycles the selectivity is not so good so far as eliminating interference is concerned but is good from the standpoint of quality. Selectivity is then another characteristic that may be improved upon, and the ideal to be reached is constant selectivity throughout the broadcast range, complete suppression of all undesired signals, and non-discrimination among frequencies over a limited range both sides of the resonant one.

Fig. 6 is an example of how far the quality of modern receivers departs from the ideal. The falling off of the low frequency part of the characteristic can be attributed to faults in the audio-frequency amplifier and loud speaker circuits. The drooping of the high-frequency end is due partly to these faults, partly to too great selectivity, and a great deal to the characteristics of the detector.

SUMMARY

Over-all measurements supply the means for obtaining first, a picture of the performance of a receiver as a whole and, with such pictures, the per-

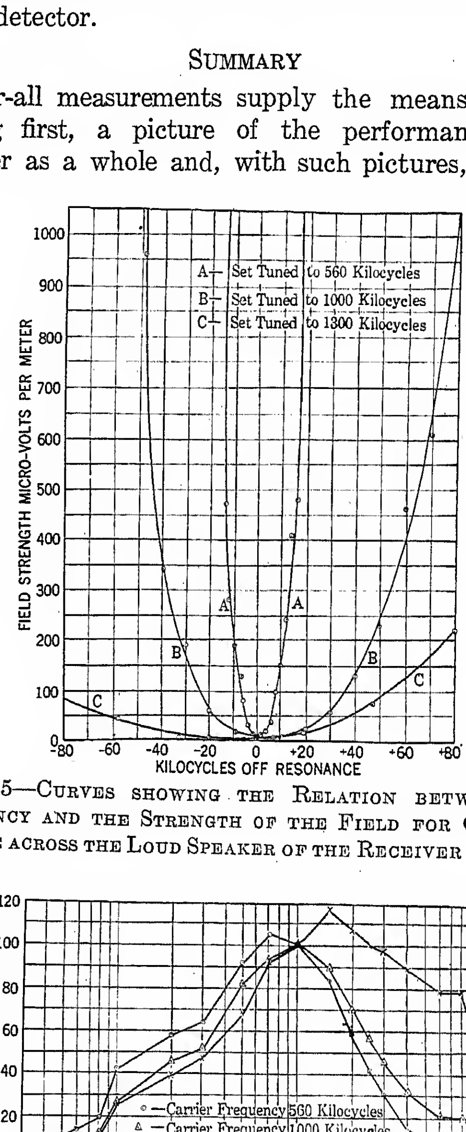

FIG. 5—CURVES SHOWING THE RELATION BETWEEN THE FREQUENCY AND THE STRENGTH OF THE FIELD FOR CONSTANT VOLTAGE ACROSS THE LOUD SPEAKER OF THE RECEIVER

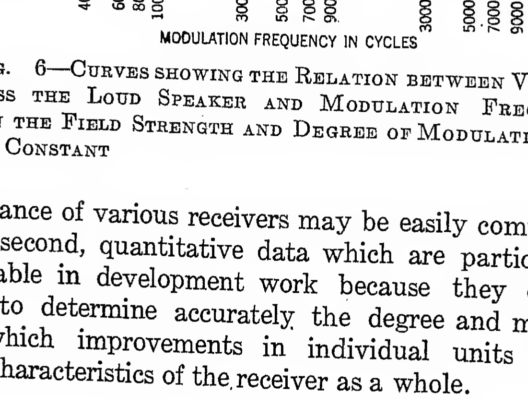

FIG. 6—CURVES SHOWING THE RELATION BETWEEN VOLTAGE ACROSS THE LOUD SPEAKER AND MODULATION FREQUENCY WHEN THE FIELD STRENGTH AND DEGREE OF MODULATION ARE HELD CONSTANT

formance of various receivers may be easily compared; and second, quantitative data which are particularly valuable in development work because they enable one to determine accurately the degree and manner in which improvements in individual units affect the characteristics of the receiver as a whole.

Discussion

A. L. Cook: I think it is a decided indication of progress in the development of sets when the manufacturers begin to test their complete sets and publish results of these tests.

I wish to ask particularly about the curves on the fifth page of the paper showing the quality of reproduction of a certain receiver. I wish to ask does the method of testing used really tell whether or not the set has good quality of reproduction?

As I understand it, the method is based upon the measurement of voltage amplification at different audio frequencies and I wish to ask if this is a true measure of the quality? That is, if this were a straight line parallel to the horizontal axis, would this represent a perfect set?

I believe that most of the energy in a complex note is in the lower frequencies, and it would seem to me that the energy amplification would be more important than the voltage amplification. I should like to ask Mr. Oakley, therefore, if an indication of the relative energy amplification at different frequencies would not be a more exact representation of the quality than is the voltage amplification?

B. V. K. French: I should like to ask Mr. Oakley about the amount of error in the attenuator used. The attenuator was described, I believe, by A. W. Hull, in the *Physical Review* of 1925, and I wonder if any errors have been calculated?

Another question I should like to ask is, how is the percentage modulation measured on the oscillator defined, and how can we all reach the same agreement on the necessary percentage modulation to simulate broadcast reception conditions?

H. D. Oakley: The point about the quality curves of receivers is at present quite a disputed one. It has already been proposed to measure the power delivered to a loudspeaker rather than the voltage across it. But even in this case, the designers of loudspeakers are not prepared to say whether a definite relation exists between the power supplied to a loudspeaker and the sound received by the ear of the listener. Variations in room conditions cause variation in the sound received by the ear. If we could measure the sound pressure at the microphone of the transmitter and the sound pressure at the ear of the listener, then a true representation of quality for a particular set of conditions could be made. Because so many variables do exist, and because it is more convenient to measure voltage than power delivered to a loudspeaker, our quality curves are plotted in terms of voltage against frequency. We depend a great deal upon past experience in interpreting the picture presented to us by the quality curves.

The other point brought up was concerning the type of inductor used in making the measurements. Calculation of inductance involves a term which is the log of the ratio of the radius of the cylindrical shell to the radius of the rod inside the shell. Slight errors in determining the magnitudes of these two radii will cause a very slight error in the calculated value of inductance. There are two other sources of error. (1) The point at which the rod enters the end plate is grounded. Consequently there may be some current flowing from the point through ground and back into the circuit again. So calculations based upon the assumption that all the current flowing in the rod return through the shell may be slightly in error. And (2) the electric field about the shell will induce voltages in the receiver in addition to those obtained from the tap to which the receiver is connected. This error has been eliminated by enclosing the inductor in a shield. Measurements on the inductance show that it is within 4 per cent of calculated values.

The degree of modulation of the current supplied by the oscillator is expressed by the ratio

$$\frac{A - B}{A + B} \times 100$$

where A is the maximum and B the minimum amplitude of the modulated current. For 50 per cent modulation, A would be three times B. No single value of percentage modulation can simulate broadcast-reception conditions, since the percentage modulation of a broadcast transmitter is continually changing and may be any value from zero to distressing over-modulation. But the audio-frequency output of a properly designed receiver should vary directly with the degree of modulation and for measurement purposes a reasonable value should be satisfactory; 50 per cent modulation was used by us, but there is at least a tentative agreement now to use 30 per cent for all receiver measurements.

High-Frequency Measurements of Communication Lines

BY H. A. AFFEL[1] and J. T. O'LEARY[1]
Member, A. I. E. E. Associate, A. I. E. E.

Synopsis.—*This paper describes briefly a testing technique which has been developed for making line measurements at high frequencies in connection with the application of carrier telephone and telegraph systems in the Bell System. The measurement of line attenuation, impedance, and cross-talk up to frequencies as high as 50,000 cycles is described, using a number of specially developed and standardized high-frequency apparatus units. These include an oscillator, a detector-amplifier, an impedance bridge, a thermo-milliammeter set, a variable attenuator, a cross-talk set, and a frequency meter. A brief description of the individual units is given, as well as their coordinated use in complete testing circuits.*

* * * * * *

PRIOR to the introduction of multiplex carrier telephone and telegraph systems, the operating telephone plant was concerned only with the transmission of frequencies in the voice range. The considerable application of carrier communication systems to long distance open-wire circuits, whereby a pair of such open wires carries several messages simultaneously by the employment of higher frequencies, has however greatly raised the upper limit of the frequency range used in the telephone plant. Among other things, this has required the development of a special technique suitable for the testing at these frequencies of the line circuits over which the various types of carrier systems are operated.

A brief description of this technique was included in a paper delivered before the Institute by Messrs. Colpitts and Blackwell.[2] It is the purpose of the present paper to describe these high-frequency measuring methods in greater detail and as they are now applied with recently improved apparatus.

The high-frequency line characteristics of chief interest are attenuation, impedance, and cross-talk for frequencies up to about 50,000 cycles. It is thought that the interest of others in the measuring methods employed may, perhaps, reside not so much in their novelty, but rather in that they represent a solution of the problem of standardizing the technique of high-frequency measurements for use under practical telephone plant conditions and of a relatively wide-spread application. The apparatus with which the measurements are made has been standardized and is in general use by the operating telephone companies of the Bell System.

Consideration may conveniently be given to the subject matter under two general headings: First, a brief description of the different apparatus units which serve as "tools" for the work; and secondly, the combination of these units in ways needed to effect particular measurements. Simple illustrations of the results attained in the work have been included.

Apparatus Units Employed

The several individual types of apparatus which have been made available are as follows:

1. An *oscillator* providing a source of high-frequency current adjustable to any frequency between 100 and 50,000 cycles and having an output of a high degree of constancy and purity of wave form.
2. A *detector-amplifier* which provides a visual or, by heterodyne action, an audible indicator of high-frequency currents.
3. An *impedance bridge* suitable for measurements within the above mentioned frequency range.
4. A *thermomilliammeter* set which provides for the absolute measurement of relatively weak high-frequency currents and which also incorporates means for calibrating the thermocouples.
5. A *variable attenuator* or resistance artificial line.
6. A *cross-talk set* or variable attenuator of special type used for measuring cross-talk between mutually interfering circuits.
7. A *frequency meter* capable of measuring frequencies between 3000 and 50,000 cycles.

These units are all designed to meet relatively severe requirements of sturdiness, stability, and reasonable simplicity of operation in order that they may be employed generally in the field under conditions of use demanding portability.

Oscillator. Practically all measurements require a source of current variable in frequency, and a satisfactory generator has been made available to meet this need. This unit is a portable vacuum tube oscillator. It supplies current of frequencies variable from 100 to 50,000 cycles. The output is under the control of a potentiometer and provides a maximum power of from 0.4 to 0.7 watt, the exact value depending upon the frequency. The frequency is varied in the usual way by changing the constants of the feed-back circuit. Different values of inductance and resistance, as well as capacitance, are provided in order to insure that the instrument may have a good wave form and stability of frequency. The wave form is such that in the range from 3000 to 50,000 cycles the harmonics do not exceed

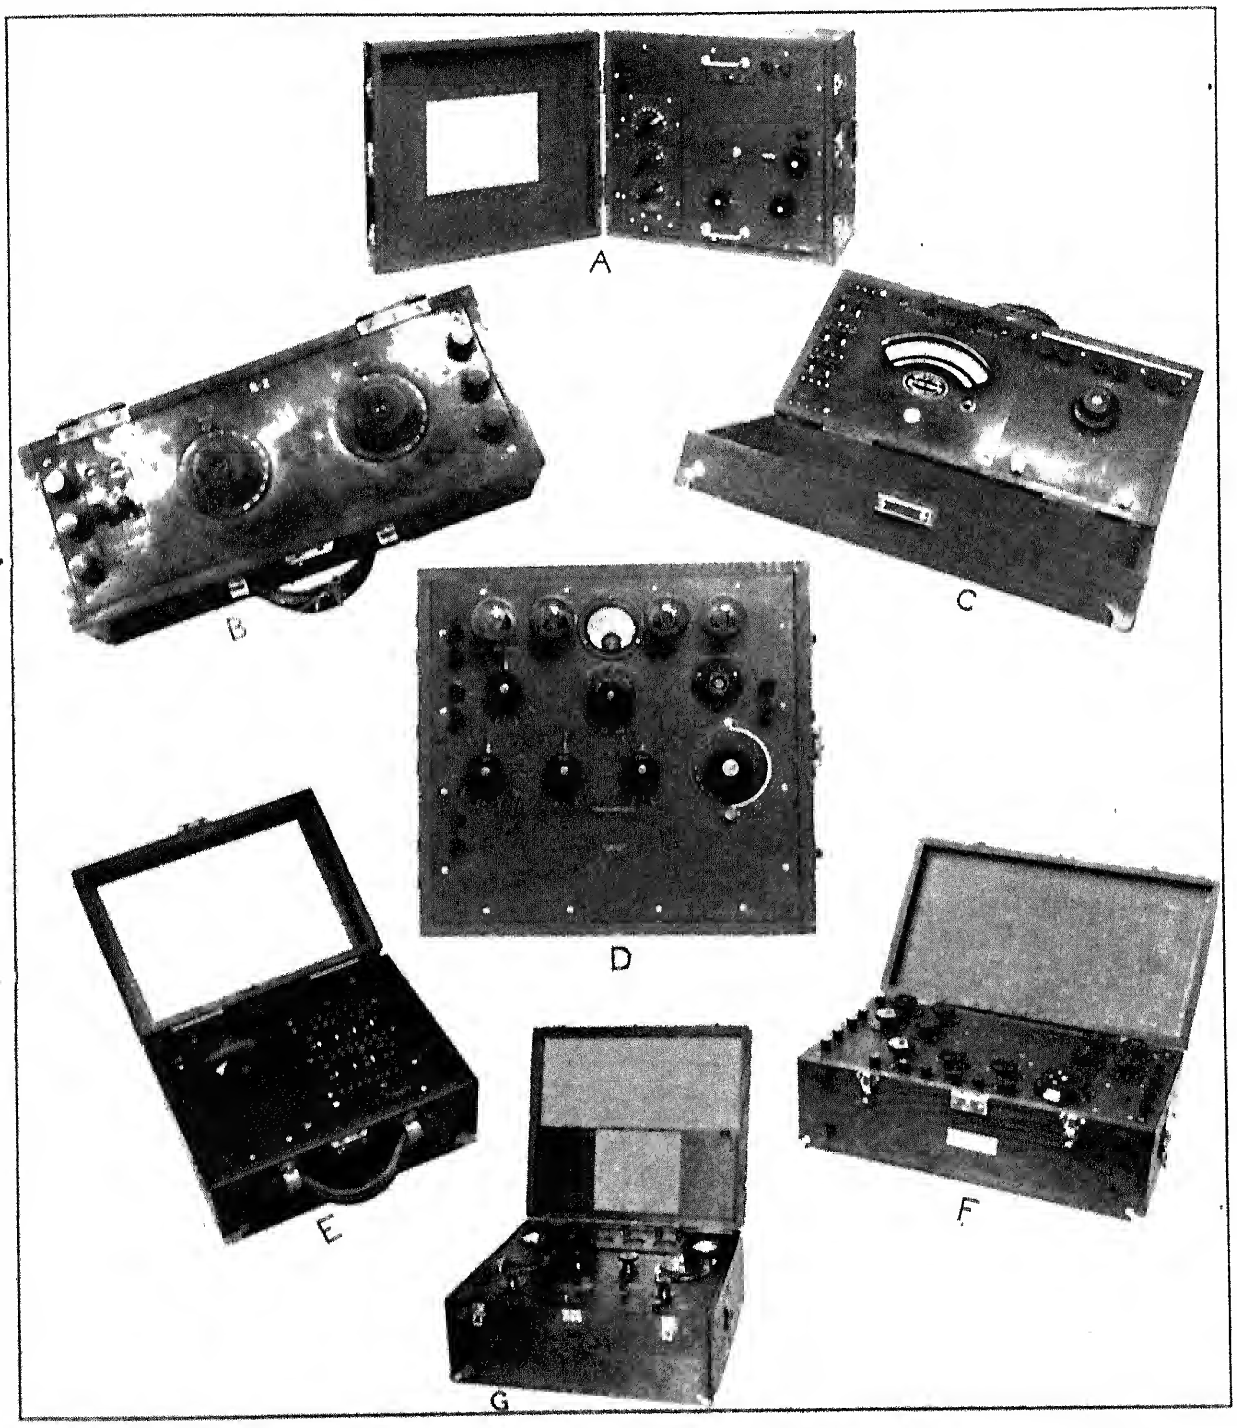
10 per cent. r. m. s. value as compared with the fundamental under the conditions of maximum output.

It is arranged to be supplied by power from the usual telephone office battery sources, plate potential at 130 volts and filament current at 24 volts. Its stability is such that for a temperature range of from 60 deg. to 80 deg. fahr., and battery voltage changes such as are ordinarily experienced the frequency variation does not exceed 0.5 per cent. The maximum variation occurs for the relatively high frequencies, and below 20,000 cycles its temperature stability is considerably better.



A. Frequency Meter; B. Attenuator; C. Thermomilliammeter Set; D. Oscillator; E. Crosstalk Set; F. Impedance Bridge; G. Detector Amplifier

The simplified circuit of the oscillator is shown in Fig. 1. It will be noted that the circuit consists of an oscillating tube and two stages of amplification, the second stage of which is formed by the use of two tubes in parallel in order to meet the necessary output requirements. The various switches and controls will be noted on the face of the panel.

Detector-Amplifier. The detector-amplifier is a sensitive device for detecting visually or by ear high-frequency currents from about 3000 to 50,000 cycles Since it is designed to be employed only in compariso.

measuring circuits or in null measurements, as in conjunction with the impedance bridge, only a limited degree of stability is necessary. When used for aural reception, the apparatus functions as a heterodyne detector, giving an audible note in the telephone receiver by beating the incoming current with a high-frequency current generated by an adjustable frequency local oscillator.

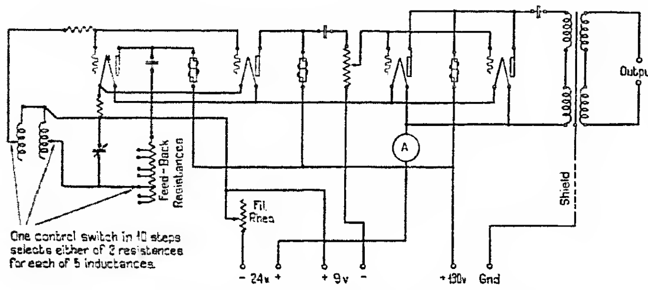


Fig. 1—Schematic Circuit of Oscillator

When the detector-amplifier serves as a visual indicator, the high-frequency current causes a deflection on a meter in the plate circuit of a rectifier tube. In the case of both the aural and visual indicator connections, other vacuum tubes in the circuit provide for substantial amplification.

The simplified circuit diagrams of the instrument, when used as a heterodyne detector and as a rectifier, are given in Fig. 2. It will be noted that four vacuum tubes are available. When used as a heterodyne detector, the first tube provides a stage of high-frequency amplification, the second tube operates as an oscillator to supply the local beating frequency, the third tube is the beat modulator or detector, and the fourth tube operates as an audio amplifier of the beat or tone frequency. The latter is usually adjusted to the order of 1000 cycles. A cam switch affords means for changing the circuit connections so that when employed as a rectifier for visual indication, the tubes provide in sequence two stages of high-frequency amplification and a final "rectifier" stage, using a three-element tube with high C potential. The fourth tube, otherwise employed as an oscillator in the heterodyne circuit, is not operated. The rectifier circuit provides for the indication on a milliammeter circuit noted at the extreme right of the diagram.

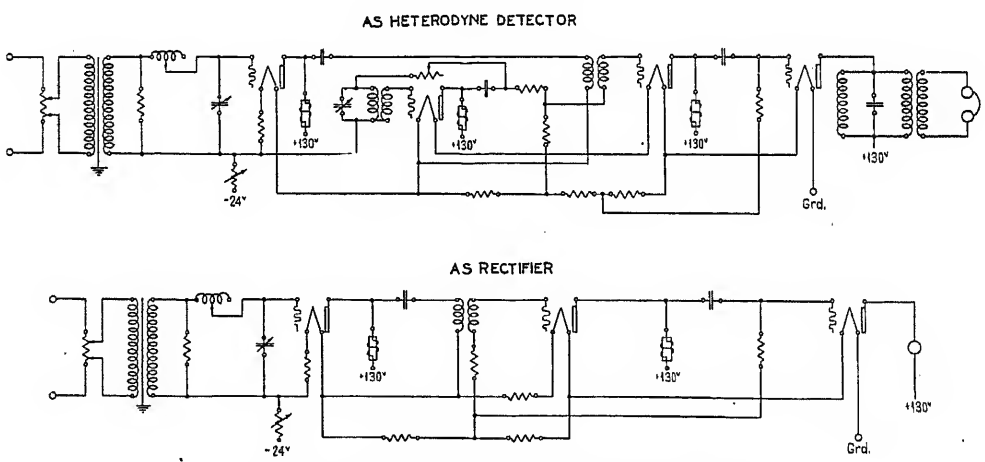

Fig. 2—Schematic Circuits of Detector Amplifier

The circuit in its rectifying connection requires into its impedance of 600 ohms, a current of from 50 to 300 microamperes, depending upon the frequency, for a fair scale deflection of the meter. In the case of the operation of the circuit as a heterodyne detector, the amplification provided is such that an input of only about 0.5 microampere gives a usefully audible note in the telephone receiver.

For many measuring purposes, it is desirable to employ some degree of high-frequency selectivity at the input of the device, and for this purpose a continuously variable tuned circuit is included in the circuit. A potentiometer adjustment at the input is also embodied in the instrument. This has been found to be particularly useful where the input to the circuit may vary in magnitude over a large range, such as in bridge measurements. It is characteristic of devices providing such a high degree of amplification that unless the input is controllable in this manner, an overloading in the rectifier or output stages may result with considerable possibility of confusion and inaccuracy in measurement.

Impedance Bridge. The impedance bridge provides a means for measuring impedances in the frequency range from 3000 to 50,000 cycles. Its greatest accuracy lies in the impedance range from approximately 50 to 10,000 ohms. It is of the balancing or differential coil type, or what, in telephone language, might be termed the "hybrid coil" type of bridge. The balancing coil is a four-terminal type of network, as noted in Fig. 3, having an input circuit to which is applied the source of high-frequency current, a detector circuit, and two balancing arms. When impedances applied to the two balancing arms are adjusted equally, the loss between

the input and detector circuit terminals is infinite; that is, the bridge is balanced as in the case of the ordinary Wheatstone bridge. The balancing coil type of structure offers for this purpose a constructional symmetry and convenient possibility of shielding.

The rheostat arm or adjustable impedance provided consists of a resistance variable from 0 to 10,000 ohms in steps of one ohm, and a capacitance continuously

FIG. 3—SCHEMATIC CIRCUITS OF IMPEDANCE BRIDGE FOR DIFFERENT KINDS OF UNKNOWN IMPEDANCES

variable from 300 micro-microfarads to 11 microfarads. Each of these known impedances is controlled by a separate switch so that it may be conveniently connected into different parts of the bridge circuit. Optional connections permit the variable resistance and capacitance to be connected in series in the balancing arm, or one in series with the line or apparatus to be measured and the other in the balancing arm, or the entire elimination of one or the other.

Thermomilliammeter Set. In measuring the currents which are higher in frequency than the usual power frequencies, the dynamometer types of measuring instruments are not generally satisfactory, and the thermocouple meter circuit has found extensive application. The thermocouple meter circuit is perhaps too

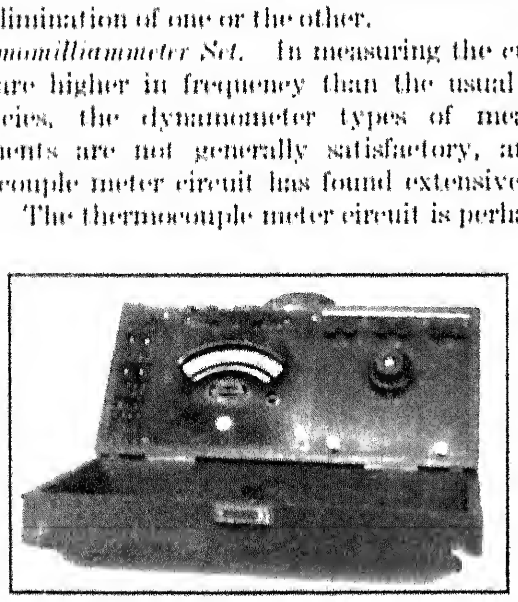

FIG. 4—THERMOMILLIAMMETER SET

well known to warrant any detailed explanations. Such an arrangement using independent thermocouples and meters has been employed extensively in laboratory and field measurements of high-frequency currents. There are cases where greater accuracy is desired than can be insured by relying upon calibrations made at infrequent intervals. For this purpose the portable thermomilliammeter set shown on Fig. 4 was designed. In one unit it provides not only a sensitive meter and several thermocouples, but also a complete calibrating circuit consisting of d-c. power source, rheostat, and d-c. calibrating meter.

The instrument provides for the optional use of one of three thermocouples of different characteristics. The thermocouples are constructed for insertion in bayonet-type sockets, and are thus easily replaced if damaged. The three available couples have the following characteristics:

	Approximate Heater Resistance	Approximate Useful Sensitivity Range
1.	600 ohms	0.2 to 2.0 milliamperes
2.	45 ohms	2.0 to 10.0 milliamperes
3.	5 ohms	10.0 to 50.0 milliamperes

These sensitivities and resistances cover the range ordinarily required in the measuring work on carrier systems in the field.

The instrument is so arranged that the meter, which in its function as a sensitive microammeter is used in the couple circuit of the thermocouple, may be switched

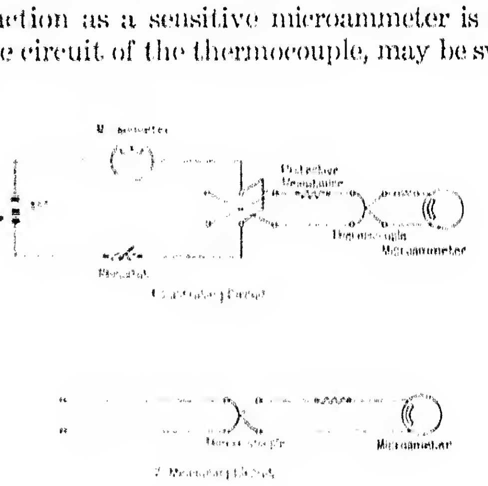

FIG. 5—SCHEMATIC CIRCUITS OF THERMOMILLIAMMETER SET FOR CALIBRATING AND MEASURING

and shunted to provide the calibrating milliammeter circuit. These calibrating and measuring circuits are shown schematically in Fig. 5. The various thermocouples and the meter which make up the instrument are under control of a number of switches which may be noted on the photograph showing the face appearance of the set. Incidentally each thermocouple has its own terminals, and if necessary they may be used independently in the same or different measuring circuits if it is not necessary to read them simultaneously.

Attenuator. The attenuator or resistance artificial line provides a simple type of network of calibrated loss and definite terminal impedances. Schematically, it comprises several sections of *H* type resistance networks as shown in Fig. 6. Since its application is largely concerned with the approximate simulation of open-wire line circuits over which carrier systems are operated and which have a characteristic impedance in the neighborhood of 600 ohms, the attenuator has been designed accordingly to have such terminal impedance.

It covers a range of attenuation extending from 0 to 75 transmission units[3] in steps of 0.5 T. U. The maximum of 75 T. U. is made up in three sections, two of these being controlled by dial switches, one graduated in 5 T. U. steps up to 50 T. U. and the other in 0.5 T. U. steps up to 5 T. U. The third section, consisting of a fixed attenuator of 20 T. U., is controlled by a single key switch. Each of the sections making up the attenuator is shielded to prevent mutual as well as external interference. The resistances making up the network are wound to a high degree of accuracy, and the attenuation derived is substantially independent of frequency in the range up to 50,000 cycles.

Cross-Talk Set. A schematic circuit of the cross-talk set is shown on Fig. 7. This is also a variable attenuator but it has certain circuit differences and includes several switches and provisions for terminating lines which adapt it particularly for cross-talk measurements. The variable attenuator feature consists of five fixed resistances associated with two slide wires which are mounted and controlled simultaneously by a single-handle and dial. Such an arrangement gives an approximate squared relation between input-output

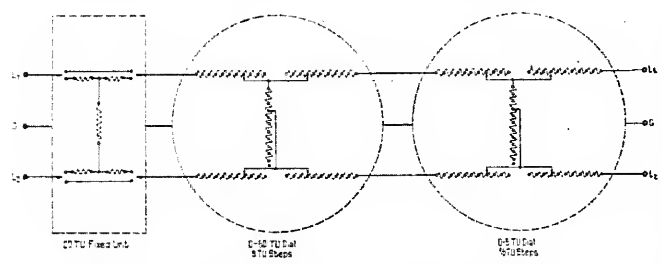

FIG. 6—SCHEMATIC CIRCUIT OF ATTENUATOR

current ratio and dial motion which makes it possible to cover a wide range of attenuation with reasonable accuracy in reading the scales at all points. The scale associated with the dial is calibrated in transmission units as well as so-called cross-talk units; *i. e.*, millionths of the transmitted current. The setting of the slide wire affects the impedance slightly. For ordinary values of cross-talk the impedance is close to 600 ohms, and for extreme values it rises as high as 640 ohms. The attenuator proper is well balanced to ground. This is necessary since it may be connected directly to an open-wire pair.

Switches for connecting the oscillator, detector, and thermocouple meter to various parts of the testing circuits, as required by the different measurements, are included in the instrument.

Frequency Meter. For the purpose of checking the calibration of the oscillator circuit, and for other uses in the telephone plant in connection with adjusting the carrier frequencies of the various systems, a frequency meter has been designed. This is shown in Fig. 8. It provides a means for checking to an accuracy of about 0.1 per cent frequencies in the range from 3000 to about 50,000 cycles.

A null method is employed using a Wheatstone bridge type circuit as shown in Fig. 9. The unknown frequency source is applied to the input of the bridge circuit, and certain known variable elements are adjusted until a balance is obtained, as evidenced by the null deflection or silence in the detector circuit. The

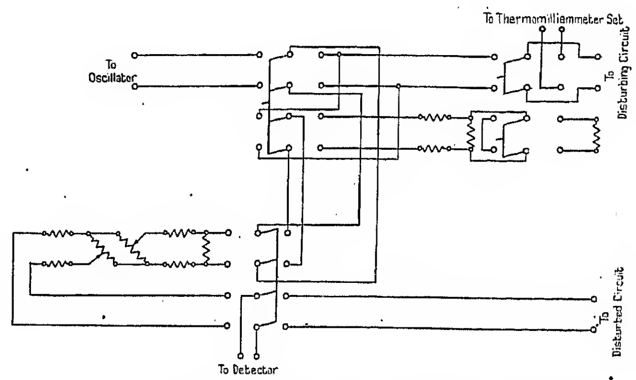

FIG. 7—SCHEMATIC CIRCUIT OF CROSS-TALK SET

bridge includes equal ratio arms and two sets of variable arms. One of the variable arms includes series inductance and capacitance, the other a pure variable resistance. The null point indication is obviously the resonance condition of the series inductance-capacitance circuit, the variable resistance being employed to establish the resistance balance and to compensate for the variation of loss with frequency in the inductance and capacitance. The settings of the different variable elements are of course calibrated with respect to frequency and, in practical use, reference is made to the calibration chart furnished with the meter. The variable elements include two inductance coils of

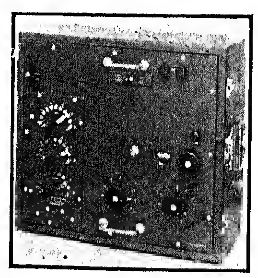

FIG. 8—FREQUENCY METER

optional use depending upon the range of operation, the selection being made by means of a key switch. The condenser includes fixed mica condensers with switching means and a precision continuously variable condenser.

MEASUREMENTS

The most important field use of these several apparatus units is in connection with the following measurement:

3. *The Transmission Unit and Telephone Transmission Reference Systems*, W. H. Martin, TRANS., A. I. E. E., 1924, pp. 797-801

1. Line attenuation.
2. Line impedance.
3. Cross-talk between different lines or pairs.

Attenuation. The general magnitude of the high-frequency attenuation of a circuit for carrier transmission is, of course, predeterminable, but there often exist specific sources of loss which may not be evident until actual measurements of attenuation are made. In a practical case, the carrier system may be applied for operation over a line of perhaps 600 to 1000 mi. in

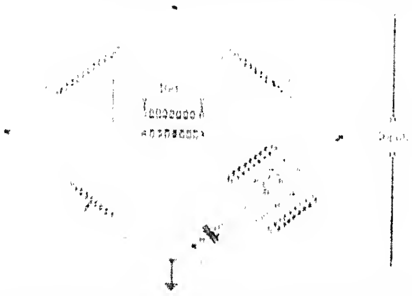

FIG. 9 SCHEMATIC CIRCUIT OF FREQUENCY METER

length. Before the system is installed it is customary to measure the attenuation of this circuit for all frequencies which are employed in the carrier transmission, so that if unusual effects are present, they may be satisfactorily remedied and a minimum attenuation achieved. A long carrier circuit, of course, is usually divided into sections joined by high-frequency repeaters or amplifiers, so that the currents as they are attenuated receive renewed energy at intervals. These intervals may range from 150 to 300 miles, depending upon the type of system employed and the frequencies involved. It is common practise to measure each repeater section separately, chiefly because the measurement of transmission over several repeater sections in tandem, by virtue of the very high attenuation, presents a more difficult problem.

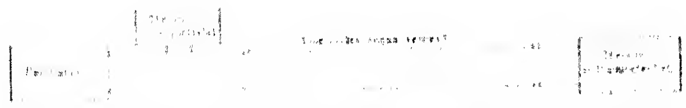

FIG. 10 MEASUREMENT OF ATTENUATION BY CURRENT TRANSMITTED—RECEIVED METHOD

The attenuation measurements are made by either of two methods; the first, a transmitted-received current comparison; and the second, a substitution method involving the use of a variable attenuator.

In the current transmitted-received method the apparatus connections employed are of the simplest type as noted in Fig. 10. At one end of the line, the oscillator supplies high-frequency currents to the pair of wires under test. The magnitude of this current is determined by the use of the thermomilliammeter set. It is common practise to transmit something of the order of 20 to 40 milliamperes and to employ the 5-ohm thermocouple. At the remote terminal of the line under test a thermomilliammeter set is similarly employed to measure received current. The impedance of the receiving thermocouple circuit is chosen to match closely the characteristic impedance of the line in order to simulate the conditions under which the carrier system apparatus is connected to the line circuit in practise. Ordinarily this condition is simply to attain to the required degree of accuracy, since the open-wire line circuits have a characteristic impedance which is close to 600 ohms with no appreciable reactance component. The 600-ohm thermocouple of the thermomilliammeter set used directly, or either of the other thermocouples in that set with the proper amount of resistance in series, provides this termination.

The results of a series of measurements using this type of circuit are usually tabulated or plotted in T. U. attenuation; *i. e.*, the current ratio is converted into the corresponding logarithmic or T. U. equivalent. From these data, it is simple, if desired, to compute the T. U.

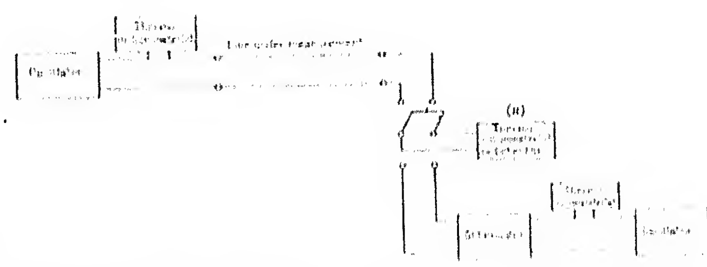

FIG. 11 MEASUREMENT OF ATTENUATION BY SUBSTITUTION METHOD

attenuation per unit length and a comparison can thus be made with the similar characteristics of other line circuits or theoretical data.

The alternative or substitution method is perhaps more useful under conditions in which both the transmitting and the receiving terminal of the circuit under test are at the same point as, for example, in the case of a test involving the attenuation of a piece of apparatus such as a filter instead of a line circuit. It may also, however, be employed for the measurement of attenuation between two remote points, in which case a second oscillator is needed at the receiving terminal. A variable attenuator is also required. The method has an advantage over the transmitted-received current method, in that the attenuation of the line under measurement is determined by the reading of the variable attenuator and the results are available in transmission units directly for each reading without further computation.

The circuit arrangement is as shown in Fig. 11. It will be noted that the transmitting end involves an oscillator and thermocouple set for measuring the output to the line as in the case of the direct measurement noted above. At the receiving terminal, the oscillator provided is similarly connected with a thermocouple circuit to transmit measured current into a variable artificial line. A double-pole, double-throw

switch is provided to connect another thermocouple circuit either to the second terminal of the variable artificial line or to the real line under test. Under conditions in which the current from the transmitting terminal oscillator is adjusted to be the same as that of the oscillator provided at the receiving terminal and transmitting into the artificial line, if the variable artificial line is so adjusted that the received current in the thermomilliammeter set, R, when connected to the artificial line is equal to that received when connected to the real line under test, the reading of the artificial line attenuation is obviously equal to that of the real line under test. Of course this is true only under conditions of exact similarity of impedance in the real line and artificial line circuits, and for most line measurements a simple circuit of this type suffices to measure the line attenuation with sufficient accuracy.

It is to be noted that this method requires no calibration of the final receiving thermomilliammeter set. For this reason, where the current received is extremely small, as would be the case in a line electrically very long, it may be more practicable to employ a more sensitive receiver such as the detector-amplifier.

Using the current transmitted-received method and calibrated thermocouples at the two terminals, it is practicable to measure with the apparatus, which has been described, attenuations as high as from 30 to 40 T. U., which is sufficient for most of the needs in the use of carrier systems in the Bell System. In the substitution method last described and the use of the detector-amplifier circuit as a detector, attenuations up to the limit of the attenuator, which is 75 T. U., may fairly readily be measured. In the latter case this means an energy ratio of about 30×10^6. The accuracy afforded by either of the methods is approximately $\pm$ 0.25 T. U. or abour 3 per cent in current ratio.

The scope of this paper does not permit an extensive discussion of the specific results obtained by the use of measuring methods of this type. It may be of interest, however, to present an example of the results of some attenuation measurements. Fig. 12 is a sample of the results of two sets of measurements on a particular line. In this case it will be noted that the attenuation of the circuit as measured initially presented two substantial absorption points which manifested themselves by "humps" of increased attenuation in the transmission frequency curve. Absorptions of the magnitude of those shown on Fig. 12 are rather extreme and are found only occasionally in practise. Remedial measures in the form of special transpositions made it possible later to remove these absorption humps entirely as shown by the subsequent measurement and thus to present a substantially smooth attenuation for the operation of a carrier telephone system.

Impedance. A line circuit of uniform constants and not subject to any substantial degree to the mutual effect of adjacent circuits such as, for example, occasionally results in absorption points as noted above, has a substantially uniform impedance. In particular, for frequencies above about 5000 cycles, this characteristic impedance is practically uniform resistance with little or no reactance component. This condition, of course, implies a theoretically infinite line or, what is its equivalent, a line terminated in its characteristic impedance. Where the line circuit loses this uniformity—for example, by the insertion of short sections of cable at intermediate points,—the impedance takes on certain characteristic irregularities. In the case of the loading of a cable circuit, if the loading sections are of irregular length by virtue of the non-uniform capacitance of the cable, the non-uniform spacing of the loading coils or the constants of the loading coils, the impedance obviously also loses its uniformity. For many reasons, such uniformity of impedance is ordinarily desirable in the application of carrier systems on the wires, and impedance measurements by the use of the bridge are

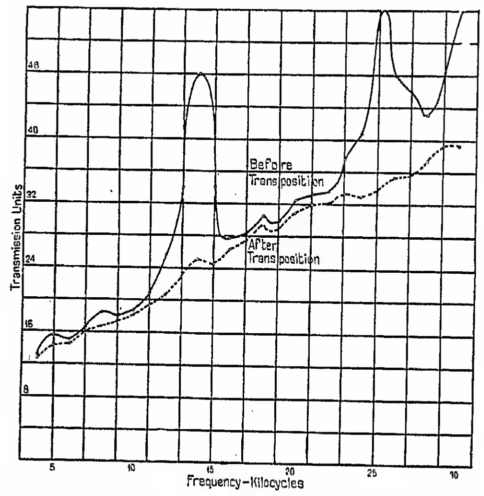

FIG. 12—ATTENUATION OF LINE CIRCUIT BEFORE AND AFTER SPECIAL TRANSPOSITION WORK

commonly carried out in order that where the departures from uniform impedance are such as to exceed reasonable limits, remedial steps may be taken.

In making these high-frequency impedance measurements, the apparatus arrangement shown in Fig. 13 is employed. It involves ordinarily the oscillator, the impedance bridge, and the detector-amplifier. It is also common practise in most measurements to terminate the line circuit under measurement at its farther end in approximately its characteristic impedance. This would generally consist of a resistance of about 600 ohms.

In the operation of the bridge circuit, the manipulations required include first an adjustment of the frequency of the oscillator, then the adjustment of the detector-amplifier circuit for required sensitivity, selectivity, and beating frequency, if the heterodyne method is employed, and finally the adjustment of the balancing arms of the bridge. The heterodyne oscillator of the detector is ordinarily adjusted to provide a note o approximately 1000 cycles. The adjustment of the

balancing condenser and resistance of the bridge results, if properly made, in entire extinction of the received detector note. Under these conditions of course the impedance of the circuit under test is made known.

In the description of the impedance bridge previously given, it has been noted that the connections of the variable resistance and capacitance permit measurements of impedance having either positive or negative reactance or resistance alone. Some experience is

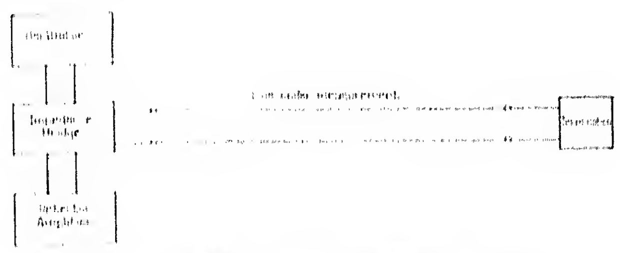

Fig. 13 Measurement of Impedance

obviously required in the manipulation of the circuit, in particular in the case where the reactance component of the unknown circuit is positive instead of negative, in which case it is necessary to switch the variable capacitance to the "unknown" side of the balancing coil. This is not infrequently the situation when measuring a line over an extended frequency range. In obtaining a balance, it is found extremely important to adjust the detector-amplifier circuit in sensitivity so that it is not overloaded, in which case, under some conditions, an increase in input current may actually

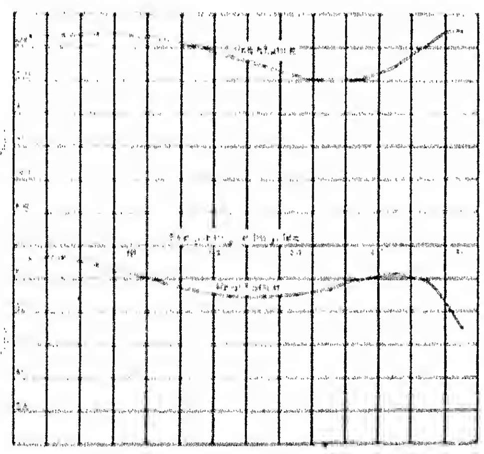

Fig. 14 Impedance of Cable Circuit

cause a decrease in the output tone or current. This gives a false impression that the bridge is approaching a point of balance when, as a matter of fact, it is doing just the opposite. The potentiometer must, therefore, be carefully adjusted so that the minimum gain in the apparatus, consistent with reasonable response in the output of the circuit, is required.

The results of a typical set of impedance measurements are shown in Fig. 14. In this case, the measurements were made for the purpose of establishing the accuracy with which high-frequency loading[4] had been applied to a short section of cable. It will be noted that the measurements show considerable irregularity in impedance, illustrating the presence of perhaps an imperfectly spaced loading coil, a condition which would have to be remedied before the line would be considered entirely satisfactory for carrier service.

Cross-talk. Carrier systems of similar type are not infrequently operated over nearby pairs on the same pole line. Satisfactory operation of the systems in that case depends upon the degree to which the "cross-talk" between the pairs concerned has been reduced. The problem of rendering circuit combinations free or reasonably free from mutual cross-talk at the frequencies employed for carrier systems is one which presents many difficulties. Its solution involves the application of very refined methods of transposing the wires concerned in order to balance out the mutual inductive and capacitive effects. It is common practise, therefore, to make measurements before and after the application of the special transposing work designed to reduce the high-frequency cross-talk.

The measuring of cross-talk is obviously but a specialized form of attenuation measurement. In the case of line transmission, it is desired, of course, that the attenuation of the line circuit be as low as possible so as to permit the ready flow of energy from one terminal to the other. In the case of cross-talk, however, it is desired that the attenuation be as high as possible. The measurement of cross-talk, therefore, involves the reception of extremely weak currents. Whereas, in the case of line attenuation measurements, a thermocouple circuit may be employed at the receiving terminal, in the case of cross-talk measurements, the sensitivity required makes it necessary to provide relatively high gain at the receiving terminal or apparatus of the type of the detector-amplifier.

Measurements of cross-talk involve a transmitting or disturbing line and a paralleling receiving or disturbed line. Where cross-talk is heard on the disturbed circuit at the terminal at which the disturbing current enters its circuit, it is termed "near-end cross-talk." The cross-talk heard at the further end of the circuit is termed "far-end cross-talk." In most cases of carrier system operation, separate measurements are desired to determine the extent of the cross-talk of both types.

In general, cross-talk measuring methods follow in principle the attenuation measurements by the substitution method which has been previously described. For this reason, near-end cross-talk measurements are somewhat simpler than far-end cross-talk measurements. Fig. 15 shows the connections of the cross-talk set when employed for near-end cross-talk measurements. As noted previously, the cross-talk set, itself, provides not only an attenuator circuit but certain switching means indicated schematically by the pair of double-

4. *Development and Application of Loading for Telephone Circuits*, T. Shaw and W. Fondiller, Trans., A. I. E. E., 1926, p. 268.

pole, double-throw switches A. The cross-talk set is employed in conjunction with an oscillator and a detector such as those previously described. For the right-hand position of switch A, the circuit provides for switching the oscillator output to the cross-talking or disturbing circuit. At the same time, the detector is switching to the disturbed circuit. Upon throwing the switch to the left, the disturbing and disturbed

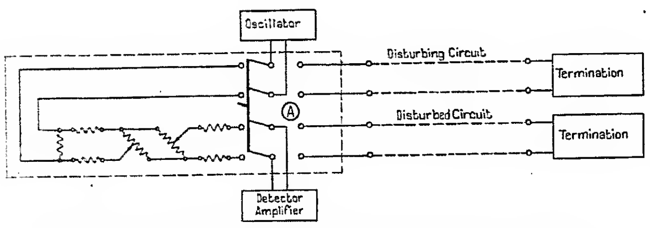

FIG. 15—MEASUREMENT OF NEAR-END CROSS-TALK

circuit connections are removed and there is substituted the attenuator portion of the cross-talk set. Carrying out a measurement involves the adjustment of the attenuator dial to such a position that when the switch is thrown alternately left and right, approximately equal deflections or sounds are obtained in the detector circuit. The reading of the cross-talk meter dial then indicates directly the attenuation or cross-talk between the circuits under test. This may be read in T. U. or in cross-talk units.

Where far-end cross-talk is being measured and the disturbing and disturbed terminals are at remote points, a more complex circuit arrangement is employed. If attenuation is also to be measured means, such as the thermomilliammeter set, are required for adjusting the output of the oscillator at the sending terminal and for noting the received current at the receiving terminal of the disturbing circuit. The circuit connections are shown in Fig. 16. At the sending end or disturbing end, the oscillator is adjusted to the frequency at which the measurement is desired and connected to the dis-

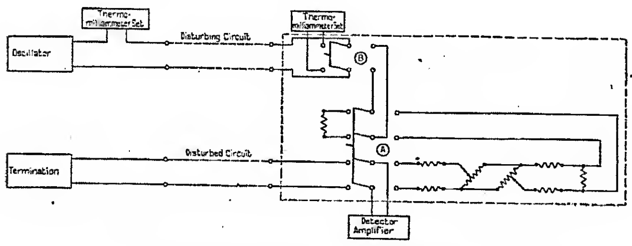

FIG. 16—MEASUREMENT OF FAR-END CROSS-TALK

turbing circuit through the thermomilliammeter set. The disturbed circuit at this point is terminated in its characteristic impedance. The amount of current flowing into the disturbing circuit is recorded. At the receiving end, through the double-pole, double-throw switch B, a similar thermocouple set is connected to the disturbing circuit and the current reading there is also noted. A comparison of the current readings at the two terminals obviously measured the attenuation of that circuit in a manner similar to that described under "Attenuation."

The switching key B is then thrown to a position which disconnects the receiving circuit thermomilliammeter set and connects the receiving end of the disturbing circuit to the switching key A. Under these conditions, when the switching key A is thrown to the left, the cross-talk received in the disturbed circuit is led to the detector-amplifier where it produces a meter deflection or an audible tone. At the same time, the disturbing circuit is properly terminated. When the switching key A is thrown to the right, however, the current at the receiving terminal from the disturbing circuit is led through the variable attenuator and thence into the detector. Here again, by throwing the key A back and forth, an adjustment can be made in the attenuator circuit so that approximately equal deflections or tones are noted in the detector for the two positions of the key. Under these conditions,

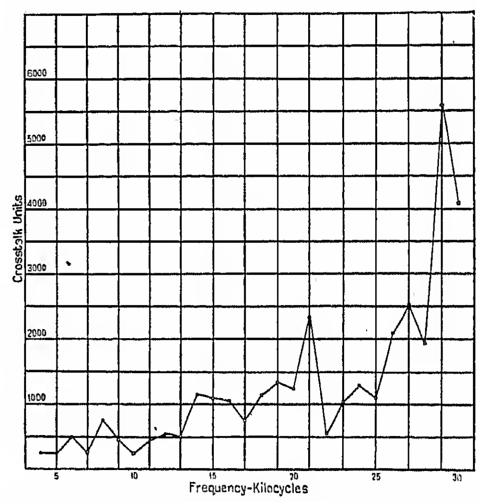

FIG. 17—CROSS-TALK BETWEEN TWO OPEN-WIRE LINES IN CLOSE PROXIMITY

the reading of the cross-talk set dial is a measure of the far-end cross-talk; *i. e.*, it is a measure of the comparative current received from the disturbing and disturbed circuits. It is sometimes useful to obtain an equivalent comparison of received current as noted on the disturbed circuit with the transmitted current as it enters the disturbing circuit, and it is obviously necessary to multiply the measured cross-talk by a factor which is the attenuation ratio of the disturbing circuit as measured initially.

The results of a typical set of cross-talk measurements at high frequencies are shown plotted in Fig. 17. The circuits involved pairs of wires in close proximity and these wires had been previously transposed for the distance of approximately 85 mi. in a special manner to reduce the cross-talk for carrier system operation. It will be noted that as might be expected, the cross-

talk increased rapidly with frequency, and it presents irregularities with frequency which are the result of the phase and magnitude reactions in a relatively complex electrical circuit.

Conclusion

The various measurements which have been described give a representative picture of the testing work which may be done in preparing a wire circuit for the installation of a carrier system. Such tests are also occasionally made in clearing troubles which may appear from time to time.

The measuring methods and apparatus employed are the results of the coordinated efforts of numerous engineers in the Department of Development and Research of the American Telephone and Telegraph Company and the Bell Telephone Laboratories. Particular credit is due those at the last mentioned institution who are responsible for the design of the individual testing units.

Methods of Measuring the Insulation of Telephone Lines at High Frequencies

BY E. I. GREEN[1]
Associate, A. I. E. E.

Synopsis—*This paper outlines the problem of measuring the insulation of open-wire telephone circuits in the frequency range from 3000 to 50,000 cycles, and discusses a method which has been used in the experimental study of insulator losses at these frequencies. The paper includes a description of a special line which has been constructed for the testing of insulators, an explanation of the essentials of the measuring technique, and a brief summary of the results which have been obtained.*

MEASUREMENTS involving the transmission of high-frequency currents over open-wire telephone lines began in the Bell System about 10 years ago, as a preliminary to the application of the first carrier telephone and telegraph systems.[2] Since that time, more or less continuous study has been given to the different problems involved in the transmission over line circuits of carrier frequencies ranging from about 3000 to 50,000 cycles. From the beginning it was apparent that the attenuation of open-wire line circuits at these higher frequencies is very much greater than in the voice range of frequencies, and undergoes wide variations due to changing weather conditions. Inasmuch as the attenuation is one of the most important factors in high-frequency transmission, its investigation has been very actively prosecuted along both theoretical and experimental lines.

The fundamental problem which originally presented itself was that of segregating the different losses which are experienced by the high-frequency energy transmitted over an open-wire circuit. It was obvious that a substantial part of the increased attenuation at high frequencies resulted from the increase in wire resistance due to skin effect, but it was equally obvious that other sources of loss were also contributing in large measure to the attenuation. It was known that radiation was a negligible factor in the line losses. It was known also that the "leakage" of the insulators increased rapidly with frequency, and that there was no direct relation between the high-frequency leakage and the d-c. leakage, which had previously been used as the principal criterion of the condition of the insulation of circuits, but information regarding the precise nature of the leakage losses at high frequencies was lacking.

The theory underlying computations of the skin effect resistance of conductors was well established at that time, and the effective resistance of the wires could be readily determined. In order to study the other losses properly, however, it was necessary to develop methods and apparatus for more accurately measuring their magnitude. These methods and apparatus, and their application in practise, form the subject of this paper.

Theory of Leakage Measurement

Transmission over wires at high frequencies is accomplished in precisely the same manner as transmission at low frequencies, the wires acting as the guiding medium for the energy in both cases, and the same fundamental equations may be applied to both. The rate of attenuation for a uniform line circuit which is terminated so as to avoid reflection effects may, therefore, be determined by means of familiar transmission formulas. The attenuation constant α determines the decrease in magnitude of the voltage and current transmitted over the circuit, according to the equations

$$\frac{E_2}{E_1} = \frac{I_2}{I_1} = \epsilon^{-l\alpha} \qquad (1)$$

where E_1 and I_1 are the voltage and current at the sending end of a section of the circuit, and E_2 and I_2 are the voltage and current at a point distant l units from the sending end.

The value of the attenuation constant at any frequency may be derived from the so called "primary constants" of the circuit, which are as follows:

R = series resistance in ohms per unit length,
L = series inductance in henrys per unit length,
C = shunt capacitance in farads per unit length,
G = equivalent shunt leakage conductance in mhos per unit length.

These constants determine the value of the well-known expression

$$\gamma = \alpha + j\,\beta = \sqrt{(R + j\,\omega\,L)\;(G + j\,\omega\,C)} \qquad (2)$$

of which the attenuation constant is the real part.

The symbol G in the above equation represents the "equivalent" leakage conductance. It is convenient to make this equivalent value of G include all of the a-c. losses suffered by the energy transmitted over the pair except the actual $I^2 R$ loss in the wires themselves.

An obvious method of finding the value of G under such conditions is that of measuring the attenuation of a section of line and computing G by means of the attenuation formula, using known values of R, L, and C. This method has been used quite extensively, and is of

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-27, 1927.

considerable value. Unfortunately, however, its use requires, for accurate results, a section of line of the order of at least 100 miles in length. Any important changes in a line of such length are quite expensive, and this method is consequently not well adapted to the experimental study of the equivalent leakage conductance obtained for different line arrangements and different conditions of insulation.

A much more satisfactory method for this purpose is to measure the leakage conductance on a short line. If the line is short enough to make propagation effects negligible, its impedance measured with the far end open will be

$$Z_x = \frac{1}{G + j\,\omega\,C} \tag{3}$$

and the value of the leakage conductance may be obtained directly.

The determination of the maximum length of line for which propagation effects are negligible is comparatively simple. The problem is merely that of making the length of the test line a small enough fraction of a wavelength to produce only a small phase change in the current or voltage transmitted over the line. It can be shown that when the total phase shift on the line does not exceed five degrees it may be neglected without appreciable error. Now the phase shift for an open-wire pair is approximately two deg. per kc. per mi. Hence, if the phase shift which is allowed is not to exceed five deg., and the measurements are to cover the frequency range up to 50 kc., the maximum length of line which can be measured is evidently 0.05 mi., or about 250 ft. It has been found that the use of lines whose length does not exceed this value gives quite satisfactory results.

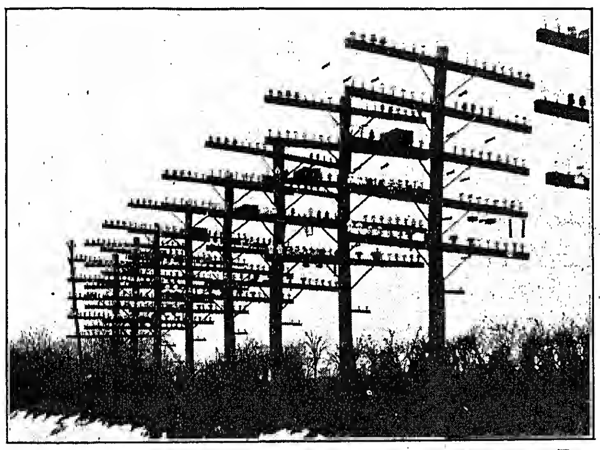

FIG. 1—INSULATOR TEST LINE AT PHOENIXVILLE, PA.

It should not escape attention that the use of a short line for measurements of the equivalent leakage conductance also involves the assumption that the short line provides all the sources of loss which are present on a longer line of, say, 100 mi. in length. The validity of this assumption has been tested by comparing the results obtained on a short line with those for a long line, and the comparison has shown that, whereas if the long line is infrequently transposed there may be some absorption of energy due to currents induced in the other circuits on the lead, the installation of transpositions required for minimizing high-frequency cross-talk ordinarily reduces such losses to a negligible value. This is only another way of saying that the shunt losses on a well transposed open-wire line occur almost entirely at the insulator points. This fact is one of outstanding importance, since it means that the insulation losses may be determined on a short line on which a considerable departure from the spacing of the insulators and the wires on a standard long line is permitted. The method of determining the leakage conductance on a short line is, therefore, extremely advantageous in the study of the effectiveness of different types of insulators at various frequencies and under various weather conditions.

INSULATOR TEST LINE

There is illustrated in Fig. 1 a short line which has been built near Phoenixville, Pennsylvania, for use in comparing the effectiveness of different types of insulators at high frequencies. This line includes about 25 poles spaced about seven ft. apart. A six-in. spacing between wires is used in order to make provision for the installation of a larger number of different types of insulators than could be obtained with standard wire spacing. About 40 different types of insulators are actually installed on the line in the picture.

In constructing this line, it was found convenient to make the length and spacing of the wires such that the value of the wire capacitance obtained was less than the minimum value desired for measuring purposes. With this arrangement, the capacitance may be increased to any desired value by shunting a condenser across the wires. The number of insulators installed on the wires was made slightly greater than the minimum value which was deemed essential for accurate measurements.

For a line only 175 ft. long, on which problems of external interference or interference between circuits do not exist, it might be supposed that the installation of transpositions would be useless. Upon investigation, however, it was found that an unbalanced relation between the two wires of a pair and the adjacent wires might produce appreciable loss at high frequencies. Accordingly, a simple transposition scheme for balancing the different capacitances between wires was devised and installed.

Owing to the comparatively small number of insulators employed on the line, it was necessary, in bringing the wires into the test station, to use every possible precaution in order to avoid having the entrance losses comparable in magnitude with some of the insulator losses which it was desired to measure. This difficulty has been obviated by the use of several interesting expedients which are illustrated in Figs. 2 and 3.

Fig. 2 shows the pole at the entrance to the test station, while Fig. 3 shows the entrance arrangements at close range. Each wire is brought into the test station through a glass tube. A special arrangement of glass shields or baffles is built over the entrance, the three narrow panes used for this purpose being barely

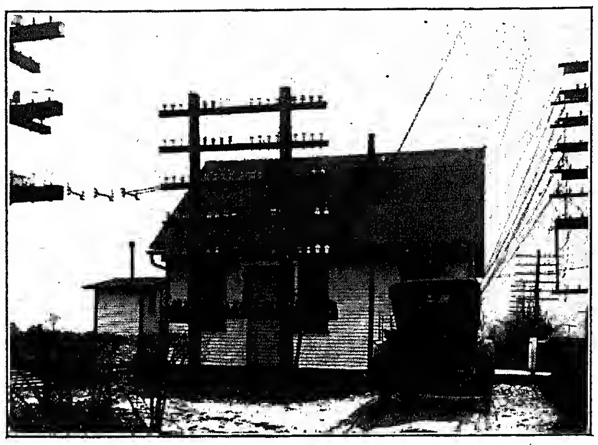

Fig. 2—Entrance Pole on Insulator Test Line

discernible in the picture. In order to prevent rain from running down the wire to the glass tube, each wire is equipped with a drip washer. Springs are used to keep the wires taut.

Testing Technique

For a test line short enough to avoid propagation effects, the impedance which is to be measured may be considered as a single conductance shunted by a given value of capacitance. This is equivalent, of course, to a leaky condenser, and a bridge method similar to those

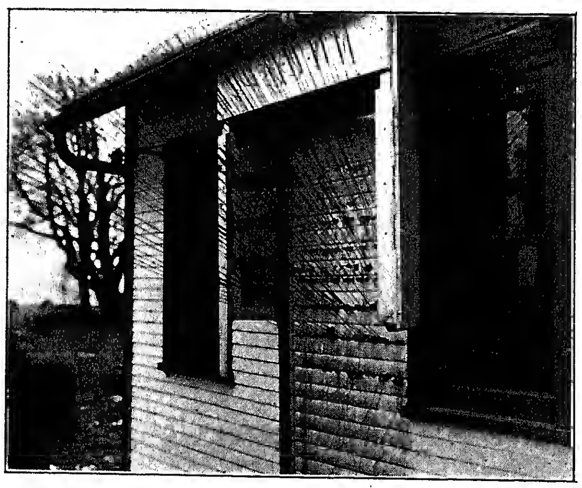

Fig. 3—Details of Entrance to Test Station

which have been employed for the determination of the loss angle or power factor of a condenser may be used in this case. Since the line wires have a large capacitance to ground, however, it is important that the bridge should be well balanced to ground.

The general arrangement of the bridge and associated apparatus used in a typical measurement of carrier-frequency leakage conductance on the test line at Phoenixville is shown in schematic form in Fig. 4. An illustration of the physical disposition of the apparatus is found in Fig. 5.

The salient feature of this bridge arrangement is a specially designed transformer consisting of three air-core coils mounted in a shielded container. In accordance with telephone parlance, this three-winding transformer is ordinarily termed a "hybrid coil." The hybrid coil type of bridge is well adapted for use in measuring impedances whose center is at ground

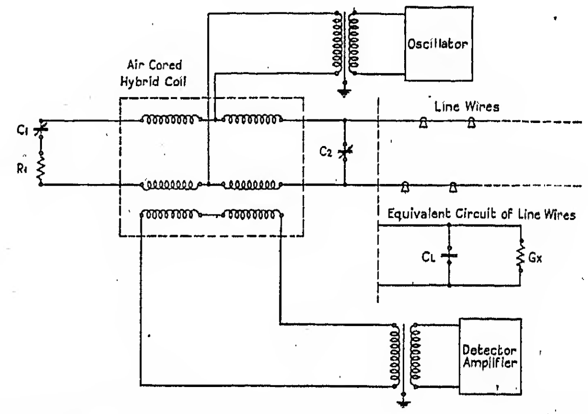

Fig. 4—Schematic Circuit for Measurement of Carrier Frequency Leakage Conductance

potential since the capacitances of the windings to ground can be balanced. The details of the design of the air-cored hybrid coil are illustrated in Fig. 6, the most important feature being the use of bifilar wire for

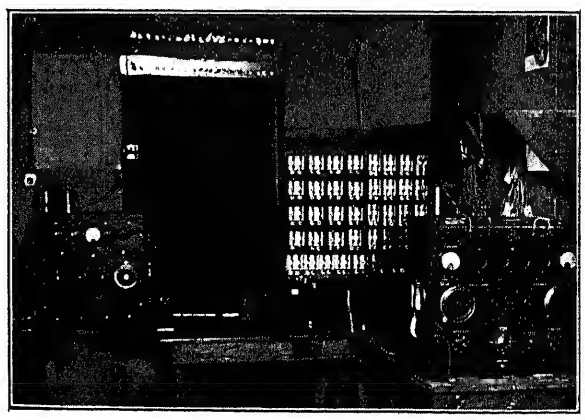

Fig. 5—Arrangement of Apparatus for Measurement of Carrier Frequency Leakage Conductance

the two windings to which the oscillator terminals are connected.

The source of high-frequency current for the bridge is a vacuum tube oscillator, and the detecting means is a detector-amplifier, both being of the types which are described in a parallel paper.[3] It is ordinarily assumed

3. *High-Frequency Measurements of Communication Lines*, H. A. Affel and J. T. O'Leary, Trans., A. I. E. E., 1927. p. 504.

that the loss in the air condensers used in the measurement is negligible. In order to justify this assumption, considerable care must be exercised in the selection of the condensers.

In the frequency range under consideration, the equivalent resistance of a small number of insulators in parallel is quite high and is therefore difficult to duplicate on the standard side of the bridge. It is well known, however, that a condenser having some dissipation of energy may be considered, at a given frequency, as equivalent to a hypothetical resistance either in series or in parallel with a perfect condenser. Hence the line impedance, which resembles that of a condenser and resistance in parallel, may be simulated on the standard side of the bridge by a resistance and condenser in series. The range of values of standard resistance required with this arrangement can be physically realized without difficulty.

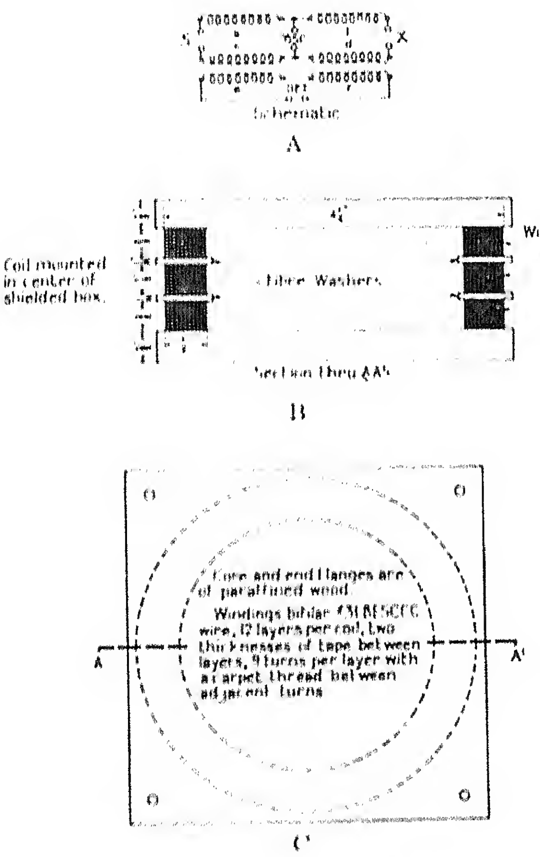

Fig. 6 Construction of Air-Cored Hybrid Coil Used in Leakage Tests at Phoenixville, Pa.

Instead of employing the obvious method of adjusting the capacitance on the standard side of the bridge to equal that on the line side, use is made of a method which is much more convenient for the computation of results. With this method the capacitance on the line side of the bridge is adjusted to the capacitance on the standard side. Thus condenser C_1 is kept at a fixed value, and the capacitance balance is obtained by varying the setting of condenser C_2 which is shunted across the line. The resistance balance is obtained by adjusting R_1. Only the frequency and the value of R_1 need be recorded for any measurement.

The theory by which the recorded values of R_1 and frequency in combination with the known value of C_1 may be converted into the desired value of leakage conductance is outlined in the Appendix, where it is shown that the unknown leakage conductance G_x is given by:

$$G_x = R_1\,\omega^2\,C_1^2 \tag{4}$$

This equation shows why it is unnecessary to read the value of condenser C_2 used on the unknown side of the bridge. It also indicates the dependence of the value of the balancing resistance R_1 upon the total capacitance on the unknown side of the bridge.

The balancing of the bridge is a rather delicate matter and extreme care is required in order to secure accurate results. The reason for this will be apparent when it is noted that the reactance represented by C_1 may be, in dry weather, several hundred times the value of the resistance R_1. The difficulty of attaining a high degree of accuracy in the reading of R_1 when the voltage across it is only a few thousandths of that applied to the bridge, scarcely needs to be pointed out.

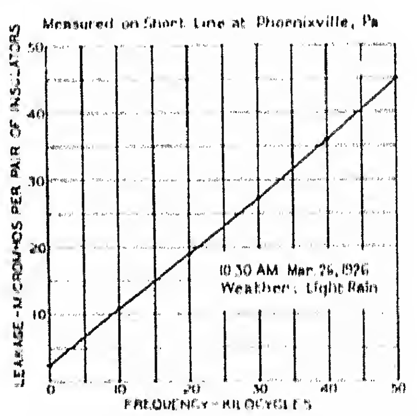

Fig. 7 Typical Curve of Measured High-Frequency Leakage Conductance

In setting up the apparatus, every precaution is taken to avoid any stray pick-up of the oscillator output in the bridge or detector circuits. Such a mischance is ordinarily obviated by keeping the various pieces of apparatus well separated.

The results of a typical set of measurements of leakage conductance at different frequencies are plotted in Fig. 7. As indicated in the figure, it is ordinarily desirable to record in some detail the weather conditions which prevail at the time when the measurements are made. In the correlation of the measured values of leakage conductance with the weather variations, a recording rain gage has been found very useful for indicating the total precipitation and the rate of precipitation throughout any testing period.

The record of the a-c. leakage conductance is generally supplemented by a record of the d-c. leakage

under the same conditions. This latter may be readily obtained with a source of direct voltage and a micro-ammeter or a high-resistance voltmeter. It has also been found desirable to secure continuous records of the d-c. leakage over fairly long periods of time, and for this purpose a recording microammeter has been used with satisfactory results. By means of a multi-record instrument, simultaneous records may be obtained on as

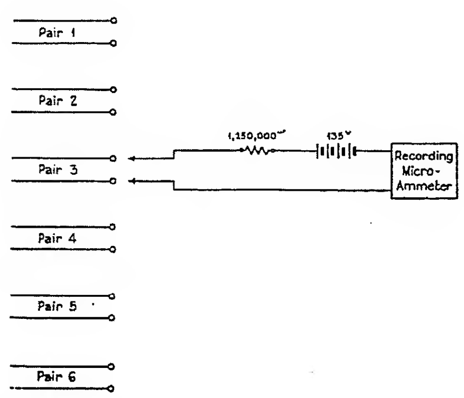

FIG. 8—SCHEMATIC CIRCUIT FOR CONTINUOUS MEASUREMENT OF D-C. LEAKAGE

many as six pairs. The general circuit arrangement for a continuous measurement of d-c. leakage is indicated schematically in Fig. 8, and a sample record for a single pair is given in Fig. 9. The rainfall record corresponding to the leakage measurements of Fig. 9 is presented in Fig. 10.

It has been recognized for some time that a method of

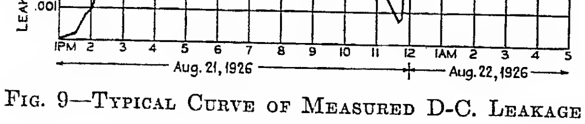

FIG. 9—TYPICAL CURVE OF MEASURED D-C. LEAKAGE

obtaining a continuous record of the a-c. leakage conductance on one or more pairs would be extremely valuable, since it would provide a record throughout the night, when the test station is normally closed, and might economize on testing time during the day. The problem of developing such a method has been attacked from several angles, but no completely satisfactory result has as yet been attained.

CONCLUSION

In conclusion it may be said that the general methods described above have been used at Phoenixville, Pennsylvania, in the study of the performance of various types of insulators over the entire frequency range up to 50,000 cycles. The work has served to illuminate the different phenomena involved in the leakage conductance of open-wire lines, and has made possible an accurate determination of the relative magnitudes of these phenomena. Finally, it has resulted in the development of insulators which have improved characteristics in the carrier range of frequencies and which are now rendering service on many lines of the Bell System.

The author wishes to state that this paper describes work in which a number of engineers of the Department of Development and Research of the American Telephone and Telegraph Company have been engaged. Particular credit is due to Mr. R. N. Hunter, who developed the air-cored hybrid coil, and began the measurements of leakage conductance, to Mr. L. T.

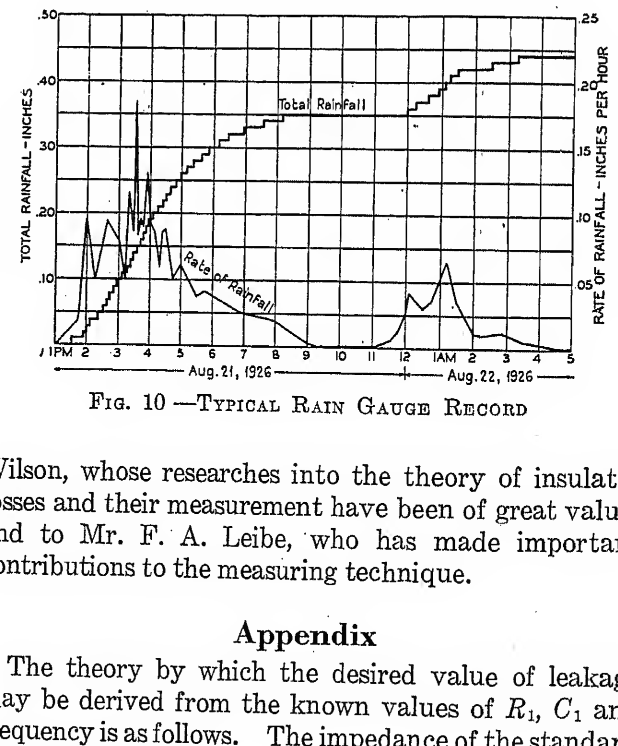

FIG. 10—TYPICAL RAIN GAUGE RECORD

Wilson, whose researches into the theory of insulator losses and their measurement have been of great value, and to Mr. F. A. Leibe, who has made important contributions to the measuring technique.

Appendix

The theory by which the desired value of leakage may be derived from the known values of R_1, C_1 and frequency is as follows. The impedance of the standard side of the bridge is

$$Z_x = R_1 - \frac{j}{\omega C_1} \tag{5}$$

If the total capacitance on the unknown side of the bridge is represented by C_x, ($C_x = C_2 + C_L$), and the leakage conductance by G, then the impedance on that side of the bridge is

$$Z_x = \frac{1}{G_x + j\,\omega\,C_x} \tag{6}$$

This equation may be reduced to

$$Z_x = \frac{\dfrac{1}{G_x}}{1 + \dfrac{\omega^2 C_x^2}{G_x^2}} - j\frac{\dfrac{1}{\omega C_x}}{\dfrac{G_x^2}{\omega^2 C_x^2} + 1} \qquad (7)$$

the values of G which are commonly measured, ase angle will be small enough so that

$$\tan \phi, \text{ which equals } \frac{G_x}{\omega C_x},$$

has a value of approximately 0.01 or less. Hence, no appreciable error is involved in simplifying equation (7) to

$$Z_x = \frac{G_x}{\omega^2 C_x^2} - \frac{j}{\omega C_x} \qquad (8)$$

It follows from (5) that

$$C_x = C_1 \qquad (9)$$

and

$$G_x = R_1 \omega^2 C_x^2 = R_1 \omega^2 C_1^2 \qquad (10)$$

High-Frequency Measurement of Communication Apparatus

BY W. J. SHACKELTON[1] and J. G. FERGUSON[1]

Associate, A. I. E. E. Associate, A. I. E. E.

opsis.—This paper describes precision high-frequency rements of a fundamental type, special emphasis being on the measuring circuits rather than on the types of apparatus red.

ndards of frequency, resistance, capacitance, and inductance are discussed briefly. Bridge measurements are described for the measurement of frequency, inductance, effective resistance, capacitance, dielectric loss, capacitance balance, and inductance balance. Circuits for the measurement of other high-frequency characteristics such as attenuation, gain, cross-talk, and modulation are included.

INTRODUCTION

)NG DISTANCE electrical communication is now being effected by means of frequencies embracing the audible range and extending from there to the alled short wavelengths employed in radio transon. According to the field of usefulness, this e range has been subdivided into the audio, the er, and the radio ranges. From the viewpoint of ower engineer, all of the frequencies embraced in ranges are high frequencies, but to the communicaengineer, only those frequencies in the upper ns are considered high.

this paper we will accept the power engineer's defin and will discuss methods of measurement and suring instruments adapted to the measurement of munication apparatus over this complete range. t of the measuring apparatus described, however, signed particularly for use at audio and carrier uencies. The measuring methods which are dised are intended primarily for laboratory use in ection with the development and inspection of phone apparatus prior to its application in the field. any of the transmission problems in the communin field involve the impedance characteristics of aratus and circuits. In the manufacture of apratus, impedance limits are used to a very great nt in inspection tests. Consequently, quantities prime importance are those defining impedance characteristics; that is, inductance, capacitance, and resistance at specified conditions, of course, such as temperature, frequency, and current or voltage. Other characteristics, of a less fundamental nature but nevertheless of considerable importance, are attenuation, gain, inductance and capacitance balance, cross-talk, flutter, and modulation. Since the three impedance components mentioned above, together with frequency, are probably of more general interest, this paper will be devoted largely to a discussion of their measurement, only brief reference being made to the methods used for the measurement of the latter group of characteristics.

As in all measurement work, standards representing the quantity are required, and these are of two classes, prime standards and secondary or working standards. In our case, the prime standards are resistance and frequency. From these we derive inductance and capacitance. Working standards are stable types of inductance coils, air and mica condensers, adjustable resistances, and for frequency, resonance type meters and highly stable oscillators.

PRIME STANDARDS

Frequency. The standard frequency used is that described by Horton, Ricker, and Marrison[2].

Briefly, it comprises a special self-driven fork held at constant temperature and having all other conditions of operation so thoroughly controlled that a high degree of frequency stability is obtained. The exact frequency is measured by driving synchronously a

phonic wheel for determining the number of cycles occurring in a given time interval. This time interval is usually a period of 24 hr. as measured by time signals received from Arlington. The average frequency of this fork is capable of being held constant and measured in this way with an accuracy of about 0.001 per cent.

The frequency of 100 cycles obtained from this fork is used to drive a 1000-cycle slave fork from which an equally constant 1000-cycle frequency is obtained. Having these frequencies, all other frequency measurements may be made with as high an accuracy as desired by direct comparison, using the cathode-ray tube as described in detail by Rasmussen[3].

Resistance. Resistance standards specially designed for use with direct currents and having a very high degree of stability may be readily purchased or constructed and calibrations to a high degree of accuracy may be obtained from the Bureau of Standards. These resistance standards are not suitable for precision measurements at high frequencies, usually being wound on metal spools, and the value of the phase angle receiving only secondary consideration. It is necessary, therefore, to use resistance standards of special construction depending upon the particular application to be made. In all cases, constancy of resistance with variations in atmospheric conditions, frequency, and time is imperative. Generally as small a phase angle as possible is also highly desirable, although for some uses a suitable degree of constancy may be sufficient provided that the angle is known, and not large enough to affect appreciably the magnitude of the impedance of the resistance over the frequency range used.

To obtain the highest degree of stability of both resistance and phase angle, it has been found desirable to wind the wire on a spool made of a material not affected appreciably by atmospheric conditions, for example, phenol fiber, and to immerse the complete resistance in a sufficient amount of a suitable sealing compound to exclude all moisture. Resistances meeting all of the requirements outlined have been constructed as described in a recent paper by one of the authors.[4] Coils such as described there, having a resistance of approximately 1000 ohms, may be constructed to have an effective inductance of less than five microhenrys, and this inductance is practically independent of frequency up to at least 100 kc. Coils having lower values down to about 10 ohms can be made with equally small phase angles. Below this value of resistance, it is more difficult to hold a low phase angle.

Coils constructed as described may be considered to have so small a change in resistance with frequency that a calibration with direct current may be used without appreciable error for all frequencies at which they are used. Both the variation in resistance with frequency and the phase angle may be most readily measured by comparison with some simple type of resistance of such geometrical form that the phase angle may be readily computed. Satisfactory resistances for this purpose are short lengths of fine wire of definite shape, sputtered metal films on glass or other insulating material, and carbon in the form of rod or film.

SECONDARY STANDARDS

Capacitance. The value of our capacitance standards is determined in terms of the prime standards of frequency and resistance. This determination may be made in several ways, the following bridge method being a simple and accurate one. The circuit, as shown in Fig. 1, consists of two equal resistance ratio arms, a resistance and capacitance in parallel in the third arm, and a resistance and capacitance in series in the fourth arm. When this bridge is balanced at any particular frequency, the relations between the impedance arms of the bridge are such that the value of each capacitance may be determined in terms of the frequency and the two resistances.

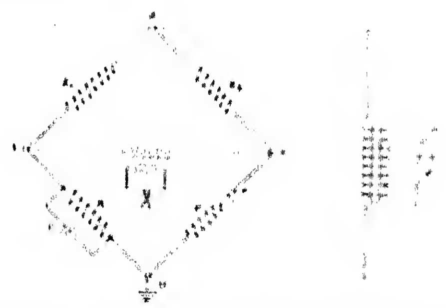

FIG. 1—BRIDGE CIRCUIT FOR MEASURING CAPACITANCE IN TERMS OF RESISTANCE AND FREQUENCY

The requirements for a capacitance standard are high constancy with variations in frequency, time, voltage, and atmospheric conditions, and a small phase difference. Mica has been found to be the best solid dielectric, used either alone or impregnated with a high quality wax such as paraffin. If mica alone is used, the condenser must be sealed to prevent the entrance of moisture.

Good mica condensers can be obtained with a temperature coefficient below 0.005 per cent per deg. cent., and having a variation of less than 0.1 per cent over a frequency range from 500 cycles to 100 kc. Variations in capacitance with voltage are also negligible provided voltages below 100 volts are used. It has been our experience that the paraffin impregnated condensers generally have a negative change of capacitance with temperature. This change is smaller than that of the unimpregnated type which has a positive change with temperature. The paraffin impregnated condensers, however, usually change more with time than the unimpregnated condensers.

Air condensers may be used as standards in small sizes. For the larger values, the air condensers become

3. *Frequency Measurements with the Cathode Ray Oscillograph,* F. J. Rasmussen, A. I. E. E. TRANS., 1926, p. 1256.

4. *A Shielded Bridge for Inductive Impedance,* W. J. Shackelton, A. I. E. E., TRANS. Vol. XLV, 1926, p. 1266.

large and cumbersome and are not as stable as the mica condensers. Even in the smaller sizes, very special precautions must be taken to obtain air condensers which have appreciably smaller phase differences than the mica condensers, which may be made with phase differences considerably less than one minute.

Inductance. Requirements for inductance standards are high constancy with variations in time, current, or saturation, atmospheric conditions, and frequency. It is also desirable that they be made with a small external field. Otherwise, very great care must be taken to avoid errors due to this cause.

In order to obtain stability with variations in saturation, it is usual to make inductance standards with air cores. This requires standards of large physical size if a time constant as large as the average iron core coil is desirable. This large size results in large capacitance distributed in the coil itself and from the coil to ground. These capacitances cause large variations in inductance with frequency and with the position of the coil with respect to ground. On account of this difficulty with air core coils, permalloy[5] as core material has been used with considerable success as described by one of the authors[4].

The calibration of these inductance standards may be made by comparison with any two of the quantities, capacitance, resistance, and frequency. Comparison with frequency and resistance may be made in a bridge circuit exactly similar to the one used for capacitance determination, substituting inductances for capacitances. A comparison with frequency and capacitance may be made by means of a resonant method, and comparison with capacitance and resistance may be made by means of the Owen bridge.[6] The resonant method is used generally except for those cases requiring large capacitance, in which cases the Owen bridge is used.

Frequency. As a secondary standard of frequency for use with the cathode ray tube, where practically only one standard frequency is required, a special 1000-cycle oscillator is used, designed particularly for high stability of frequency with ordinary variations in external conditions. This oscillator is shown in Fig. 2. It allows the use of a cathode ray tube for frequency measurements with a high degree of accuracy under conditions where the prime standard of frequency is not accessible.

Where a portable frequency standard is desirable, for instance, as a means of shop frequency checks, a resonance type of meter is used. This is shown in Fig. 3. It is essentially a resonance bridge circuit consisting of two equal resistance ratio arms, a third arm containing a resonant circuit, and a variable resistance as the fourth arm. The capacitance and resistance are variable over wide ranges by means of decade switches, and the capacitance is capable of fine variations by the use of a form of precision variable air condenser having provision for fine control. There are four air-core inductance coils which give, in conjunction with the

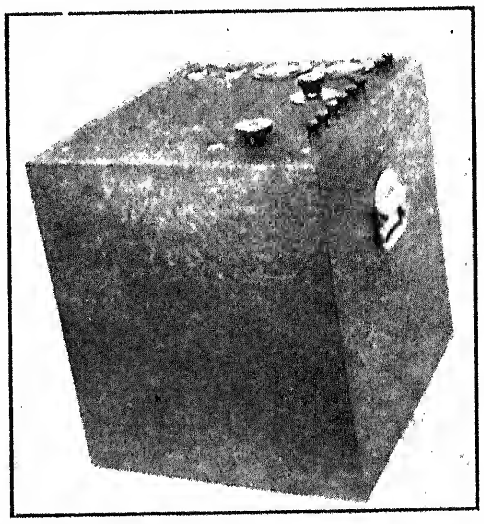

Fig. 2 Single-Frequency Vacuum Tube Oscillator used as Secondary Standard of Frequency

variable capacitance, a frequency range of about 100 cycles to 150 kc.

The meter is calibrated by balancing the circuit by means of the variable resistance and capacitance with a known frequency input, and recording the coil and condenser settings. It is used for checking frequencies

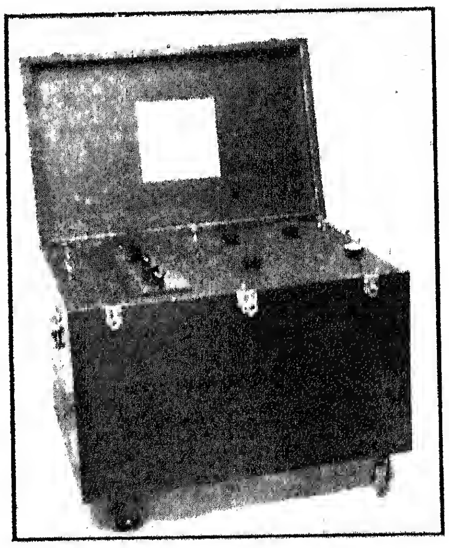

Fig. 3 Resonance-Type Frequency Meter

by reversing the process, that is, connecting the source of unknown frequency to the bridge, balancing as before, and determining the frequency by reference to the calibration. There are no input or output transformers connected to this circuit and on this account certain precautions must be taken in connecting the output and

6. D. Owen, "A Bridge for the Measurement of Self-Inductance," *Proceedings of the Physical Society of London*, October, 1914.

input circuits to it; but it is a relatively low impedance circuit, and troubles due to this cause have not been found serious.

Resistance. A convenient secondary standard of resistance is a dial box having the resistance units designed to meet the same requirements as the prime standards. Commercial dial boxes are available, having satisfactory stability with variations in frequency and atmospheric conditions, and having sufficiently small phase angles for all frequencies but the highest radio frequencies.

A dial box, requiring as it does, a certain amount of wiring between dials, and having all of the dials connected permanently whether they are used or not, always has more capacitance and inductance associated with it than a single resistance of the same value. A certain amount of compensation between the capacitance and inductance may be effected by proper design, but it may be generally accepted that the inductance of the wiring makes the phase angle of the low resistance values comparatively high and the capacitance between dials and between units of each dial makes the phase angle of the high values comparatively high. This effect can only be overcome by a compact design using coils of small physical size. This sets a limitation on coils for use in dial boxes which is not present to such an extent in the case of single resistance units or single value prime standards.

Methods of Measurement

We have discussed already measurements of frequency and resistance in connection with the description of standards, and we will not discuss them further here. We are particularly concerned with the measurement of impedance of all types, it being understood that any resistance having a phase angle which is not negligible or which is of special interest is to be considered a special type of impedance.

In measuring impedances, we have found that those methods which determine the unknown in terms of circuit constants are superior to those requiring the measurement of current and voltage. Accordingly, bridge methods are used almost exclusively, and furthermore, the bridge type which is used wherever possible is the equal ratio arm bridge in which a direct comparison is made of the unknown impedance with a known impedance adjusted to that same value. This type of measurement has the disadvantage of requiring standards of the same value as the quantity measured over the whole range of impedances used, but it has the compensating advantages that, having standards whose value is known, this circuit is extremely simple, very easy to check at any time, and may be made extremely accurate.

Auxiliary Apparatus. Without going into details regarding the auxiliary apparatus used in connection with bridge measurements, we may state briefly that vacuum tube oscillators are used almost exclusively for furnishing all frequencies, and that the telephone receiver is used almost exclusively as a detector, due to its simplicity and the rapidity with which it may be used. For frequencies below 200 cycles, it is used with a chopper to give a tone of about 1000 cycles, and above 3000 cycles, it is used with a heterodyne detector to give a beat note of about 1000 cycles. In the audio frequency range, it is used alone or with an amplifier, if necessary.

While it is impossible to draw a distinct line between the methods of measurement of different types of impedances, certain bridge circuits have been designed primarily for certain types of measurements, and we will therefore classify them in this way, although in general they have a considerably wider sphere of usefulness than indicated.

Inductance. A simple shielded bridge for the measurement of inductance and resistance has been described by one of the authors[4] and is shown in schematic

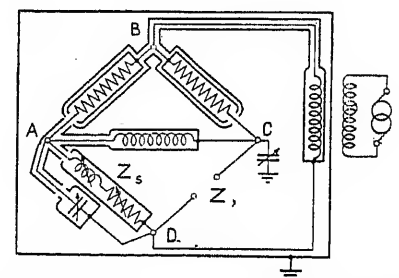

Fig. 4—Shielded Impedance Bridge Circuit

form in Fig. 4. It comprises two equal resistance ratio arms, an adjustable standard of self-inductance, an adjustable resistance standard, a thermocouple milliammeter, two reversing switches, two transformers, and two air condensers. This apparatus is grouped into three separate units, as shown in Fig. 5, one comprising the standards of inductance, one the resistance standard and one the remaining parts of the circuit. Each of these units is shielded electrostatically. The last assembly constitutes the balance element of the system, by means of which the unknown and standard impedances are compared. This unit may be used alone for the comparison of two impedances of any type since the only condition for balance is the exact equality of impedances in the two arms. Using in addition the standard inductance and resistance shown, it is adapted particularly for measuring inductance and effective resistance. The inductance standard may be made with a range from 10 henrys to a minimum of two millihenrys, using an inductometer having a minimum scale division of 0.1 millihenry, or the range may be any simple multiple of this. Values as low as one microhenry at frequencies as high as 150 kc. are measured in this way.

By connecting the resistance in one arm of the bridge and a capacitance in series with an inductance in the other arm, we may use it to indicate resonance, and if we

measure the frequency we may use this method for the comparison of capacitance with inductance. This is the method actually used for the calibration of the inductance standard used with the bridge. The bridge may be used for the comparison of capacitance. The bridge described later for the measurement of capacitance, however, has certain special features which make it peculiarly adapted to the measurement of capacitance and conductance.

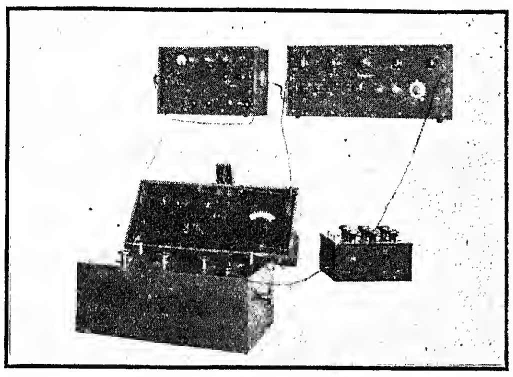

FIG. 5—SHIELDED IMPEDANCE BRIDGE AND STANDARDS, CONNECTED TO VACUUM TUBE OSCILLATOR AND HETERODYNE DETECTOR

Inductance with Superposed Direct Current. In telephone work, it is often of value to know the performance of apparatus, particularly of iron core impedances, when used at telephone frequencies while at the same time carrying direct current. The bridge shown in schematic form in Fig. 6 will measure the inductance of the coil at audio frequency with a direct current flowing through it. As shown in the figure, the direct current is kept out of all of the arms of the bridge except one ratio arm and the test arm, by means of condensers, and the alternating measuring current is separated from the direct current by means of a choke coil. None of these added features affect the bridge balance except the capacitance in the standard arm, and this is made large enough (26 μ f.) to have an impedance small compared with the impedance measured. In any case, a correction may be made by taking first a zero reading which will be slightly positive due to the inductance necessary to compensate for the capacitance in this circuit. This correction will vary with frequency but at 1800 cycles, for instance, with 26-μ f. capacitance, the correction is only about 0.3 millihenry and the inductances measured are usually considerably larger than this.

The circuit is extremely simple and convenient to use. The values of alternating current and direct current can each be measured separately outside of the bridge circuit and the inductance standards do not need to be constructed to carry the direct current. The only part of the bridge required to carry the direct current is one ratio arm and in consequence, it is a comparatively simple matter to construct such a bridge to carry several amperes of direct current. Where very high direct currents are required, the ratio arms may be reactances wound on a single core, instead of resistances, thus reducing the loss due to the passage of the direct current.

Flutter. In telephone circuits used for joint telephone and telegraph service, it is desirable to know the effect of the telegraph impulse on the telephone frequency inductance and effective resistance of the loading coils used on the lines. This effect, known as "flutter," with a method of measuring it, is described in detail by Fondiller and Martin[7]. The measuring circuit consists of a double bridge, the inner one consisting of two similar loading coils on which the flutter effect is to be measured and two other coils of comparatively high impedance approximately equal in value and which have negligible flutter effects, the four coils being connected to form a balanced bridge. The low frequency corresponding to the telegraph impulse is introduced at two diagonal corners and the other two corners, which are at a common potential with respect to the low frequency, are connected to the usual test terminals of an impedance bridge of the type already described. With no low frequency current passing through the coils, a continuous balance may be obtained on the main or high frequency bridge using an audio frequency input. From this, the normal effective resistance and inductance of the coils may be obtained.

When the low-frequency current passes through the coils, the inductance and effective resistance are different for every point of the low-frequency cycle. Thus, only an instantaneous balance of the outer bridge is possible. This instantaneous balance for any particular point in the low-frequency cycle may be made by

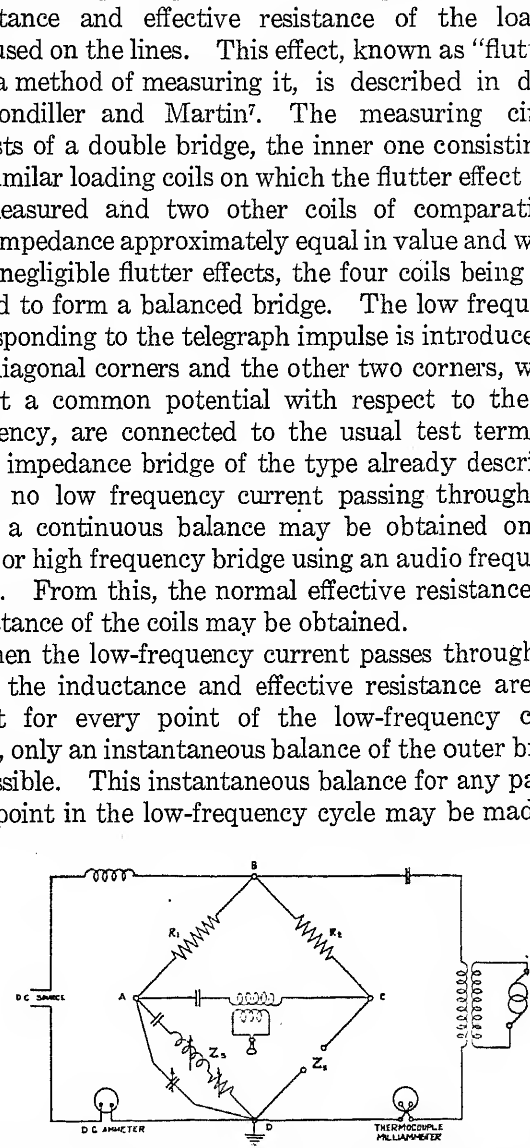

FIG. 6—BRIDGE CIRCUIT FOR MEASURING IMPEDANCES WITH SUPERPOSED DIRECT CURRENT

the use of an electromagnetic oscillograph. By this means as described in the paper already mentioned, it is possible to obtain the curve of variation of inductance and effective resistance of the coil over one low-frequency cycle.

Another method used at the present time employs the same bridge circuit but an entirely different method of detecting the cyclic variation in the balance. This method of detection uses the cathode-ray oscillograph

7. W. Fondiller and W. H. Martin, TRANSACTIONS of the A. I. E. E., 1921, Vol. 40, p. 553.

and is as follows. The low-frequency source is connected across a high resistance and condenser in series, the two having equal impedances. The potentials across the condenser and resistance are then placed respectively across the horizontal and vertical plates of the oscillograph. These two potentials, being equal in magnitude but 90 deg. apart in phase, give a circle on the screen. The output of the main bridge is now connected through a transformer whose secondary is connected in series with the oscillograph cathode

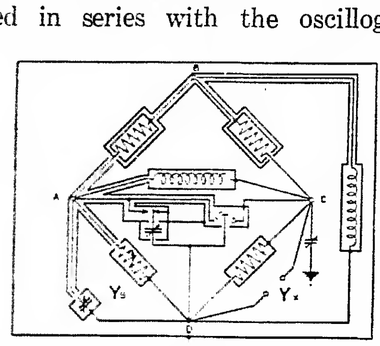

FIG. 7—SCHEMATIC CIRCUIT OF CAPACITANCE AND CONDUCTANCE BRIDGE

potential. Due to the fact that the sensitivity of the tube to deflections by the plate potentials varies with the cathode potential, the radius of this circle produced by the low frequency is a function of the telephone frequency input from the bridge, and instead of a circle we get a band, the width of which is a measure of the degree of unbalance of the bridge. The point in the cycle at which the bridge is balanced, is indicated on the screen as the point where this band diminishes to a line, and the angular position of this point in the band determines the phase position of this balance with respect to the low-frequency cycle. It is possible in this way to balance the bridge for any angular position corresponding to any point in the low-frequency cycle, and by taking sufficient points, to obtain a curve of variation of the coil constants over a complete cycle. This method is found to be simpler and faster than the method using the mechanical oscillograph.

Inductance Balance. A simple form of bridge for measuring inductance balance of the two windings of a transformer or other coil uses the two windings of the transformer for two arms, the other two arms being resistances, one of which at least is variable. The balance is made by means of the variable resistance, the ratio of the two resistances at balance then giving the unbalance of the transformer. If one of these resistances is made 100 ohms, the variation of the other from 100 ohms at balance gives directly the percentage unbalance. Any unbalance in resistance is usually comparatively small and may be taken care of by low resistances in series with the transformer windings.

Ratio of Transformation. A similar bridge may be used for the measurement of ratio of transformation. There are many cases where the secondary of a step-up transformer has an inductance which is inconveniently large to measure directly, and the ratio of transformation circuit eliminates this necessity. The circuit used is practically the same as that already described for measuring inductance balance, the ratio of transformation being equal to the ratio of the resistance arms of the bridge at balance.

Capacitance. The direct comparison of capacitance is made in a special bridge known as the Campbell-[8] Colpitts[9] capacitance and conductance bridge. The ratio arms, input and output circuits, and the shielding, are similar to the impedance bridge already described. The unique feature of this bridge is the method of connecting the standard air condenser to eliminate the dielectric loss in the measurement of capacitance. The schematic diagram of the bridge is shown in Fig. 7. Instead of connecting the standard condensers in the arm *A D* as in the case of the impedance bridge already described, a special switch is used to switch these condensers from *A D* to *C D*, and in the case o fthe continuously variable condenser, the three-plate construction is used, causing a decrease in the capacitance in *C D* as the capacitance in *A D* is increased.

The method of construction of the unit air condensers is shown in Fig. 8. It may be seen from this figure that all capacitances which include dielectric material are permanently connected across *C D* or *A C* and so are not changed when the condenser is switched, or else

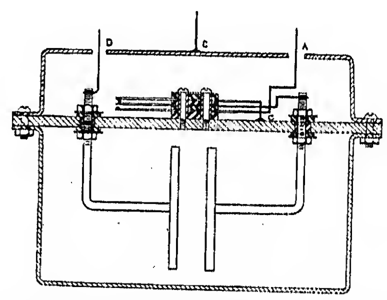

FIG. 8—AIR-CONDENSER CONSTRUCTION EMPLOYED IN THE CAPACITANCE AND CONDUCTANCE BRIDGE

they are switched so that capacitances across *A C*, which do not enter into the bridge balance, are short-circuited on switching. This scheme eliminates all dielectric loss in the standards when measuring condensers by comparison with them. It has the additional advantage that the capacitances in the bridge have twice the effect they would have if simply switched in and out of the circuit.

By the use of this bridge, it is possible to measure capacitances up to the maximum limit of the range of the air condensers with a negligible loss in the standard condensers. This capacitance range is usually up to 0.01 μ f. and for condensers above this value the conductance is measured by comparison with that of the

8. G. A. Campbell, "The Shielded Balance," *Electrical World and Engineer*, April 2, 1904, p. 647.

9. G. A. Campbell, "Measurement of Direct Capacities," *Bell System Technical Journal*, July, 1922, p. 18.

maximum value of the air condenser, assuming it to have negligible conductance. Of course this method of eliminating dielectric loss is not applicable to the use of mica condenser standards and if a range greater than 0.01 μ f. is desired, the mica condensers are simply connected in the usual way across *A D*.

Another feature of this bridge is the method of measuring conductance. The connection of a variable resistance, either in series or in shunt, with the standard condenser for the measurement of loss in the test

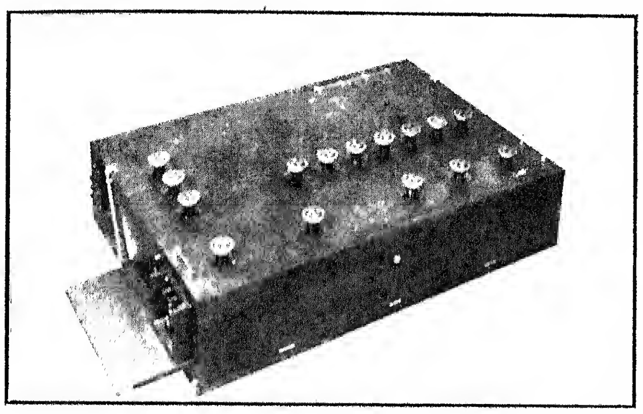

Fig. 9 Capacitance and Conductance Bridge

condenser has objections due to the wide range of resistance values required to cover the possible variations in losses. A compromise is effected in this bridge by connecting a 10,000-ohm shunt across each of the arms *C D* and *A D*. A slight difference in the losses in these two arms can then be measured by varying one of these resistances slightly. Since the standard condenser practically always will have lower losses than the condenser tested, it is usual to place a fixed 10,000-ohm resistance across *C D* and a resistance across *A D* variable in 0.01-ohm steps to 10,000 ohms. A change of one ohm in this resistance, when balancing a condenser, is equivalent to shunting it with a resistance of 100 megohms or 0.01 micromho. Accordingly, the conductance of a condenser may be measured in micromhos by simply dividing the resistance change in ohms by 100. This, of course, is only approximate in the case of large conductances, but is correct to 1 per cent for values up to one micromho.

Due to the condensers forming such an integral part of the bridge circuit, they are all built into the bridge. The complete bridge is shown in Figs. 9 and 10. Fig. 9 is a top view showing the capacitance and resistance dials for effecting a balance, and Fig. 10 is a view with the cover removed, showing the method of shielding the individual parts. The range of capacitance is from 0.1 $\mu\mu$ f. up to three μ f., and the frequency range is from about 10 cycles up to about 150 kc., the only modifications required in the bridges to cover this whole frequency range being a change in input and output transformers, as it is not found practicable to design these transformers to give efficient operation over such a wide frequency range.

A comparison of this bridge with the impedance bridge already mentioned shows it to be essentially the same circuit, the capacitance bridge having conductance shunts not included in the impedance bridge which allow a conductance balance to be made more readily. It is obvious that any two impedances can be compared on this bridge. Inductances may be measured by parallel resonance by simply placing them in the *A D* arm in parallel with the standard condenser and effecting a balance with it. This method is used to some extent for the measurement of large inductances.

Capacitance Unbalance. In order to keep cross-talk low in long cable circuits, it is necessary to have a high degree of capacitance balance between the various conductors in the cable, more particularly between the four conductors of a phantom group. The unbalances of interest are the phantom to each side circuit and the side-to-side unbalances. These may be measured on a capacitance bridge by measuring all of the direct capacitances[9] associated with the group and computing the unbalances required. A special circuit, however, is generally used which measures directly the particular unbalances in which we are interested. It consists of an input and an output transformer, two equal resistance ratio arms, a variable air condenser of the three-plate type, four binding posts for connecting the four conductors of the quad, and switches for making the various connections. By means of the switches, the cable conductors are connected to the circuit in such a way

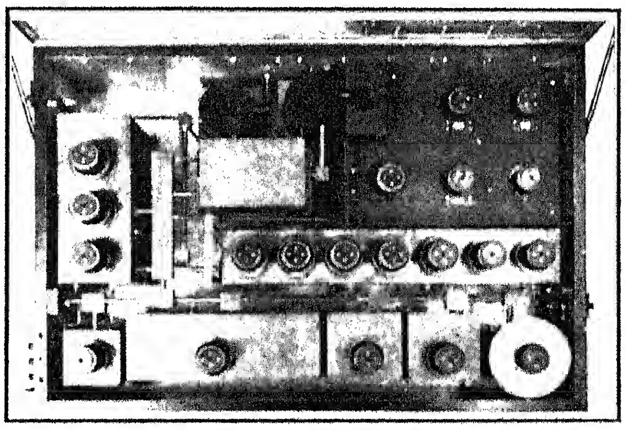

Fig. 10 Capacitance and Conductance Bridge with Cover Removed

Showing method of assembly and shielding

that the reading of the air condenser when a balance is obtained indicates directly the unbalance, either side-to-side or phantom-to-side, according to the switch positions. This circuit is capable of measuring capacitance unbalance as low as 1 $\mu\mu$ f.

Attenuation and Gain. So far, we have discussed the measurement of the fundamental impedance characteristics of apparatus. When the component parts have

been found to meet their individual impedance requirements and are assembled to form the completed apparatus, it is desirable to have tests made of the over-all performance of this apparatus. In a large number of cases, the requirement of greatest importance is the attenuation frequency characteristic. It is fairly obvious that this characteristic, of all apparatus used in telephone lines, is of interest, and this is particularly true of all types of filter circuits which are designed primarily for the purpose of furnishing definite attenuation frequency characteristics. These measurements are particularly required on apparatus used in carrier-current telephony and telegraphy.

From the very nature of the measurements, it is difficult to obtain a null method of measuring attenuation. The most direct method is to measure the input and the output of the apparatus under test simultaneously, from which the attenuation may be computed. The practical difficulty in doing this is to measure the extremely small outputs which are obtained from apparatus having high attenuations, where the characteristic must be obtained with the normal input, which is usually low. In general, it has been found necessary to use some form of amplifying device in the output circuit and it has not been found desirable to rely on the constancy of amplification of this device. Accordingly, the usual method used for the measurement of attenuation is a substitution one. The circuit is shown in Fig. 11A. There are two branches in this circuit, one of which includes the apparatus under test and the other containing a variable standard attenuator. The output of each branch is arranged to connect either to a detector of impedance Z_1 equal to the impedance of the standard attenuator or to a fixed impedance of the same value. If the apparatus under test has the same impedance as the standard attenuator, the input impedances Z_1 and Z_3 are made equal and the matching impedance Z_2 is omitted. Then the two branches of the circuit will be identical, provided the attenuation of the standard attenuator is equal to that of the apparatus under test. Accordingly, the method of measurement is to switch the detector to first one and then the other branch, adjusting the standard attenuator until an equal output is obtained for either switch position. The attenuator then reads directly the loss in the apparatus. The total input of the circuit is independent of the switch position, since the impedance conditions remain unchanged in switching.

If the apparatus under test has not the same impedance as the standard attenuator, the input impedance Z_3 and the matching network Z_2 are adjusted so that the circuit still reads directly.

The standard attenuator is a resistance network capable of variation in small steps, each step consisting of a network of the L, T, or H type, the resistance values being such as to give the desired attenuation between the output and input terminals. It is usually calibrated in 0.1-T. U. steps and may read as high as 100 T. U. corresponding to a ratio of power output to power input of ten billion to one or, if the impedances are the same, which is usually the case, corresponding to a current or voltage ratio of 100,000 to 1.

The calibration of these attenuators is based on the measurement of the individual resistances. Of course, sufficient measurements are made to determine that any capacitances which enter do not affect appreciably the accuracy of the attenuator at the maximum frequency used, which may be as high as 150 kc.

By modifying the circuit of Fig. 11A, we may use it to measure gain as shown in Fig. 11B. In this arrangement, the lower branch contains an impedance Z_4 that is adjusted to introduce a loss equal to that of the matching impedance Z_2 in the upper branch. In other words, with the amplifier under test out of the circuit and the standard attenuator set at zero, the detector will read

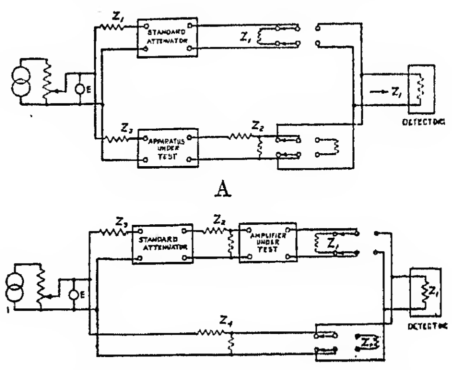

FIG. 11—CIRCUITS FOR MEASURING ATTENUATION AND GAIN
a. Arrangement for measuring loss
b. Arrangement for measuring gain

the same for either position of the output switch. Then when the amplifier is introduced into the circuit, the attenuator is adjusted until the detector reads the same for either switch position, which means that the gain of the amplifier is just neutralized by the attenuator and the setting of the latter is read as gain.

This circuit is used principally for the measurement of gain of audio frequency amplifiers, and is capable of measuring gain as high as 120 T.U. corresponding to a power output of 1,000,000,000,000 times the power input.

Cross-Talk. When there is an appreciable amount of coupling between two telephone circuits, any mutual interference which results is known as cross-talk. It is measured in cross-talk units, a cross-talk unit being defined as the relation existing between the two circuits when the current in the disturbed circuit is one millionth of the current in the disturbing circuit, the impedances of the two circuits being the same. Under these conditions, one cross-talk unit may be assumed the same as 120 T.U. Cross-talk in long toll cables is caused principally by unbalances in the cables and in the loading coils. The cross-talk due to the cable is measured simply by measuring the capacitance unbalance. The cross-talk due to loading coils is of a

much more complex type, produced by a combination of capacitance, inductance, and resistance unbalances in the windings. Since the actual cross-talk caused by an unbalance in the coil is dependent upon all of the conditions of the circuit, it is necessary that any measurement of cross-talk made on the individual coils be made in a circuit as nearly as possible the equivalent of the line in which the coil is to be used. Consequently, all cross-talk circuits for the measurement of loading coil cross-talk consist of networks simulating the impedance of an ideal line of the type for which the loading coil is designed. The principle of the method is to apply to the disturbing circuit a definite input of a single frequency, usually 900 cycles, and to measure the cross-talk in the disturbed circuit at the desired point in it by comparing the tone heard in the telephone receiver connected at this point with the tone obtained from a cross-talk meter which is simply a device for obtaining a definite part of the input, and having a scale reading in millionths, that is, in cross-talk units. The measurement is made by switching from the cross-talk meter to the disturbed line and adjusting the cross-talk meter until the tone heard in each case is the same. The method is therefore not a null method and depends to some extent on the judgment of the operator, but results accurate to one or two cross-talk units may be obtained by this method. The coils as commercially produced after adjustment for this requirement are usually within 10 cross-talk units, representing an unbalance in the circuit due to the coil unbalance of less than one part in 100,000.

Conclusion

We have described in this paper a number of the more important high frequency methods of measurement and measuring circuits. It has been impossible to cover all of the different methods and circuits used, but we believe that the information given will be of value to those interested in this field of work.

We have not been able, in a paper of this type, to go into details concerning any specific circuits used, but we have referred to papers which describe in greater detail some of these methods and circuits, and it is expected that other papers will be published in the future covering other circuits which have received only brief mention here.

Discussion

J. R. Craighead: Will the authors kindly clarify the definition of a crosstalk unit? The definition of a unit as a "relation" is not easy to use for measurement purposes.

N. E. Bonn: Messrs. Shackelton and Ferguson have mentioned a vacuum-tube oscillator the frequency of which they can keep constant to within one part in 250,000 under ordinary variations in external conditions. If this is meant to include variations in plate voltage and filament current, the statement would appear to be at variance with universal experience which indicates that the frequency of vacuum-tube oscillators is profoundly affected by changes in tube impedance. In view of the importance of the subject will the authors please discuss the particular features of their circuit that make it so stable?

W. J. Shackelton: We are very glad to have had Mr. Craighead's comment on the matter of crosstalk. I will not attempt to redefine the crosstalk unit, but will simply try to explain what is meant by it, and then you can make your own definition.

If we have two circuits which, due to some undesired coupling, are so related that the current flowing in one of the circuits causes a current to flow in the second circuit, and if the current so induced (I am assuming that these circuits have the same impedance) is one-millionth part of the current in the circuit causing the disturbance, we say that the relation between the two circuits is such that one unit of crosstalk exists. If the induced current is twice as much the relation is such that we have two units of crosstalk. We don't have two relations, but you see we do have a different relation from that in the first case.

Mr. Bonn has raised some questions regarding the 1000-cycle oscillator. I think he assumed the statement that I made regarding the smallest division of the capacity element of the oscillating circuit to indicate the frequency stability of the oscillator as a whole. I said that the condenser could be set to one part in 250,000, but we do not claim that to represent the stability of the oscillator. We consider that to be, with respect to variation of filament current or plate potential, about one part in 100,000. I will ask Mr. Ferguson to explain in a general way how it is that we are able to obtain that degree of stability.

J. G. Ferguson: The frequency variations of the current in any oscillating circuit are due to a number of causes. One of the principal causes of variation would be variations of load. This is taken care of in this particular case by the use of one tube for an oscillator and a second tube as the amplifier. The load taken by the amplifier does not affect appreciably the oscillating circuit.

A second cause of variation is the variation in the level of oscillation in the oscillating circuit itself. In this case, we have to deal with only a single frequency, and it is possible to design the circuit so that the best conditions prevail for that frequency, that is, the degree of coupling controlling the level of oscillation is such that variations of plate potential, or of filament current, have the minimum effect on the frequency.

This is not so easily accomplished when we have an oscillator that covers a wide range of frequency, but in this case, for a single-frequency oscillator, it is comparatively easy to design the circuit so that the variations are very small due to changes in the level of oscillation.

Aside from these variables, the oscillating circuit itself, that is, the tuned circuit, is the greatest cause of variation, and this has been taken care of as described already by having the temperature variation due to the condenser equal and opposite to the temperature variation due to the coil and placing the whole tuned circuit in a separate assembly which is arranged so that any temperature changes take place very slowly, and the coil and condenser can be considered always to be at the same temperature.

Another way in which the characteristics are improved is to have a large capacity in the tuned circuit. In this particular case, the capacity is approximately ¼ microfarad. This means that variations in stray capacity and other variations which would cause frequency variations in the circuit if the circuit capacitance were small are reduced to a minimum.

The actual characteristics of this particular oscillator may be of interest. The frequency variations are less than 0.001 per cent with changes of B battery from 125 to 135 volts, the nominal voltage being 130 volts, and for current variations from 1.9 to 2.1 amperes, total current through the two-tube filaments in parallel.

The variation of the oscillator over a period of six months is less than 0.02 per cent. Such variations with respect to time, can be taken care of by recalibration. Over a period necessary to make a measurement or a series of measurements the stability is better than 0.001 per cent.

Impedance of a Non-Linear Circuit Element

BY EUGENE PETERSON[1]

Member, A. I. E. E.

Synopsis.—*Experimental determinations of the impedance of a variable element, such as an iron core coil worked at a high flux density, or a heavily loaded vacuum tube, are found to depend upon the impedance-frequency characteristics of the measuring circuit, as well as upon the complexity of the applied (measuring) potential wave. A physical picture of the action of a non-linear element in producing harmonics is built up, and it is shown that the flow of harmonic currents affects the measured impedance, at the fundamental frequency, of course, in two ways which are designated as the loading and reaction effects. The loading effect is that produced by the superposition of currents without any regard to the production of new frequencies, and the reaction effect, in accordance with energy conservation ideas, is that due to energy storage and dissipation at harmonic frequencies which appear as impedance reactions at the fundamental frequency.*

The physical picture set up in the above discussion appears to be capable of accounting for the experimental observations mentioned above in a qualitative way at least. In accordance with these ideas, it appears that even when the fundamental current is specified, there is no one definite value which can be assigned as the impedance of a variable element because of its dependence upon the circuit impedance-frequency characteristics. Several measuring methods are reviewed by which the impedance of the variable element may be determined under definite circuit conditions.

The above discussion is confined to the effects occurring with a sinusoidal applied electromotive force, for simplicity, but the results with complex waves applied are analogous, as indicated by reference to the energy conservation principle.

IMPEDANCE determinations of non-linear elements, among which are included vacuum tubes and inductance coils with a more or less saturated iron core, involve factors additional to those present in the determination of impedances of ordinary invariable circuit elements. Such matters as impedance of the measuring circuit, impurity of the applied wave, and current or potential amplitude, which, except for extreme values leading to breakdown, do not ordinarily affect the impedance of the linear element, are found experimentally to be of considerable importance in the non-linear case.[2]

For our purposes we may assume a linear circuit element to be one distinguished by this property, that the relation between instantaneous current and instantaneous potential drop is a fixed and definite one expressed by a constant over the entire cycle. This is true not only of resistances but of reactances, in which the relation between current and potential drop is constant over the cycle, even though a constant phase angle is involved. A non-linear element, in contrast, is one in which the instantaneous current and potential are not related invariably throughout the cycle. Examples of this type of element which are of practical importance come readily to mind. For example, the two-electrode or the three-electrode vacuum tube will serve as an illustration of a variable resistance, and an iron core coil worked at high flux densities will serve as an illustration of both variable resistance and variable inductance. An important point in our distinction between linear and non-linear circuit elements has to do with the current-voltage relation over an entire cycle since it is possible in a non-linear element to have a relation between r. m. s. current and r. m. s. voltage as given by the usual type of a-c. meter, independent of amplitude. This particular condition arises in rectifiers in which the current wave for positive potentials has substantially the same wave form as the impressed potential wave, while for negative impressed potentials the current is zero. Here the relation between instantaneous current and instantaneous potential is specified by one of two values, depending upon the polarity of the applied potential wave. The relation between r. m. s. current and r. m. s. voltage, on the other hand, it is readily seen, is a perfectly linear one.

If now we attempt to determine the impedance of a non-linear element at a definite frequency and at a definite amplitude of fundamental current or potential by a-c. bridge measurements, in the usual manner, we should find the measured impedance to depend upon several factors which are not ordinarily considered in this connection. These are the presence of harmonics in the supply current, the magnitude of the ratio arm resistances, the impedances of the detector and of the current source at the fundamental frequency and at a number of harmonic frequencies, and finally the method used in attaining balance. To illustrate the last point, we might consider the non-linear inductance, with which it is observed that the measured resistance and reactance differ, when we balance the coil with a standard resistance and inductance, from the value obtained by resonating the coil with a standard capacity and balancing the resultant against a pure resistance.

The fact that in a non-linear element the relation between instantaneous current and potential is not constant over an entire cycle, and in which the impedance may be considered consequently as variable, means that the element serves as a generator of new frequencies which are ordinarily harmonics when but a single frequency is applied initially. It turns out that the effects mentioned above, which differ so markedly

---

2. We shall not specifically consider those factors involved in impedance measurements which are common to linear and to non-linear elements, such as ground capacities; these are dealt with in the paper by Shackelton and Ferguson, p. 519.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

from our experience with impedance measurements of invariable elements, are to be explained by reference to the production of these harmonic frequencies in the circuit. To summarize the above account of the phenomena met with in measuring the impedance of a variable or non-linear element, we may say that the result depends upon the circuit to which the element is connected as well as upon the source of supply.

There are then two possibilities in general as to impedance measurements which are of practical importance. First, we may obtain a measurement characteristic of the non-linear element, and second, we may determine the impedance under specific circuit conditions. It is convenient to take the impedance of the element with harmonic currents suppressed as representative of the element, and this will be done in the following.

Generation of Harmonic Frequencies with a Single Impressed Frequency

Variable circuit elements may be definitely distinguished according to the manner in which the variations are produced; in one type, variations are produced by the current or the impressed potential; in the other, they are produced by means external to the circuit. In the first category belong the two variable elements discussed above; in the second belong the voice-actuated carbon transmitter and the mechanically driven generator. In general, when a circuit containing a variable element is subjected to a sinusoidal electromotive force, the reaction of the variable element causes a distortion of the current through it, or the potential across it, or both, depending upon circuit conditions to be discussed later, so that in consequence, harmonic currents and potentials exist in the circuit. These components may be determined in simple cases with the aid of Fourier's theorem from a detailed inspection of the wave form, or they may be measured experimentally with the aid of current or voltage analyzers as discussed in Mr. Horton's paper on that subject.

In order to provide a physical picture for the phenomena of harmonic production by a variable circuit element with a purely sinusoidal electromotive force impressed on the circuit, we may employ as a first approximation to the actual state of affairs a procedure which has proved fruitful and which is in agreement with mathematical analyses in the simple cases to which it has been applied. Here we assume the variable element replaced by a fixed impedance element together with a number of generators of the harmonic frequencies, each harmonic frequency being represented by an individual generator. The generators represent the driving potentials of harmonic frequency operative in the circuit, and to a first approximation the amplitudes of these potentials depend upon the fundamental current magnitudes and upon the properties of the non-linear element. This is a most important conception which serves as a basis for further discussion. From this it is evident that the amount of any one harmonic current flowing in the circuit depends upon the generated harmonic potential or upon the fundamental current, and upon the total circuit impedance at the harmonic frequency.

No simple law exists governing the dependence of the harmonic electromotive force upon the fundamental currents which is generally applicable, since the law varies with the type of element involved. Some of the harmonic electromotive forces may be zero at all fundamental amplitudes; thus, as is well known, the even harmonic potentials and consequently currents are substantially zero in unpolarized iron core coil circuits, just as the odd harmonic potentials and currents are substantially zero in the particular type of tube rectifier mentioned above. This is, of course, a particularly striking difference between the harmonic producing properties of different elements, which serves to emphasize the fact that the particular type of non-linearity in each case determines the connection between the harmonic driving electromotive force and the fundamental current which gives rise to it.

Although we cannot, in the light of the above examples, discuss the relations existing in non-linear elements in general, we can of course consider specific cases, and for illustrative purposes we propose to deal with the harmonic potentials developed in an iron core coil. In order to present data on harmonic production which shall be characteristic of the non-linear element and not of the circuit in which it happens to be connected, we shall discuss the equivalent generated or driving harmonic potentials. These, as we have previously suggested, may be thought of as depending solely upon the fundamental current in any specific type of non-linear element and are therefore independent of the impedance-frequency characteristics of the connecting circuit. Contrast this situation with that existing with regard to the harmonic currents. Here the total circuit impedance in magnitude and phase angle to each harmonic under consideration must be specified, since it is evident that the harmonic current will vary with the circuit impedance and has therefore no definite value characteristic of the core or the core material under investigation. If, however, the total circuit impedances are known, it is then possible to determine the driving voltages by multiplying them by the corresponding harmonic currents as determined by current analysis.

In the measurements to be described, the simpler procedure was adopted in measuring the harmonic driving potentials of providing a high circuit impedance to the harmonic frequencies and measuring the harmonic potential existing across the coil by a voltage analyzer. The arrangement is shown in schematic form in Fig. 1. This is equivalent to measuring the open circuit voltage of a generator so that an exact determination of the circuit impedances is unnecessary.

The results with a specific coil are given on Fig. 2 in which potentials across the coil are plotted as ordinates in terms of the current of fundamental frequency. The harmonic potentials are less at all fields than the fundamental potential drop and, at any field, the higher harmonics are of smaller amplitude than the lower ones. The lower harmonic potentials are roughly of the same order of magnitude as the fundamental and it becomes apparent that comparatively large harmonic currents

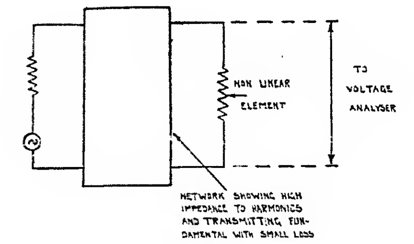

Fig. 1

may be made to flow in circuits which have low impedances to these harmonics; this would be the case if the impedance of the circuit external to the coil were capacitive and of the same value as the inductive reactance of the coil at the harmonic frequency. The ratio of harmonic to fundamental potential decreases rapidly as the fundamental field decreases, the rate of change being greater the higher the harmonic, so that at the low fields characteristic of high quality communication systems the ratio may be of the order of 1/1000 for the third harmonic. The higher fields are of course met with in magnetic frequency multipliers, for example, and in general in power work. The same sort of effect is observed to hold for other types of variable element—the low value of the ratio at small fundamental currents, the rapid increase of the ratio at high fundamentals. It may be found in certain cases that some of the harmonic potentials pass through a maximum. This last is observed in heavily loaded vacuum tubes, for example.

The problems that confront us here are those resulting from the complex form of the resultant current wave, a wave which includes the fundamental frequency together with those of its harmonics which are determined by the nature of the non-linear element and by the connecting circuit. Thus with a low external impedance to a harmonic, the harmonic potential across the circuit is small and the harmonic current relatively large. The situation is evidently reversed with a high circuit impedance to the harmonic under investigation. The effects produced by the flow of harmonic currents are two-fold: first, a different region of the non-linear current-voltage characteristic is traversed so that the impedance of the variable element is in general changed; and second, because of the relations between the harmonic current and the fundamental there is a further effect directly upon the fundamental current itself. To distinguish clearly between the two effects we shall find it advantageous to consider each effect independently.

Suppose now that by removing the effect of the introduction of new current components due to the non-linearity of the circuit with the aid of appropriate circuit impedances, we investigate the mutual effects of two independent currents of different frequency impressed on the circuit. In general, the impedance of the variable element to any current is influenced by the presence of other currents, although the effect decreases rapidly with the amplitudes of the currents in question. The presence of a small component has negligible effect upon the flow of a large component in the case of a two-component wave, although the impedance offered to the small component is greatly influenced by the large one. This is true of a vacuum tube, for example, while for saturated iron cores the effects depend not only upon the component amplitudes but also apparently upon their frequency ratio.[3] This effect, the alteration of impedance through the presence of a superposed current independently generated, we shall designate, in the following, as the loading effect.

Figs. 3A and 3B are reproduced from the paper referred to and illustrate the loading effect in a silicon steel core coil. Fig. 3A shows how the flux density of a definite frequency and corresponding to a definite magnetizing force depends upon the amplitude and frequency of a superposed magnetizing force; the ordinates are expressed in thousands of lines per cm.[2] Fig. 3B shows the corresponding effect of superposition upon energy

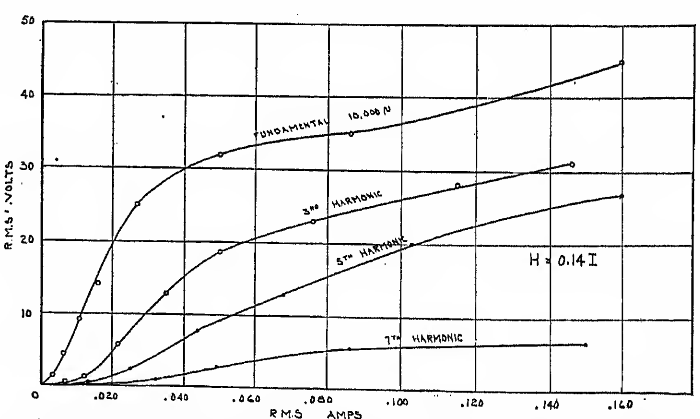

Fig. 2—Voltage Components Across Silicon Steel Core Coil as Function of Fundamental Magnetizing Current

loss expressed in thousands of ergs per cubic centimeter per cycle. It will be readily appreciated that the flux density and energy loss could be expressed in terms of inductance and resistance. For our present purposes it is sufficient to recognize the existence of the loading effect from these two figures.

We are now in position to investigate the second factor in determining the impedance of a variable element, which is quite distinct from the loading effect.

3. *Phys. Rev.*, Vol. 27, No. 3, pp. 323, 325.

For this purpose we consider a non-linear element in which the loading effect is not appreciable, such as the carbon button microphone externally agitated. Here the absence of what we have termed the loading effect is manifested by the fact that the button resistance over a certain range is independent of the current traversing it. The button develops a variable resistance, however, in view of the externally applied force, so that new

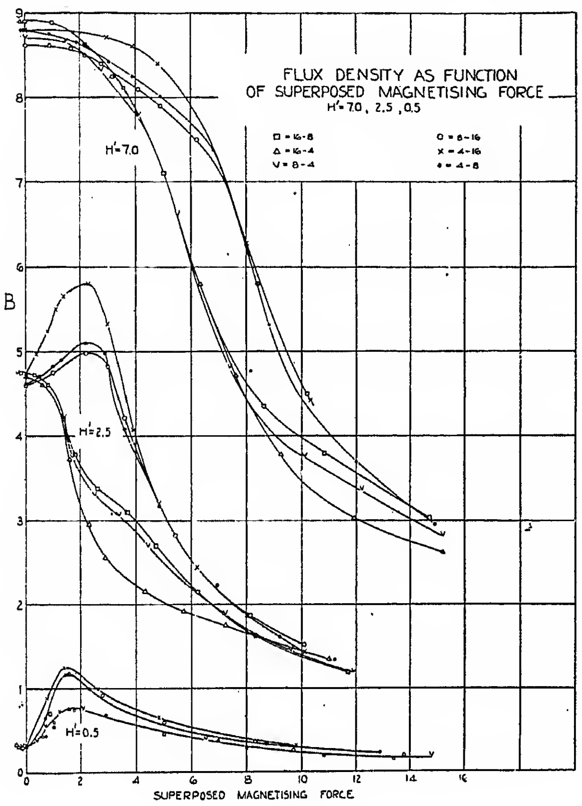

Fig. 3A

frequencies are generated in the circuit when an electromotive force is applied. The currents produced by non-linearity dissipate and store energy, which must be supplied by the energy source. It is evident, therefore, that the circuit impedance at the impressed frequency depends upon the circuit conditions to the new frequencies developed. This effect is denoted in the following as the reaction. The energy dissipated or stored in this additional fundamental resistance and reactance term must then be sufficient to account for the energy dissipated or stored by the new frequencies, at least if we are to retain our ideas on energy conservation. The two effects of harmonic current flow, loading and reaction, may of course be present simultaneously, as in a vacuum tube circuit or in an iron-core coil circuit. The justification for the separation of the net effect into two factors lies in the fact that the two factors depend upon radically different circumstances, so that the separation permits us to follow the phenomena somewhat more closely.

Another way of looking at the same effects is to consider the phenomena involved from the standpoint of the potentials developed, rather than from that of energy, as above. To do this, we may regard the non-linear circuit impedance as having harmonically variable components. Thus a vacuum tube would be regarded as having a constant resistance component together with other resistance components which vary at the fundamental and harmonic frequencies. Hence, when the fundamental current flows through the variable part of the tube resistance, an harmonic potential is produced which corresponds with the harmonic driving potential. The reaction of the harmonic flow on the fundamental is now to be obtained by considering the flow of a harmonic current through the variable element. It is found by a detailed consideration[4] that there is produced a voltage component of fundamental frequency across the variable element due to the flow of harmonic. Now assuming the harmonic resistance components involved to have fixed values, it becomes clear that the fundamental potential developed depends upon the harmonic

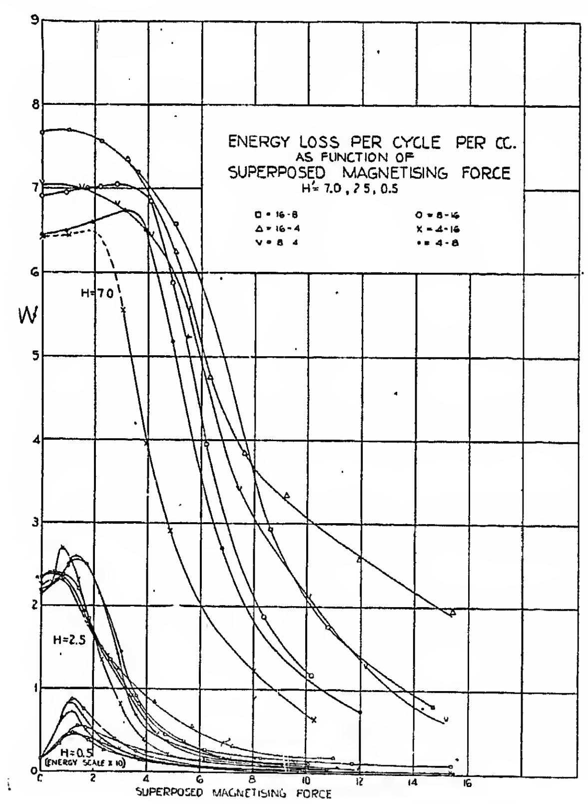

Fig. 3B

current as well as upon the phase of that current, since a shift of 90 deg. converts a resistive component to a reactive one. Since the fundamental potential drop may be interpreted in terms of the fundamental impedance, the reaction of harmonic current flow is evident, quite apart from the loading effect.

Consideration of the problem from the standpoint of harmonically varying impedances yields the same

4. Appendix I.

general results as those obtained above in which the presence of harmonic generators was assumed; in fact, the harmonic electromotive forces generated may be derived from a consideration of the variable impedance. The harmonic generator circuit, however, appears to offer a clearer picture of the manner in which harmonic currents are affected by circuit impedances, and has been developed to somewhat greater length for that reason. Fundamentally, of course, the two methods appear to be equally acceptable.

With the effects of harmonic current flow in mind—we have designated them as loading and as reaction—it becomes possible to explain in at least a qualitative way the difficulties which were enumerated at the start. The influence of harmonics in the supply source will be recognized as primarily a loading effect of the same nature as those discussed in connection with Figs. 3A and 3B which applied to iron core coils. The magnitude of the ratio arm resistances in the bridge used for measurement, together with the impedances (invariable with time) of the detector and the generator source, determine the magnitude as well as the phase of the harmonic currents flowing at any fixed value of fundamental current, since it is these quantities which fix the impedance offered to the harmonics. In the same way, the measured impedance of a non-linear reactance depends upon the method of attaining balance, since by resonating the variable reactance we may introduce an impedance to the harmonics which is considerably lower than that offered by balancing the reactance by a standard reactance of the same sign.

When we speak of attaining a balance, it is understood, of course, that we refer to balancing a voltage of the fundamental frequency against another voltage of the same frequency, amplitude, and phase. When this is attained, any harmonic potential differences are in general not balanced, so that harmonic potentials are applied to the detector or telephones which are used to provide an indication of balance. Under these con-

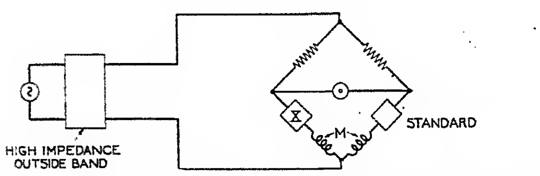

Fig. 4—Bridge for Measurement of Modulator Impedances

ditions, it is difficult, if not impossible, to determine the balance point since, generally speaking, it is obscured by the harmonics, and the values assigned to the impedance will depend upon the individual making the measurement. For this reason the detecting apparatus is provided with frequency selective apparatus which transmits the fundamental to the exclusion of the harmonics. This is, obviously, quite apart from any consideration of the influence of the detector impedance upon the actual value of the impedance of the element being measured.

Impedance Measurements, Harmonics Suppressed

The complicating effect introduced by impurity of the impressed potential wave is removed without much difficulty by the introduction of tuned circuits or other frequency selective circuits in the generator supply circuit. The suppression of harmonics generated by the variable elements requires other means which will be discussed for two distinct circuits, one a modification of the usual bridge method, and the other, a method of the a-c. potentiometer type. The use of these circuits for impedance measurements is well known, of course, so that in the following we shall cover only those features which bear directly upon harmonic current flow.

Bridge Method

Any alternating currents developed by the non-linear element may be suppressed by two high inductance coils having high coupling, one of which is inserted in each of the two unity ratio bridge arms as shown in Fig. 4.

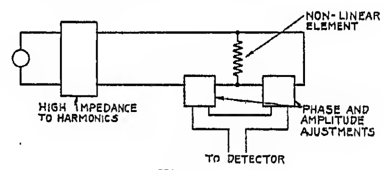

Fig. 5

These two auxiliary coils are balanced so that their insertion causes no alteration in the bridge settings. At the balance point, equal currents flow through the two windings so that the two fluxes are substantially equal in magnitude and opposite in phase. This is not true of the harmonic currents which meet the series-aiding impedance of the coils rather than the series-opposing impedance. With high inductance coils, this series-aiding impedance may be made so high as to suppress harmonic currents effectively. A parallel path is offered to the harmonic currents through the fundamental source which includes but one of the two coils. A network is provided in the generator circuit to oppose a high impedance to the harmonics so that the high-mutual coil may not be effectively short-circuited.

In practise, any lack of balance between the two inserted coils may be made up by corrections to the bridge settings determined by a separate balance when the two coils are balanced against one another. The null point is not as sharply defined with the two coils inserted because of the added impedance for departures from the balanced condition, so that it is well to keep the inductances down to the minimum value at which effective harmonic suppression is assured.

A-c. Potentiometer Method

Here harmonic suppression is attained entirely by a network which passes the fundamental freely while offering a high impedance to the harmonics generated by the element. The potential drop across the coil is

changed in amplitude and in phase to balance the drop across a resistance in series with the non-linear element as indicated in Fig. 5. The phase and amplitude adjustments may be so arranged as to have a negligible effect upon the quantities being measured. The impedance of the element may be calculated from the constants of the circuit used to attain balance. The principles involved here were applied to the measurements represented in Figs. 3A and 3B.

Impedance Measurements, Harmonics Flowing

The two methods discussed above were used to insure freedom from the effects of harmonic current flow and

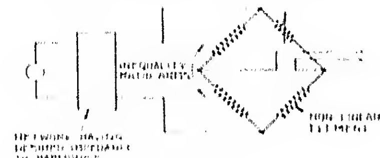

Fig. 6

are fixed and definite and independent of the measuring means so long as the harmonics are suppressed. Under practical conditions of use, however, harmonic currents flow in the circuit and react on the fundamental impedance in the manner which has been discussed above. In this situation, therefore, the impedance can be determined only in the circumstances of use, so that the measuring circuit is required to leave the circuit impedances unaltered, or to duplicate them. For this purpose two measuring circuits are available, one a bridge modification, the other a potentiometer method, which are derived more or less obviously from the two methods previously considered.

Inequality Ratio Bridge

The arrangement shown in Fig. 6 has been used to provide any desired impedance to the harmonics despite the fact that the harmonic circuit forms part of the bridge network. The bridge arms are made much higher than that of the element to be determined since they are connected in shunt to the standard and the unknown, and they are made unequal so that but a low series impedance, that of the standard, may be inserted in the harmonic path. The desired impedances to the harmonic frequencies are then inserted in the generator path. It is clear that when the ratio arm resistances are sufficiently high, the detector impedance may be neglected.

The circuit of Fig. 7 was set up for the impedance measurement of a small, two-element vacuum tube such as is used for low power rectification. It was desired to determine the impedance of the tube when the harmonics were permitted to flow through a series resonant circuit, the tuning of which was varied so as to cover the frequency range up to the fourth harmonic. The circuit details are given in Fig. 7, in which it is seen that the two ratio arms were made 10^5 and 10^4 ohms, respectively, so that the shunting resistance was about 100 times that of the element under measurement, while the series resistance to the harmonic was about one-tenth that of the tube. A direct current was supplied through a distinct circuit including a large choke coil so as to avoid shunting the alternating currents. The fundamental was supplied through a filter which at the same time maintained a high impedance to the harmonics, so that they were restricted to the tuned circuit provided for them, and so that the fundamental current maintained constant at 11.8

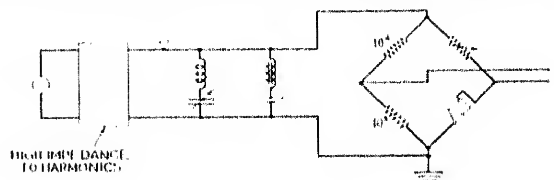

Fig. 7

mils could be measured by a thermocouple as indicated, without error through the presence of harmonics.

The experimental results are set forth in Fig. 8 in which measured resistance and reactance are plotted as ordinates in terms of the capacity of the harmonic tuned circuit. Impedance changes are observed to occur when the tuned circuit approaches resonance for any harmonic. The nature of the impedance variation is observed to be in accord with the conclusions derived from the energy conservation argument, as well as with the general analytical conclusions of the appendix. These last are, in brief, that the fundamental resistance decreases as the harmonic impedance decreases, and that a reactance to a harmonic appears as a reactance of

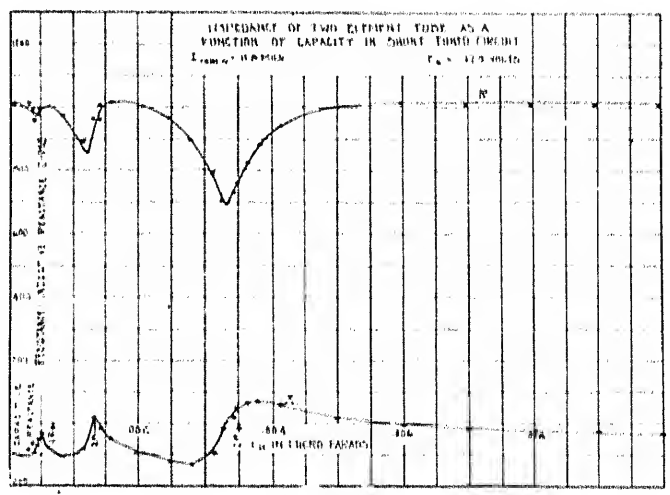

Fig. 8

the same sign in the fundamental circuit. The dips in the resistance curve decrease in magnitude as the harmonic frequency increases, which is due partly to the fact that the harmonic driving electromotive forces decrease as the frequency increases.

Potentiometer Method

With the preceding case in mind, the modification of the circuit of Fig. 5 to permit harmonics to flow is rather

obvious and nothing further need be said about it beyond the statement that the desired end may be attained by shunting a harmonic current path around the input filter.

Extension to Complex Applied Electromotive Forces

The discussion up to this point has been confined for simplicity to the production of harmonics, with a sinusoidal electromotive force applied to a non-linear circuit. The same effects, at least in a general way, exist when a complex electromotive force is applied to the circuit. In this case, as is well known, we have developed not only the harmonics of each of the input frequencies but we have also a group of frequencies produced which include sums and differences of integral multiples of the input frequencies. Here we have the same reaction of the harmonics on the fundamentals which gave rise to them as we had in the sinusoidal input case, and in addition we have the reaction of the combination frequencies, which also affects those fundamentals from which the combination frequencies are derived. For example, if we suppose the combination frequency $m f_1 + n f_2$ to be developed in a non-linear circuit when the frequencies f_1 and f_2 are impressed on the circuit (m and n being integers), the impedances to both f_1 and f_2 are influenced by the flow of the combination frequency. From the energy standpoint, we can say that the energy dissipated and stored at the combination frequency is accounted for by the reflected reactance and resistance terms of the two fundamental frequencies. Some very interesting conclusions may be drawn from this relation, one of the most striking of which is that the resistance introduced to one of the fundamentals, due to the flow of the combination frequency $m f_1 - n f_2$, may be negative, a result which has been confirmed by experiment under suitable conditions. This conclusion, of course, far from violating the energy principle, is in accord with it, since it appears that the only condition to be satisfied is to have the energy absorption in the reaction to one fundamental, sufficient to account for the energy dissipated by the combination frequency, together with the energy delivered to the other fundamental.

I am indebted to Mr. C. R. Keith and to Mr. L. B. Arguimbau for the experimental results.

Appendix

Reaction of Harmonic Current Flow on Impedance to the Fundamental. If we have a potential of $E \cos p t$ impressed on a non-linear circuit in which the instantaneous resistance is expressed in the particularly simple form

$$r = R_k + R \cos p t \tag{1}$$

where R_k represents the circuit resistance at a frequency k, the current wave contains harmonics in addition to the fundamental. Considering the effect of but one of the harmonics for simplicity, the current wave may be expressed as

$$i = I_1 \cos p t + I_2 \cos 2 p t \tag{2}$$

Multiplying the instantaneous current and resistance together and setting the product equal to the impressed potential, we have

$$E \cos p t = \left(R_1 I_1 + \frac{R I_2}{2} \right) \cos p t + \left(\frac{R I_1}{2} + R_2 I_2 \right) \cos 2 p t \tag{3}$$

in which R_1 is the steady resistance at fundamental frequency and R_2 applies to the second harmonic. Inspection of this equation shows that the fundamental frequency term contains I_2, so that it depends upon the second harmonic current. Solving for I_2,

$$I_2 = - R I_1 / 2 R_2 \tag{4}$$

and the impedance at the fundamental frequency is given by the expression

$$R_1 - \frac{R^2}{4 R_2} \tag{5}$$

which is obtained by putting (4) in (3).

From this it appears that the condition for maximum fundamental power dissipation in the variable element requires a lower generator impedance than that required when no harmonic flows. The power dissipated by the second harmonic is

$$W = \frac{1}{2} I_2^2 R_2 \tag{6}$$

while the power expended in the resistance effectively introduced into the fundamental path is

$$\frac{1}{4} R I_1 I_2$$

which, with the aid of (4) reduces to (6).

The same general relations are found to hold when the circuit resistances are replaced by impedances, in that the energy stored and dissipated at the harmonic frequency is represented by a corresponding effective resistance and reactance at the fundamental frequency. Thus the fundamental impedance may be written

$$Z_1 - \frac{R^2}{4 Z_2}$$

from which it is seen that an inductive reactance in the harmonic path is reflected as such into the fundamental path.

The Empirical Analysis of Complex Electric Waves

BY J. W. HORTON[1]
Associate, A. I. E. E.

Synopsis.—In many problems dealing with electric waves, particularly those encountered in electrical communication, it is necessary to examine with some care the several sinusoidal components present. Both qualitative and quantitative methods are in use.

A convenient qualitative examination may be made by heterodyning the complex wave with a sinusoidal wave of variable frequency and providing means for detecting any low frequency beat currents which may be produced.

In practically all methods for the quantitative measurement of the individual components of a complex wave, means are provided for selecting a single component and for preventing other components from reaching the indicating apparatus. The general arrangement of the selecting and measuring elements depends upon the character of the information sought. If the problem involves an exploration of the frequency range of the complex wave, primarily for the purpose of determining what components may be present, automatic analyzers are available which cover the field point by point and plot its spectrum. There are also analyzers which permit the field to be covered by heterodyning with a variable frequency so as to cause the resulting wave to be swept across a fixed selective circuit.

For the precise measurement of any single component, particularly a component of small amplitude in the presence of others of larger amplitudes, analyzers have been developed which employ the well known heterodyne principle which utilizes selectivity at a frequency below that of the unknown wave, thus effecting an appreciable increase in the percentage separation between adjacent components.

* * * * *

IN the more usual measurements on electric waves it is sufficient to determine the magnitude of some quantity which is indicative of the amplitude of the wave. The most common example is, of course, the alternating-current ammeter or voltmeter the indications of which are proportional to the r. m. s. value of the current or voltage being measured. Similarly, certain devices are available which read directly the maximum amplitude attained by the wave in question.

For many purposes, the information furnished by measuring instruments of these types, together with some idea as to the shape of the wave, is all that need be known. The increasing refinement of electrical communication systems, however, makes it necessary to look for methods whereby the composition of a complex wave may be more accurately determined. This is particularly true when we come to systems in which the components constituting the normal signal wave are replaced by components lying upon some other portion of the frequency scale. In such systems it is necessary to employ modulators or similar devices which have a non-linear relation between the impressed wave and the resulting output wave. The characteristics of such devices, unlike those of selective networks or filters, cannot be determined adequately by direct comparisons between the input and output waves but must be studied through measurements upon the individual components present in each.

The value of information of this character has become very great through our increased knowledge of the relation between the steady state conditions in a system and its behavior with respect to transient phenomena. It is probably true that the exact statement of the requirements of a system for the electrical transmission of speech is one of the most difficult in the entire communication field, due to the lack of means by which the properties of the signal wave, either acoustic or electrical, may be quantitatively stated. It has been found possible, however, to specify certain steady state conditions, which must be fulfilled by a system in order that the inevitable modifications of such transient waves as are involved in communication shall be within the limits of tolerance. For this reason, measurements relating to steady state conditions become of the first order of importance and have resulted in the development of numerous methods for determining the individual components of complex sustained waves.

One of the earliest means for examining the composition of a current or voltage wave was that used by Lenz in 1849 and later developed to the point of satisfactory practical use by Joubert[2]. This employs a sliding contact driven in synchronism with the fundamental period of the wave and so arranged as to connect an electrostatic voltmeter or similar indicator to the circuit carrying the wave at any desired time during its fundamental cycle. By repeating the measurement at a series of points throughout the cycle, the shape of the wave may be plotted point by point. The more recent development of the oscillograph to its present perfection has practically supplanted the sliding contact as a means for securing a graphical picture of the shape of an electric wave. Having obtained a trace corresponding to the instantaneous time variation of amplitude, it is possible by mathematical means to resolve it into its several harmonic components, determining the phase and amplitude of each. The quantitative precision of this method is not great, however, being limited by the resolution of the wave tracing device and by the accuracy with which the analysis may be carried out.

That the oscillographic method is totally inadequate

1. Bell Telephone Laboratories, Inc., New York, N. Y.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

2. *Comptes Rendus*, Vol. XCI, p. 161, 1880.

for many of the problems arising in communication work may be shown by using the multi-channel repeater of a carrier telephone system as an example. In such a repeater, the complex wave being amplified may contain components associated with three or more individual signals. As is well known, any distortion in amplifiers or other electrical circuits results in the development of wave components of frequencies other than those present in the impressed wave. These new components may have frequencies corresponding to multiples of the frequency of a single impressed component or to algebraic combinations of the frequencies of several impressed components. In the case of the multichannel carrier repeater, such developed components due to one or more of the impressed signal groups may well fall within the frequency range allotted to the group of components associated with some other signal. Having once been introduced into this portion of the frequency range, these extraneous components thereafter proceed with the proper signal components to the terminal equipment, and appear either as intelligible cross-talk or as noise superimposed upon the desired speech wave reproduced by the receiving equipment. The requirements of satisfactory speech transmission make it desirable in many cases to determine the amplitude of these extraneous components where their value is 0.1 per cent or less of the amplitude of the components properly associated with the signal. The detection of a component of this amplitude in the presence of the components producing it, is beyond the reach of the usual oscillographic method. The exact determination of its value by such a method is obviously quite impossible.

As is usual in all analytical work, we are interested in both qualitative and quantitative determinations. For the detection of the presence of a component of very small amplitude in, say, a complex electric current, the heterodyne beat method, to mention one of several, has been found very practicable. The unknown wave and a sinusoidal wave of variable frequency are impressed jointly upon a detector circuit. This detector circuit may take the form of a three-element vacuum tube so biased, that no current flows in the plate circuit when no alternating electromotive force is set up in the grid circuit. When a wave is impressed on the grid circuit, however, there is present in the plate circuit a current containing components of zero frequency and of frequencies corresponding to the sums and differences of the frequencies of the components of the impressed waves. By the use of a suitable d-c. meter in the plate circuit, the amplitude of the d-c. component may be observed directly. Such a-c. components as are present are ordinarily of frequencies to which the moving parts of the meter are incapable of responding. When, however, the frequency of the sinusoidal current is brought close to the frequency of some component in the unknown wave, the component in the plate circuit of the detector which corresponds to their difference frequency will be of such low value that it may be followed by the needle, which will therefore vary periodically about the value corresponding to the d-c. component. By adjusting this difference frequency to the natural frequency of the meter, it is obvious that the beat due to a very minute component in the unknown complex wave may be detected. The amplitude of the beat does give some general idea, of course, as to the magnitude of this component although the method is not well suited to quantitative work. By arranging the detector tubes in a bridge circuit as shown in Fig. 1, the d-c. or zero frequency component may be balanced out, thus making it possible to use for the detection of the low frequency difference component, a meter of higher sensitivity than would be possible when this component appears as an increment superimposed on a zero frequency component of greater magnitude.

The complete quantitative determination of the components of a complex wave involves, of course, a

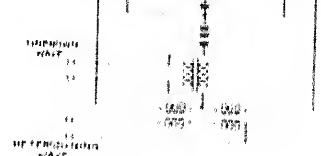

FIG. 1 CIRCUIT FOR THE DETECTION OF COMPONENTS OF A COMPLEX WAVE

determination of the amplitude and of the phase of each of the individual components. For most purposes, however, a knowledge of the amplitude alone suffices and many of the methods of analysis which have been developed are confined entirely to this determination.

The type of analyzer of necessity depends upon a number of factors among which are the resolution, the sensitivity, the frequency range, the precision, and the nature of the problem. Considering the last factor, it is apparent that an analyzer suitable for observing small variations in a single component, might be unsuited to a rapid determination of the number and frequency of the several components present in an unknown wave. In all cases, however, the system involves some selective device whereby the indicator may be rendered responsive to a single sinusoidal component and, at the same time, be unaffected by other components.

The possibilities of this general method were first recognized, about 1894, by Pupin,[3] who used it to investigate the harmonics generated by alternators. The application to waves of the magnitude of those encountered in communication was not possible, however, until the vacuum tube amplifier became available.

Practically all analyzers for waves of small amplitude are modifications of the elementary form in which a

3. *Resonance Analysis of Alternating and Polyphase Currents*, TRANSACTIONS of A. I. E. E., Vol. 11, 1894 p. 523.

selective circuit couples a vacuum tube amplifier to the circuit containing the wave to be investigated. The output of the amplifier is thus determined largely by the amplitude of the particular component in the complex wave to which the selective circuit is tuned. In the examination of complex currents, a convenient form of coupling is to introduce a low resistance into the given circuit and to shunt this resistance by a series tuned circuit. As far as the original circuit goes, therefore, the effect is comparable to that of inserting an ordinary ammeter. For coupling to the vacuum tube amplifier, it is necessary simply to connect the grid of the first stage directly across the condenser or the inductance of the tuned circuit. By the proper choice of elements, the voltage thus resulting on the grid for the particular component to which the circuit is tuned will be many times the voltage drop across the resistance due to that component. The voltage step-up of the tuned circuit at resonance, it will be recalled, is given by the expression $\frac{\omega L}{R}$, or $\frac{1}{\omega C R}$, where R is the effective resistance in series with the inductance and the capacitance. In the frequency range between several hundred and several hundred thousand cycles per second the value of this quantity, which is frequently designated by Q, may well be of the order of 150 or more. In the case of carefully selected elements for use with radio frequencies, it may become, on occasion, as high as 300.

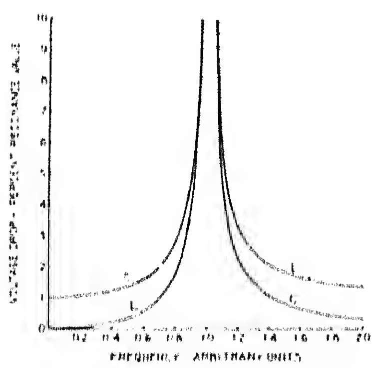

FIG. 2—CURVES SHOWING THE VOLTAGE DROP ACROSS THE INDUCTANCE AND THE CAPACITY OF A SERIES RESONANCE CIRCUIT FOR IMPRESSED VOLTAGES OF CONSTANT AMPLITUDE AND VARYING FREQUENCY

The choice between the inductance and the capacitance as the source of the voltage drop for connection to the grid depends upon whether most effective discrimination is required for components having higher or lower frequency than the component being measured. The curves of Fig. 2 show the voltages across the inductance and across the capacitance of a fixed tuned circuit, plotted as a function of frequency, for a constant voltage maintained across the entire series resonant circuit. Thus, greater discrimination may be secured against components of lower frequency than that to which the circuit is resonated, by using the voltage drop across the inductance, whereas for components of higher frequency greater discrimination may be secured by using the voltage drop across the condenser. This point is of significance, for example, in the measurement of the harmonics of a given fundamental. For a given voltage due to the second harmonic across either the inductance or the capacitance, the voltage across the inductance due to the fundamental will be only one-fourth of that across the capacitance. With higher harmonics the advantage of using the inductance will be even greater.

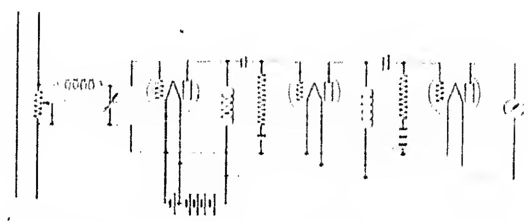

FIG. 3—ELEMENTARY FORM OF CURRENT ANALYZER CIRCUIT

To analyze a voltage wave rather than a current wave, an anti-resonant circuit in series with a high resistance may be connected across the potential to be measured in the same fashion as the ordinary voltmeter. The properties of this circuit, with respect to the currents in the several members, are analogous to those of the previously described circuit with respect to the voltages across its members. In practise, it is more convenient to use an initial vacuum tube stage having a high input impedance and arranged to work into a current analyzer circuit.

Having secured as the output of the vacuum tube amplifier a voltage indicative of the amplitude of a single component of the complex wave, it is a simple matter, by suitable amplification, to obtain sufficient power to operate any desired indicating device. One of the most convenient methods is to use as the final stage a vacuum tube having sufficient negative bias on its grid to prevent the flow of space current when the a-c. input wave is zero. The arrangement of the elementary analyzer, therefore, is similar to that shown in Fig. 3. The determination of the absolute value of the amplitude of any component which may be selected requires simply that the sensitivity of the analyzer be determined as a function of the frequency over the range for which it is to be used.

A circuit similar to the elementary arrangement just described was constructed during the World War for the purpose of analyzing the currents present in various submarine sound detectors. Here the problem involved the exploration of a considerable range of frequencies to determine what components might be present, as well as a measurement of their relative magnitudes. The first tests were carried out by laboriously adjusting the capacitance of the tuned circuit to the values corresponding to a succession of different frequencies separated by small increments. For each capacitance setting, the deflection of the

rectified current meter was noted. With this arrangement, the time required to cover the frequency range between 100 and 3000 cycles was several hours. Subsequent modifications in the apparatus to facilitate the manual labor reduced this somewhat but still left it so high as to make it impractical for most purposes. This led to the suggestion of employing some automatic method both for varying the tuning and for recording. A paper[4] presented by Wegel and Moore before the A. I. E. E. in 1924, describes the final form of an analyzer suited to this type of problem. This employs pneumatic relays for operating the condensers, the relays being controlled by a perforated paper roll similar to that of the familiar player piano. The record is made photographically on a sensitized tape moved at a uniform speed by the same mechanism which drives the perforated paper. At certain selected frequencies an auxiliary lamp, directly controlled by the perforated paper, traces lines across the photographic tape, identifying values along the frequency scale. An illustration of a record made by this analyzer is shown in Fig. 4. Its value in the qualitative exploration of an unknown wave is obvious. It is capable, furthermore, of considerable accuracy quantitatively.

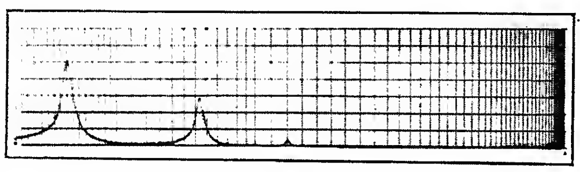

Fig. 4—Record made with Automatic Current Analyzer

The analyzer just described is admirably suited for the investigation of many questions arising in electrical communication, particularly where it is necessary both to discover what components may be present and to determine their relative amplitudes. There are occasions, however, when a more rapid survey of the frequency range is all that is required and for which the elaborate recording mechanism is not justified. To meet these conditions, an analyzer has been developed by Moore and Curtis[5] in which the entire frequency range is swept over by the manual adjustment of a single continuously variable condenser. To accomplish this result, the unknown wave is heterodyned by a variable frequency wave, whereby it is effectively transferred on the frequency scale in such a way, that the several components may be made to fall in succession within the field of a fixed selective measuring device. By properly choosing the frequencies of the heterodyning wave, it is possible to make the interval between the limits over which it must be varied, considered as a fraction of their absolute value, smaller than the corresponding interval between the limits of the original wave. The region over which the heterodyne wave must be adjusted is thus brought within the range of a single controlling element.

In replacing the unknown wave by a wave occupying a higher position on the frequency scale, in order to reduce the fractional separation between the limits, the fractional separation between adjacent components of necessity has been correspondingly decreased. In order to retain the required resolution in the analyzer as a whole, the fixed tuned circuit on which the wave components fall as the wave is moved along is made to have extremely high selectivity through the use of mechanical resonance. In fact, the high selectivity of the particular element chosen, as compared with the selectivity of the elementary analyzer previously described, more than compensates for the loss in selectivity resulting from the frequency translation. Means are provided, as described in detail in the published paper referred to, whereby the amplitude of any unknown current component may be determined. This type of analyzer is of particular value in examining the composition of sustained vocal or instrumental tones, or other periodic waves of comparatively short duration.

In many investigations, particularly those relating to modulation or to distortion occurring in non-linear circuit elements, it is desirable to examine the variations in a single component of a complex wave as conditions affecting it are varied. Here, the ability to explore the entire range of the wave need not be considered. Analyzers designed for this last mentioned type of problem, in general, require high selectivity in order to permit measurements to be made of components of very small amplitude in the presence of components of very much greater amplitude. In the case of the carrier repeater already mentioned, it may be necessary to examine quantitatively a component the amplitude of which is 10^{-5} times that of the amplitude of the components producing it.

A simple method of securing this selectivity is to use a number of units, similar to the elementary analyzer, connected in tandem. This may be accomplished readily by providing the output of each amplifier stage with a step-down transformer of high turns ratio, thus securing proper coupling between the output of the vacuum tube and the resistance element of the selective circuit. In tests made of modulation occurring in the Havana-Key West telephone cable, three such units were used in tandem, successfully. There are advantages in this arrangement. First, the discrimination against any unwanted component is the product of the discrimination of the several elements. Second, by alternating units containing amplification with units containing attenuation, the differences between the energy levels at any two parts of the system may be kept small. Third, the manipulation of the system is simplified because the tuning of one element may be carried out without affecting the adjustment of any of the others.

4. Transactions of the A. I. E. E., Vol. XLIII, 1924, p. 457.
5. *Bell System Technical Journal*, April, 1927.

This relatively simple arrangement of multiple stages has recently been found inadequate for the exacting requirements which are to be met in the study of high frequency transmission apparatus. There has been developed, therefore, a heterodyne analyzer in which the frequency range to be examined is moved to a position on the frequency scale below that which it normally occupies. In this case, the translation is accompanied by a considerable increase in the fractional separation between the components. By varying the frequency of the heterodyning wave, the component produced by its interaction with any component of the original wave may be made to fall, as before, within the field of a fixed tuned circuit. Due to the increased fractional separation, a circuit of given selectivity is more effective at this lower frequency than at the frequency of the original component. Furthermore, inasmuch as the selective circuit need not be adjusted to any of a number of frequencies, a more elaborate design is possible, giving much greater selectivity than could be obtained with a circuit capable of convenient adjustment. These two effects working together make the discrimination of the heterodyne analyzer much greater than could be obtained by other means.

It is apparent, since we are concerned with a particular component which has resulted from the transmission of one or more other components through a distorting device, that care must be taken to prevent these other components from reacting in the measuring equipment in such a way as to modify the amplitude of the component in question. This end may be secured in two different ways. First, the interacting components may be prevented from reaching the modulator in which the heterodyning is effected and, second, the design of the modulator itself may be such as to prevent components resulting from interactions between components present in the incoming wave from reaching the indicating device.

In the actual arrangement of the heterodyne analyzer, which is described in detail in a paper published elsewhere by A. G. Landeen,[6] both of these methods are employed. The modulator is preceded by two stages of simple selectivity and amplification so that any components other than the particular one to be measured are materially reduced in amplitude before reaching the modulator. The modulator is of the well-known balanced type in which any product of modulation between two waves impressed conjugately upon the input is delivered to the output circuit. Any modulation products resulting from interaction between two or more components of one of these conjugately impressed waves are differentially combined in the output with a subsequent reduction in their disturbing effect upon the reading. A schematic diagram of this

analyzer is given in Fig. 5. The curves of Fig. 6 represent actual data taken with one system as adjusted for use. Curve *A* shows the discrimination, expressed in transmission units,[7] of the initial stage of this analyzer. It corresponds to the discrimination which might be secured with ordinary circuit elements arranged as in the elementary form of analyzer. Curve *B* shows the added discrimination resulting from using two stages in tandem. Curve *C*, as compared with Curve *A*, shows the gain from the standpoint of resolution obtained by translating the complex wave in such a way as to increase the separation between its components, and by using a fixed complex selective circuit in place of a simple variable circuit. Finally, Curve *D* gives the over-all discrimination of the complete analyzer.

With a system containing as many variable elements as that just described, any general calibration is practically worthless. The alternative is, effectively, to calibrate the system for each individual measurement. In practise, this is relatively simple. A variable frequency oscillator is provided, the output from which is substantially sinusoidal. After a particular component has been selected and the sensitivity of the analyzer adjusted to give a suitable deflection on the indicating meter, the complex wave is replaced by the output of this sinusoidal oscillator, the frequency of which is then adjusted to give a maximum deflection on the indicator, thus insuring that the frequency of the sinusoidal wave is practically identical with that of the selected component of the complex wave. The output of this reference oscillator is maintained at some convenient amplitude, such as one milliampere or 10 milliamperes, and is impressed upon the analyzer through a calibrated attenuation box. By adjusting this attenuation so that the deflection of the analyzer meter is the same as that obtained with the complex wave, it is apparent that the sine wave impressed upon the analyzer is a duplicate of the component of the complex wave with respect to both frequency and amplitude. The amplitude is thus determined in terms of the known output of the oscillator and the known attenuation of the adjustable network. It would be possible, of course, to measure directly the amplitude of the sine wave current impressed upon the analyzer, but for many of the problems for which this apparatus is used it would be necessary to employ measuring devices of such high sensitivity as to be far more cumbersome than the method described.

The several analyzers just considered are primarily intended, as has been apparent, for the examination of the complex waves occurring in electrical communication. The various types, nevertheless, are adapted to meet the requirements of such a wide range of problems that they may be applied generally in the investigation of electric waves. For other specific problems, however, it will undoubtedly be found desirable to work out still other arrangements, better suited to the particular conditions encountered. It is hoped that the several modifications of the elementary analyzer which have been discussed in this paper will be of value in suggesting further modifications which will extend its usefulness.

7. For a discussion of this method of expressing current ratios, see *The Transmission Unit and Telephone Reference Systems*, by W. H. Martin, TRANSACTIONS A. I. E. E., Vol. XLIII, 1924, p. 797, also *Bell System Technical Journal*, July, 1924, Vol. III, No. 3 also "The Transmission Unit," R. V. L. Hartley, *Electrical Communication*, July, 1924, Vol. III, No. 1.

Discussion

N. E. Bonn: The last method described in Mr. Horton's paper and the one which he evidently prefers, involves the use of a sine-wave oscillator of variable frequency. Now a sine-wave oscillator, especially one whose frequency may be varied over a large range without disturbing the wave form, would make a very valuable adjunct to many a laboratory. Will Mr. Horton please state what method he uses to make certain of the purity of the wave form?

A method of wave analyis not mentioned by Mr. Horton, but somewhat similar to the one referred to above, was described in a well known French publication a little over a year ago by R. Thornton Coe (*Revue de l' Electricite*, XIX, 203-207, February, 1926). This method makes use of an astatic electrodynamometer. A sinusoidal current of adjustable frequency is passed through the stationary coil, while the moving coil carries the current whose wave form is sought. The deflection of the dynamometer at unity power factor is a direct measure of the amplitude of the particular harmonic, since the instrument will respond only to that component of the complex wave the frequency of which is equal to the frequency of the current passing through the fixed coil. As the method appears very simple, I should like to hear from Mr. Horton whether it received consideration and whether, in his opinion, it could be used at audio or carrier frequencies.

J. W. Horton: The first question concerns the purity of wave shape of the oscillator. I presume this refers to the oscillator used in the substitution method. As a matter of fact most measurements do not require an abnormally high degree of purity in this oscillator. For example, should the total harmonics aggregate, say, 5 per cent of the fundamental, the only error introduced is that the current used in the substitution method as measured by the thermocouple will appear to be about 5 per cent higher than the correct value. In other words, the absolute value of the component measured will be in error by the amount of the harmonics. These harmonics may, however, be determined by other measurements and a correction applied to take account of their presence.

In the actual oscillator used, the total amount of harmonics under normal conditions, that is, the square root of the sum of the squares of all components other than the fundamental, is less than 4 per cent of the total amplitude of the current as measured by a thermocouple. If the measurements demand that greater purity be obtained it is generally most economical to do it by using a low-pass filter in the output of the oscillator. There have been provided for certain measurements a series of such low-pass filters, the cut-off of one filter being approximately twice the cut-off of the other. With any filter of the series it is possible to obtain a current free from harmonics over the frequency range extending from just above one-half the cut-off frequency to just below the cut-off frequency. The several filters are so chosen that these ranges overlap.

The second question refers to the dynamometer method for measuring individual components. I have had no experience with that method. From what little I know of it I should imagine it might possibly be somewhat cumbersome to apply in cases where the component to be measured is of the order of 0.0001 of the fundamental components in the circuit. I should also imagine that it might not be very accurate in cases where the components are so small that a considerable amplification is required to bring them to the point where they could be made to give a reliable reading on some indicating device, or where the frequencies are so high that distributed capacities within the dynamometer become effective.

A New Thermionic Instrument

BY S. C. HOARE[1]
Associate, A. I. E. E.

Synopsis. A new form of vacuum tube voltmeter that has certain merits not possessed by existing instruments is described by this paper. Advantage is taken of the properties of a bridge circuit, one of whose arms is the plate-filament impedance of a common three-element pliotron to permit the building of very sturdy instruments of unusual sensitivity and dependability.

A number of schemes using standard three-element thermionic tubes has been used in various phases of electrical measurement work. The amplifying characteristics of these well-known devices immediately suggest themselves to those having unusual measurement problems. A number of voltmeters of the vacuum tube type have been described in

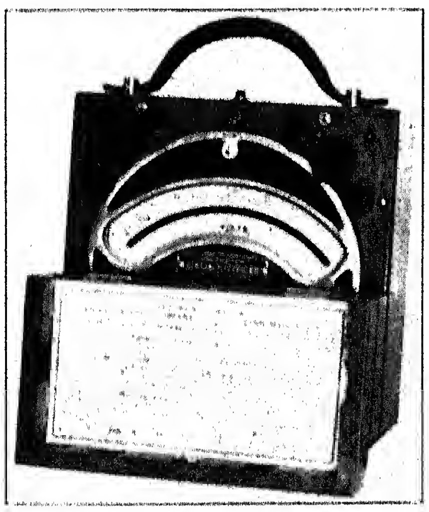

FIG. 1 TYPE DP-2 THERMIONIC VOLTMETER

the literature and some of these have reached the commercial stage. Unfortunately, however, most of these schemes have been quite complicated or required considerable auxiliary equipment and other measurement devices, to adjust the various currents and voltages of the circuits to a standard value. These complications have served as deterrents to the more general application of vacuum tubes to measurement work.

Recent work has shown the practicality of ideas of using vacuum tubes in very simple circuits for measurements of reasonable precision where unusual electrical conditions must be met and where ordinary measuring instruments cannot be used or, if usable, are highly special and delicate. This new development permits the housing of all necessary circuit parts except the exciting battery in the case of a standard high torque d'Arsonval microammeter. There is but one adjustment necessary and this is made by a rheostat which is one of the parts incorporated in the case. The only battery required is one for the excitation of the filament. Due to the particular circuit used, the adjustment of the current from this battery by the rheostat adjusts the filament current, the grid bias, and plate voltage. This adjustment is made by turning the rheostat until the instrument pointer indicates zero. The instrument then becomes direct reading.

The circuit is essentially a Wheatstone bridge with three arms of fixed wire resistors and one arm, the plate-filament resistance or impedance of a three

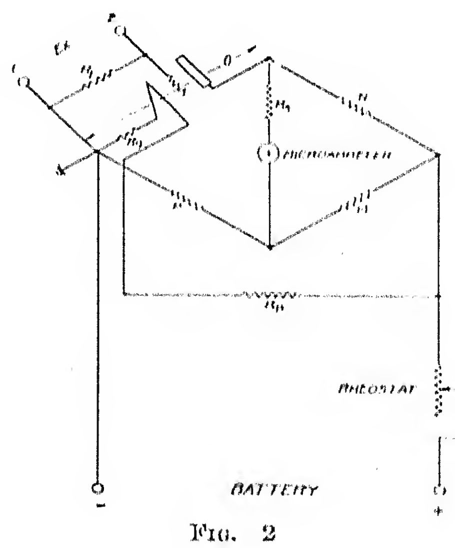

FIG. 2

element vacuum tube. This impedance, as is well known, is a function of the grid potential and is radically changed by relatively slight changes of the grid potential. Thus, an e. m. f., either direct or alternating, applied to the grid, upsets the balance of the bridge. The degree of unbalance which is a measure

1. Standardizing Laboratory, General Electric Co., West Lynn, Mass.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

of the applied voltage is read on the galvanometer or instrument element. A diagram of connections is given in Fig. 2. The resistances R_g and R_l serve to adjust the potential of the grid with respect to the filament to a definite value. These resistances are fixed in value, the adjustments being made at the time of calibration at the factory. The potential is determined by the $I\ R$ drop in R_g. R_l can be omitted when the test circuit forms a closed connection to the binding posts 1 and 2. R_l ordinarily lies between 50,000 ohms and 10 megohms, depending upon the proposed use of the instrument, type of tube used, etc.

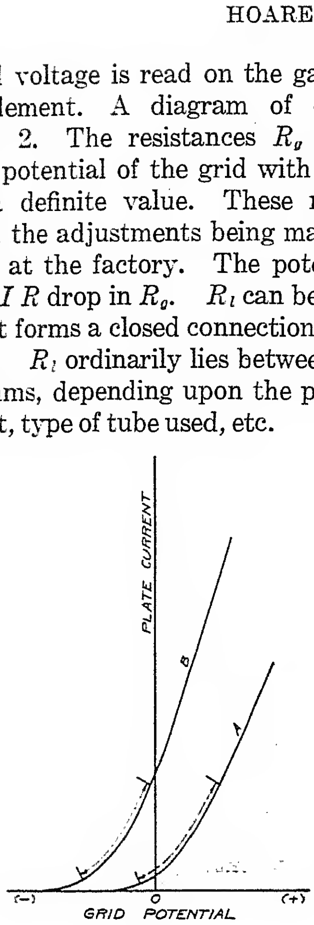

Fig. 3

The bridge arms, M, N, and P are of manganin. Resistors R_g and R_p are also of manganin and serve the double purpose of limiting filament current and of supplying (by virtue of their $I\ R$ drops) the requisite grid and bridge (*viz.*, plate) potentials. The relation of R_g to R_p is such that the tube is worked at a point near the lower knee of its grid voltage-plate current characteristic curve.

The preliminary manufacturing adjustments are made by setting R_g and R_p to approximately predetermined values, then adjusting P to bring the instrument pointer closely to the zero point. R_p is next given a slight readjustment to cause normal flow of filament current, with nominal value of excitation voltage and with the adjustable rheostat in its half-way position. The half-way setting of the rheostat during this adjustment of R_p insures sufficient latitude of control in the completed instrument with slight variation in battery voltage.

Normal filament current is conveniently determined from the measurement of filament voltage as given by either a potentiometer or a very high resistance voltmeter connected across the filament of the tube. After making this adjustment it will be found that the bridge is still unbalanced as indicated by the movement of the microammeter pointer above or below zero. The network can now be balanced by readjusting P. During this work R_l is in position but with no external connections to the grid.

As previously mentioned, a voltage, either alternating or direct, impressed upon the grid when the bridge is in normal balance, causes an unbalance because the impedance of the tube is altered. The indications of the microammeter form a measure of the unbalance of the bridge and, hence, of the voltage applied across 1 and 2. With d-c. circuit, the terminal 2 is connected to the positive side of the line. This results in making the grid less negative, thus lowering the impedance of the tube and thereby causing an increase in the plate current. When an a-c. voltage is impressed across 1 and 2, the negative loops of the voltage wave are, in effect, suppressed, and thus the indications of the microammeter are somewhat less than half of those from a similar d-c. voltage application. The indications of the microammeter element are substantially proportional to average values. The resulting action of the complete device is somewhere between an "average value" and an "effective value" instrument. For most purposes the error resulting from distorted waves is not serious. The calibration is made by applying known values of sinusoidal voltage or current.

The current drawn from the lines by this instrument is determined by the grid bias voltage, which is controlled by the $I\ R$ drop across R_g in Fig. 2. With a six-volt excitation battery it is possible to build these instruments as alternating-current voltmeters with 10,000 ohms (effective) per volt. By making the grid bias more negative it is possible to reduce the current drawn by the grid to less than 1 microampere. This requires a higher excitation voltage. A number of

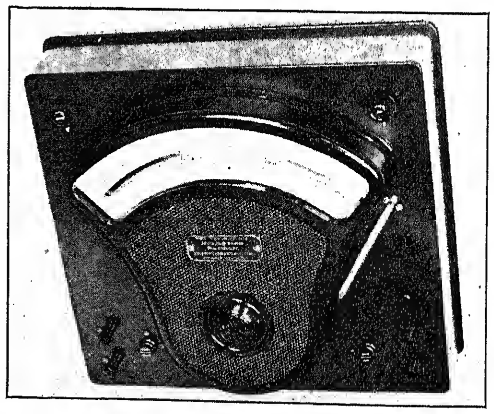

Fig. 4—Type DL-2Y Laboratory Standard Microammeter—Thermionic Type

instruments working from a 24-volt battery have been built. Some of these have required less than 0.1 microamperes as their operating current. The reason for the higher grid bias values is seen in Curve B of Fig. 3. This curve is the 24-volt characteristic of a tube and Curve A is the 6-volt characteristic. It is seen that with Curve B a much wider voltage range may be measured without having the grid positive. The grid does not draw current while negative.

The general arrangement of this circuit results in

instruments with fairly uniform scales, as may be seen in Fig. 1. This is an unusual feature of thermionic instruments. The electrical and mechanical zeros are also coincident which is another feature not common in such devices.

These instruments have been built as low-range voltmeters, especially for alternating voltages, and as low capacity microammeters for alternating-current and direct-current. The microammeters are operated from the drop across a resistance in series with the line current to be measured. It has been found possible to construct such an instrument to have a full scale range of 0.1 microamperes direct-current with only 0.3 volt drop. This instrument is shown in Fig. 4. Its scale is 12 in. long.

If care is taken to use resistances of proper design for high frequency work, and if the parts are properly mounted and shielded, this scheme would serve effectively for measurements at high frequency. It is especially necessary that R_l be of proper construction and shielded if high frequency measurements are to be made. R_l can, of course, be replaced by a series or shunt condenser.

TABLE I

ALTERNATING-CURRENT VOLTMETERS

	Ordinary electro-dynamic	Thermo-couple type	Thermionic 6-volt battery	Thermionic 24-volt battery
Volts, full scale	5.0	5.0	5.0	5.0
Resistance between terminals (ohms)	20.0	700.	50,000.	Infinity
Ohms-per-volt sensitivity	4.0	140.	10,000.	"
Current consumption at full scale (amperes)	0.25	0.0071	0.000100	nil
Torque, full scale (mm-g.)	1.5	0.05	0.9	0.9
Weight of moving element (grams)	4.8	0.3	1.8	1.8
Damping: Full scale to zero (seconds)	5.0	..	3.4	3.4

These data are representative of certain commercial instruments. Others with characteristics somewhat different might have been chosen. These, however, serve to show the possibilities of this type of thermionic circuit.

These instruments have some advantages over thermocouples, which are of necessity worked close to the burn-out point, because moderate overloads will not change the instrument and will not permanently impair the tube. The disadvantages of these instruments are the varying characteristics of tubes throughout their useful life, the need for an external excitation source, the need for accurately balancing the bridge before measurements are made, and the wave-form error when used on alternating-current. These disadvantageous features, however, are common to all thermionic instruments.

By careful selection of tubes for constancy of characteristics and by conservative selection of operating temperatures, it is possible to obtain quite long and useful lives for the tube. To some extent the circuit arrangements compensate for changing tube characteristics.

The external potential source can be a group of ordinary dry cells. It has been found that these, when in fresh condition, will require readjustment of the rheostat only infrequently.

Tests have been made to show the error resulting from inaccurate balancing of the bridge network. When the balance as indicated by the microammeter is within 0.010 in., (about three needle widths of the pointer), the calibration is within 0.5 per cent of full scale value.

The wave-form error is inherent in devices of this kind. For many measurements at high frequency where resonant circuits are used, the error will be quite inappreciable. For most measurements in the power frequency range the error will also be negligible. A test with a wave consistency of 30 per cent third harmonic and 10 per cent fifth gave but 4 per cent deviation from a sine of the same effective value. The fundamental in this case was 60 cycles.

As previously mentioned, this arrangement is one that is not especially susceptible to damage from moderate overloads. This is borne out by the data in the accompanying tabulation.

TABLE II

DIRECT-CURRENT VOLTMETERS

	Ordinary d'Arsonval	Special d'Arsonval	Extreme sensitivity d'Arsonval	Thermionic 6-volt battery	Thermionic 24-volt battery
Volts, full scale	5.0	5.0	5.0	5.0	5.0
Resistance between terminals (ohms)	500.0	5,000.0	100,000.	200,000.	Infinity
Ohms-per-volt sensitivity	100.0	1,000.0	20,000.	40,000.	"
Current consumption at full scale (amperes)	0.010	0.001	0.000050	0.000025	nil
Torque, full scale (mm-g.)	5.0	3.2	0.3	0.9	0.9
Weight of moving element (grams)	1.8	2.2	1.8	1.8	1.8
Damping: Full scale to zero (seconds)	2.0	1.6	3.8	3.4	3.4

TABLE III

DIRECT-CURRENT MICROAMMETERS

	Laboratory standard thermionic 48-volt battery	Thermionic 24-volt battery
Microamperes, full scale	0.1	1.5
Resistance between terminals (ohms)	3,300,000.	750,000.
Drop at full scale (volts)	0.33	1.12
Torque, full scale (mm-g.)	0.9	0.9
Weight of moving element (grams)	2.8	1.8
Damping: Full scale to zero (seconds)	7.6	3.4

Some of the advantages of this general scheme are shown by the tabulations (Tables I and II) which compare ordinary instrument constants and the constants of some thermionic instruments and by Table III, which tabulates data of some microammeters of ranges well beyond the possibilities of ordinary d'Arsonval construction.

TEST DATA

Variation with full load self-heating (maximum, during a 30-minute period in terms of initial indication) (per cent of full scale).......	−0.4
Variation per deg. cent. ambient rise (between 25 degrees and 50 degrees Centigrade) (per cent of point)........................	−0.05
Variation at 1000 cycles, sine wave (in terms of 60 cycle sine wave indication) (per cent of full scale).............................	−0.2
Variation with irregular wave form at 60 cycles (in terms of 60 cycle sine wave indication) peaked wave, form-factor = 1.13 (per cent of full scale)...........................	−4.0
Variation due to inaccuracy of zero adjustment (pointer purposely set three thicknesses off true zero position) (±0.010 in.) (in terms of indication with correct zero adjustment) (per cent of full scale).........................	±0.5
Variation with application of overloads (without reactivation) in terms of indication prior to overloads	
2-minute grid overvoltage of 100 per cent (per cent of full scale).......................	+0.3
5-minute filament overvoltage of 10 per cent (per cent of full scale)......................	+1.0

Discussion

N. E. Bonn: Mr. Hoare's instrument will undoubtedly be found very useful for certain special applications. For general laboratory work and as a detector in ordinary bridge and potentiometer circuits its value is very much limited by the exceptionally high internal impedance. True, it can be made to give a full-scale deflection while drawing only 0.1 microampere from the circuit, but it takes fully 0.3 volt to do so, and such high voltage is not available when one measures temperatures by means of thermocouples or in ordinary Wheatstone bridge and potentiometer circuits.

Throughout the paper the instrument is referred to a number of times as a microammeter. Now a microammeter is a current-measuring device the impedance of which must be much lower than the impedance of the circuit in which it is being used. To express the sensitivity of an instrument having an internal impedance in excess of 3 million ohms, in terms of microamperes is somewhat misleading. This instrument is strictly a voltmeter, but not a microammeter in the accepted meaning of the term.

B. W. St. Clair: (communicated after adjournment) Vacuum tube thermionic instruments are by no means new. There has been a number of different instruments on the market for several years. There are certain differences between the schemes proposed by Mr. Hoare and those that have been used heretofore and it is to the differences in these various instruments that this discussion is dedicated.

The biggest difference between this instrument and the more ordinary type of thermionic or vacuum-tube voltmeter is in the elimination of all auxiliary equipment with the exception of one exciting battery. Heretofore vacuum-tube instruments have required either B batteries or C batteries, or auxiliary ammeters or voltmeters in addition to the A battery required by this instrument. In several of the schemes the accuracy of the final measurement is determined by a setting of an auxiliary instrument.

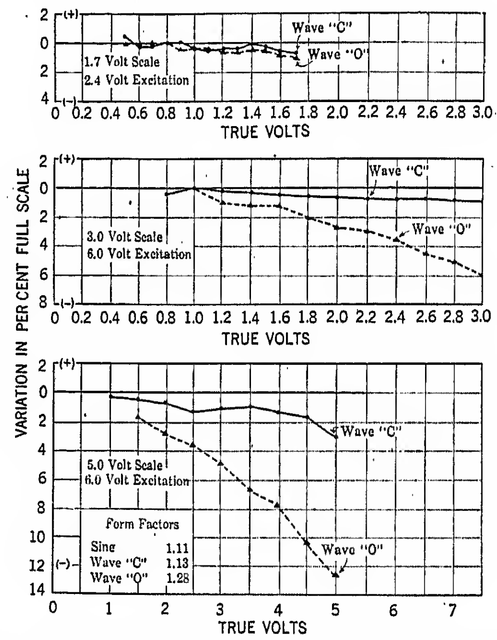

Fig. 1—Alternating-Current Thermionic Voltmeter Variation with Wave Form. Given in Terms of Sine-Wave Indications Tested at 60 Cycles

Another very real difference between this instrument and the older ones lies in the type of scale that results and also in the position of the electrical zero. In few of the previous schemes do the electrical and mechanical zeros coincide. Mr. Hoare's instrument is the only commercial one I know of that has coincident mechanical and electrical zeros. Most of the instruments proposed heretofore have scales that depart very seriously from a uniform law. The departure from a linear law of the scales of these instruments is not very serious. In fact, the scale can easily be read with about the same linear accuracy at any part of its length. This is not true in the older commercial instruments we are familiar with as they have scales that correspond more to reciprocal laws than to straight line laws. For many test purposes the uniform type of scale is very much to be desired.

S. C. Hoare: Under ordinary conditions, I doubt if many will object to the resistance of these thermionic microammeters since when measuring current values of the order of 20 to 1 microamperes or less, the resistance of the circuit is so many

	FOR DIRECT CURRENT			FOR ALTERNATING CURRENT	
	Thermionic Type	d'Arsonval Type	d'Arsonval Type	Thermo-couple Type	Electrodynamic Type
Ampere, full scale	0.0000001	0.0005	0.010	0.002	0.010
Resistance between terminals (ohms)	3,300,000	800.0	100.0	600.0	5000.0
Drop at full scale (volts)	0.33	0.4	1.0	1.2	2.8
Torque full scale (mm-g.)	0.9	2.2	1.9	——	2.8

times that of the instrument that 3 megohms would not be serious. A common use of these instruments is for photoelectric cell photometry where the circuit resistance is many times that of the instrument. In such work the instrument resistance can be considered almost insignificant.

Errors due to irregular wave-forms are inherent in those types of thermionic instruments in which the grid is worked at positive potentials. The errors become smaller with the reduction in positive grid potentials, and are quite negligible in those instruments in which the grid is kept always at a negative bias.

The accompanying characteristic curves illustrate the magnitude of wave-form errors with different conditions of grid-biasing. The upper set are typical of an instrument in which the grid is never permitted to become positive. In this type the current consumption in the input circuit is practically nil. The lower set represents the other extreme, wherein the grid is permitted to become appreciably positive. This type draws about 100 microamperes in the input circuit.

Waves *C* and *O* are badly distorted, *C* containing prominent fifth and seventh harmonics and *O* containing third and seventh harmonics.

I doubt if Mr. Bonn appreciates the magnitude of the voltage drop necessary in an instrument for the measurement of very small currents. Alternating-current instruments especially require quite an appreciable drop when the current range approaches milliamperes or microamperes. In the brief tabulation above are given some values for ordinary d-c. instruments and for a-c. instruments. It is there seen that the drop across the thermionic microammeters is not excessive when compared with some of the more ordinary types of test instruments.

The Oscilloscope: a Stabilized Cathode-Ray Oscillograph with Linear Time-Axis.

BY FREDERICK BEDELL[1]
Fellow, A. I. E. E.

and

HERBERT J. REICH[1]
Non-member

Synopsis.—*A method is described for using a cathode-ray oscillograph for the simultaneous observation of a number of variable quantities by means of a distributor. A linear time-axis, obtained by means of a gas-discharge lamp connected to a source of direct-current through a resistance or thermionic tube, is stabilized by introducing into this circuit a small e. m. f. derived from the same source that supplies the unknown quantities under observation. By making stabilization definitive rather than casual, distortion is avoided. The unknown quantities are thus shown in a form convenient for observation, appearing as stationary curves plotted with time as abscissa. The curves may be superposed about a common zero line, or displaced with reference to each other with separate zero lines. The name oscilloscope is applied to the apparatus here described, assembled as an instrument.*

THE oscillograph employing a vibrating cathode ray, first used by Braun and later so admirably developed by Ryan and others, has certain distinct advantages over the oscillograph of the Blondel or Duddell type in which a vibrating mirror is used. Foremost among these advantages is the fact that the cathode beam is free from inertia and can readily follow the variations of an electric or magnetic field even at high frequencies. The cathode-ray oscillograph, as hitherto commonly employed, has, however, the disadvantage that it has not been possible with it to show the variations in a number of quantities at the same time, nor to show these variations, as is done with the vibrating mirror oscillograph, as curves with time as abscissa in rectangular coordinates with which everyone is familiar.

While the cathode-ray oscillograph has proved a

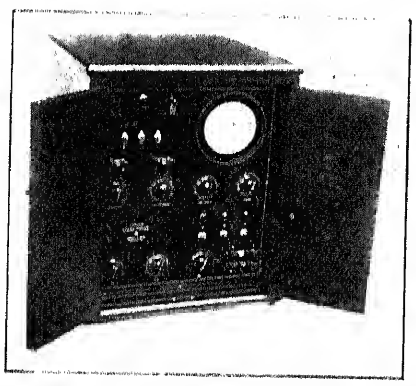

FIG. 1—STABILIZED OSCILLOSCOPE, FIELD TYPE
Made by R. C. Burt, 327 S. Michigan Ave., Pasadena, Calif.

highly valuable tool for a wide range of engineering and scientific investigations, including both cyclic and transient phenomena, and, in certain respects, is superior to the oscillograph of the mirror type, it has suffered by the two limitations just described. These limitations, however, may be removed and the field of usefulness of the cathode-ray oscillograph so widened that it becomes practically a new instrument. As the instrument developed for this purpose, (shown in Fig. 1), is primarily intended for visual observation, we have given it the name "oscilloscope." Permanent record may be obtained, when desired, by a photograph in the usual way. On the other hand, an *oscillograph* of the Blondel or Duddell type, both in name and in fact, is primarily for graphical record.

Not being limited to a single cyclic phenomenon, the oscilloscope is polycyclic; furthermore, it is stabilized so that the wave or waves stand stationary for observation and this becomes particularly important when several waves are observed at one time. Recurrent transients, as well as more usual periodic phenomena, may be observed.

The cathode-ray oscillograph tube is so well known that it needs no description. The cathode beam, focused on a fluorescent screen or photographic plate, is deflected in one direction by one set of plates or coils, and in a perpendicular direction, by another set of plates or coils.

An admirable and full account of various types of cathode-ray oscillographs and their development from the beginning is given by A. B. Wood and others in the *Journal* I. E. E. (Nov., 1925), with 63 pages and 125 references. So complete is this account (with its bibliography), and so admirable is the presentation that further discussion here is unnecessary.

THE POLYCYCLIC DISTRIBUTOR

In using the cathode-ray oscillograph, it occurred to the writers that if one pair of deflecting plates or coils could be successively switched by a distributor from circuit to circuit in rapid succession, the cathode beam would follow each in turn, making possible the simultaneous observation of several unknown quantities. We have found this to be the case and that when switched at proper intervals, the curves appear to the eye as simultaneous and continuous, due to persistence of vision, and likewise so appear in a photographic record.

The development of a four-way experimental distributor for this purpose is shown in Fig. 2. A resistance is included in each of the four circuits as protection in case of short-circuit. A brush B bears on a continuous slip-ring to which are connected staggered quadrants. Each of the remaining four brushes comes in contact, in turn, with one of these quadrants. The terminals Y_0 Y are connected to one pair of deflecting plates of the oscilloscope, the terminals Y_0 Y_1, Y_0 Y_2,

1. Both of the Cornell University.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

$Y_0\, Y_3$, $Y_0\, Y_4$ being connected to the several circuits under test. It will be noted that Y_0 is a common terminal; if any of the circuits cannot be so connected, an insulating transformer should be interposed between such circuit and the distributor terminals. Avoiding the common terminal, a double distributor can be used in a special case when necessary.

Linear Time-Axis

A linear time-axis, desirable for the observation of a single quantity, becomes almost a necessity in order to make a satisfactory interpretation possible when several quantities are simultaneously studied.

The need for a linear time-axis with the cathode-ray oscillograph has long been recognized and various ingenious methods have been proposed for its accomplishment, often, however, with but limited application. Mechanical devices are limited in range of frequency; electrical devices, although not thus limited, are liable to be unstable, and stability, as has been pointed out, assumes prime importance when several curves are simultaneously observed, as any motion of the curves creates hopeless confusion. Even for a single curve, stability is needed if the curve is to be carefully studied and perhaps sketched, traced, or photographed. Furthermore, electric devices without proper precautions are liable to produce distortion.

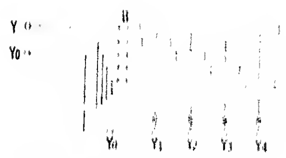

Fig. 2—Polycyclic Distributor

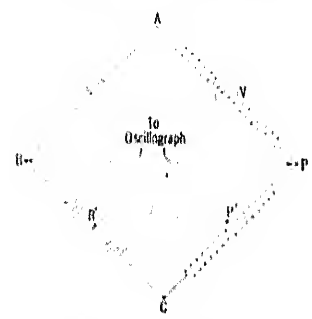

Fig. 3—Battery Operation

A linear time-axis may be obtained if we have available either a synchronous mechanical switch or a synchronous electric valve. Thus, if a condenser is charged at a uniform rate through a resistance, or otherwise, and is periodically discharged by a synchronous switch, the difference of potential across the condenser terminals will increase linearly with time while the switch is open, and drop suddenly to zero each time the switch is closed.

The Corona Valve

A mechanical synchronous switch is cumbersome and can be operated only at low frequency. A synchronous electric valve that would automatically perform the same function at high or low frequency would evidently be better. Such a valve is found in the gas-discharge lamp, containing commonly neon or argon, the characteristics of which are well known. (See bibliography.) When subjected to an increasing voltage, no current will flow through such a lamp until a certain critical "ignition" voltage is reached. Current then flows (analogous to the closing of the switch) and continues to flow until a definite lower "extinction" voltage is reached. Current then stops, analogous to the opening of the switch. The difference between the ignition and extinction voltages depends upon the frequency and type of lamp.

Each gas-discharge lamp possesses a certain capacity, so that, when connected to a source of e. m. f. through a resistance (in excess of a certain "critical resistance"), the lamp will light and re-light at definite frequency. This frequency may be varied through a wide range by varying the resistance and capacitance of the circuit. The gas-discharge lamp acts as a synchronous electric valve, performing the functions of a synchronous mechanical switch. Due to its nature, it may be referred to as the "corona valve."

Many theoretical and experimental studies (see bibliography) have been made of this phenomenon. Suffice it to say that the oscillation frequency is under control by adjustment of resistance and capacitance, the maximum frequency being obtained by reducing capacitance—including the capacitance of all circuit connections—to a minimum. Capacitance may be obtained by means of condensers in parallel with the corona valve or in parallel with a series resistance.

While the oscillating circuit can be adjusted for audio, commercial, and lower frequencies, frequencies much higher than audio-frequencies are not readily obtainable with usual apparatus. A frequency of 95,000, however, is reported by Oschwald and Tarrant, using a resonant circuit; but resonance tends to produce a sine-wave oscillation rather than the straight saw-toothed wave required for a true linear time-axis,

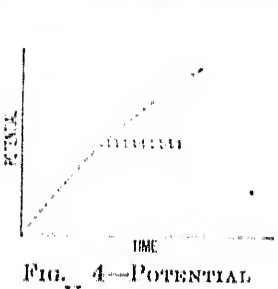

Fig. 4—Potential Variation

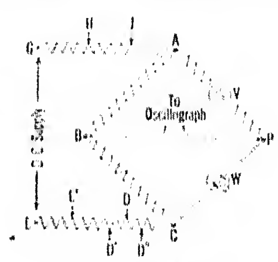

Fig. 5—Resistor Operation

and is to be avoided in an oscilloscope in which accurate reproduction of wave-form is sought. On the other hand, low frequencies, of, say, one every minute or, indeed, every hour, are obtainable and there is no obvious reason why with sufficient capacitance, (and patience), one could not reduce the lower limit almost indefinitely, if there were any object in so doing.

Oscillating Circuit

Circuit connections for obtaining a linear time-axis, are shown in Fig. 3. In the resistance circuit $A\ P\ C$, connected to the battery $A\ B\ C$, is inserted the corona valve V, which, either alone or with supplemental condensers in parallel with it, has a capacitance c,

and a potential difference $v = q/c$. The corona valve passes no current, acting as an open switch, until the potential difference between its terminals, as charge accumulates, reaches the ignition voltage. Current then flows and the potential difference drops until extinction voltage is reached; the current then stops, the potential difference again builds up and the cycle is repeated.

Fig. 4 shows the variation in the difference of potential between a point P in the resistance circuit and a point of reference B of fixed potential. The curve of potential-rise is exponential, as shown by the dotted curve. By using only a short element of this curve, the rising part of the saw-toothed curve is sufficiently straight to give the desired linear time-variation, when P and B are connected directly or through an amplifier to the deflecting elements of the oscillograph. Other points, as P' and B', give a similar but smaller variation, the amplitude of the time variation being capable of adjustment in this manner. The short, falling part of the saw-tooth curve, corresponding to the brief interval during which current is flowing through the corona valve, is so rapid that the spot of light on the oscilloscope screen shows only a negligible trace as it sweeps back to repeat the cycle.

Fig. 5 shows the connections for operating the oscillating circuit when a thermionic tube W replaces part or all of the resistance in series with the corona valve. A constant current through W, when operated above saturation, gives a uniform increase in v during the rising part of the saw-tooth curve, and so assures a linear time-axis.

Connections are likewise shown in Fig. 5 for operating the oscillating circuit when resistors, supplied with direct current from a generator or battery eliminator, are used in place of batteries. The same resistor system may supply the accelerating potential for the cathode-ray tube as well as any voltages that may be needed for bias or for the vertical or horizontal displacement of the cathode-ray beam. Operation with such a resistor system is very convenient, giving a nicety of adjustment not possible with batteries, provided precautions are taken to design the circuits, (including the circuits of a battery eliminator, if used), so that the several adjustments are sufficiently independent. The use of more than one eliminator would, of course, obviate the difficulty, but a single eliminator, properly compensated and designed for the purpose, will suffice. After the use of such an eliminator, batteries seem cumbersome and are a source of error when they do not give just the proper voltage. When a generator supply is used, commutator ripples may be filtered out, if necessary.

Stabilizing

In order that the curves shown by the oscilloscope may be stationary, it is necessary first to synchronize and then to stabilize the oscillating circuit; that is, the frequency of the oscillating circuit is first so adjusted that the cathode beam sweeps back once every half cycle, or some multiple of it, of the varying quantity under observation, and is then locked in step and so stabilized. As an automobile engine is first synchronized and then thrown into a particular gear, the oscillating circuit is synchronized and then thrown into the desired gear, electrically, so the curve shown includes one or more cycles, or half cycles, of the quantity observed, as may be desired. Without being thus stabilized, the curves are liable to move and make observation difficult.

Stabilization may be effected in various ways, the simplest method being by introducing into the oscillating circuit a very small e. m. f. of the same frequency as the circuit under observation. This may occur in a way that is *casual* and uncontrolled (whether by accident or design), through leakage or induction; thus, under certain conditions, we found that curves stood still when the operator merely raised his hand as though warning an animate being. Such stabilizing was promising and fascinating. Casual stabilizing, however, produces distortion; for, unless the stabilizing e. m. f. is controlled, some of it will affect the oscillograph circuit. To avoid distortion, stabilizing must be *definitive*, and the e. m. f., whether introduced conductively or inductively, so localized and controlled as not to affect the oscillograph. Thus, without attempting to discuss all possible methods of stabilizing, it is obvious that the distortion produced by the introduction of an e. m. f. at $J\,D$, (Fig. 5), while appreciable, would be far less than if the e. m. f. were introduced at $P\,B$. The authors have found that, for the apparatus employed, it is possible to obtain a definitive stabilization without distortion and with an amount of energy so small that the disturbance to the circuit under test, even when it is very sensitive, is practically negligible.

The oscillating circuit may be brought to the proper frequency and then stabilized so as to show a single cycle or half cycle; or it may be brought to a lower frequency, (whereby more time is taken for the spot to sweep across the screen along the time-axis) so that several cycles or half cycles are shown. In observing 60-cycle phenomena, the oscillating frequency may, for example, be stabilized at 30, 15, 10, or 5 cycles, with, however, a decrease in stability. In this way, for the same phenomenon, different gear ratios may be used and curves as shown in Fig. 6 be obtained.

Zero Line

Curves are ordinarily superposed, as in Fig. 7, either with or without a zero line. A zero line is obtained by a short-circuiting connection between Y_0 and Y_1, Y_2, Y_3, or Y_4, in Fig. 2.

Displacement

A curve may be displaced (raised or lowered) with respect to the others by interposing a battery, or other source of d-c. voltage, between it and the common terminal Y_0. Several curves may be so displaced,

up or down, by varying amounts, depending upon the voltage and polarity of the battery.

A displaced zero line is similarly obtained by using a battery instead of a short-circuiting connection referred to above. Two zero lines may be used, one displaced with respect to the other, as in Fig. 8.

When a resistor system as shown in Fig. 5 is used for

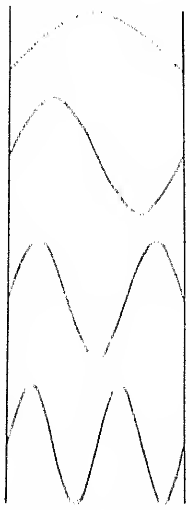

Fig. 6 Stabilizing with Gear Ratios ½, 1, 1½, and 2

supplying accelerating potential to the cathode tube, displacement without batteries may be obtained by connecting the unknown not to Y_0 (and so to some point as D on the resistor) but to D' or D'' displaced therefrom.

Uses

The oscilloscope may be used not only in the varied fields of investigation in which the vibrating mirror or cathode-ray oscillograph is used but, on account of the characteristics here described, in additional fields as well. The stability of the linear time-axis, together with the multiple use of the oscilloscope by means of the polycyclic distributor, at once opens the way to

Fig. 7

Fig. 8

Fig. 7 Simultaneous Curves, Superposed, with or without Zero Line

Fig. 8 Simultaneous Curves, Displaced, with or without Zero Lines

many varied applications. With the oscillating circuit switched off, the instrument becomes available for all the uses of a cathode-ray oscillograph in the usual manner. The stabilized linear time-axis is an added feature extending its usefulness.

On the other hand, the oscillating circuit may be used independently as a convenient source of current of controllable frequency. An ammeter in circuit may be used to indicate the frequency. A loud speaker connected through an amplifier becomes a source of sound of controllable, known pitch.

Although not limited to any one type of cathode-ray tube, a well-known low-voltage tube described by Johnson (*Journal* Opt. Soc., 6, 701, 1922) has been found well adapted for the oscilloscope and arrangements have been made for its use.

The principles of operation of the oscilloscope are simple. Practically, we have found that, in order to avoid error due to leakage or induction, many details though simple in principle are perplexing in execution, particularly when we are not seeking an elaborate laboratory equipment, limited in use on account of its scattered complexity, but an assembled, self-contained instrument, simple in operation and readily portable. Its availability adds materially to its usefulness. The senior author desires to express his appreciation of the assistance rendered by his colleague in the development and construction of the finished instrument.

Discussion

K. B. McEachron: It seems to me that the material in this paper will be of considerable value to all of us who are interested in the study of recurrent phenomena of a character that requires a measuring device which takes little or no energy from the circuit.

The paper describes a very interesting and ingenious scheme for securing two or three sets of measurements all on the screen at the same time by the use of the distributor. Also, a method is given for getting a linear time axis by the use of the so-called Schroeter valve which I believe is perhaps better known abroad than in this country.

I do want to say something, however, regarding the statement made in the first few paragraphs of this paper with reference to linear time axes of other investigators and to say something about the work which we have been doing ourselves along that line.

Some two years ago[1] Mr. Wade and myself showed a group of cathode-ray oscillograms having a linear time axis.

It is well known that for a few degrees either side of zero, the current of a sine wave will vary directly with the time and the linear time axis shown in the paper referred to was obtained by using such a portion of a sine wave of current in the oscillograph deflecting coils. Thus when the current is zero the electron stream impinges on the middle of the photographic film, the synchronous switch usually being so arranged that the unknown transient occurs at this moment.

For taking volt-ampere curves, it has been necessary to develop a special form of motion in which the spot moves at a uniform rate to the middle of the film where it undergoes deflection by reason of the transient being studied and then resumes its uniform motion, thus carrying the spot off the film.

For transients of very short duration it is necessary to use as a time scale a high-frequency wave which gives an approximately linear axis only near the middle of the film. With such a time scale either end is very much condensed.

It should be remembered that the oscillograph which is used by Professor Bedell and Mr. Reich is quite different from that used by ourselves, since the transients we study occur but once, while with the oscilloscope they must necessarily be recurrent to obtain satisfactory records. For our work it is necessary to place the photographic film within the vacuum chamber which is not necessary with the oscilloscope.

P. A. Borden: What I have to say in discussing Professor Bedell's paper on the oscilloscope may appear irrelevant; but I take this opportunity to press the plea that I have always put forward for better standardization in engineering nomenclature.

In this connection I want to call attention to the word "oscilloscope." There was a device produced in England a few years ago by a Mr. Elverson, designed for visualizing the movements of rapidly oscillating mechanisms. It is purely mechanical and optical in its nature and is now generally known as the Elverson *oscilloscope*. Now Professor Bedell shows us a new and valuable application of the cathode-ray oscillograph, which has been styled the "oscilloscope:" and while on a basis of technical exactitude, his right to use this term would appear to be quite as great as that of Mr. Elverson, I cannot but feel that this double use of the term does not serve to clarify our technical nomenclature. I am of the opinion that we need among our standards committees some "inter-technical" body which will endeavor to oversee the naming of new developments in different branches of science and thus prevent such overlapping as I have cited, without the formality of having terms registered in the Patent Office.

1. A. I. E. E. Trans., Vol. 44, 1925, p. 832.

H. M. Turner: Professor Bedell explained how it is possible by means of a distributor to observe on the screen of the cathode-ray oscillograph several curves at the same time. I have obtained a similar result with considerable success by using a device called the transient visualizer which was described in the A. I. E. E. Journal of June, 1924, which permits photographic records to be made of certain types of phenomena as well as visual observations on the cathode-ray oscillograph.

By means of the transient visualizer associated with the General Electric oscillograph we have taken as many as twelve separate exposures on a single film which makes it convenient for comparing curves taken under different conditions.

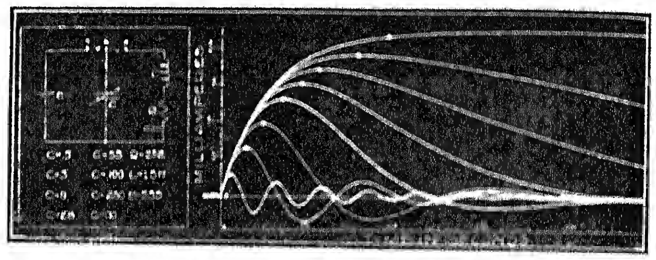

Fig. 1

F. Bedell: I wish to express my keen appreciation of the wonderful work done by Mr. McEachron and others in this country and by various workers in Europe in developing so successfully that type of cathode-ray oscillograph wherein a photographic plate is placed inside the cathode tube, so that the cathode rays impinge directly upon it. I admire the skill and patience of those who have done this work. In the hands of an expert, if expenditure of time and money be neglected, certain results can be thus obtained that can be obtained in no other way. Our object, however, has been to develop a simple instrument, fool-proof and portable, useful even for the man in the street with limited time and limited money, who wishes an instrument he can take where he will, as he would a voltmeter, observe the wave-form and get immediate results. He wants the results then and there, and does not want to wait until next week.

I am quite in sympathy with the desirability of uniformity in nomenclature. The oscilloscope is for viewing oscillations; the name is both descriptive and correct. If, as Mr. Borden points out, an instrument for viewing oscillations has already been termed an oscilloscope, all the more reason for retaining the name when a new instrument, even though operating on a different principle, is developed for performing this function.

Prof. Turner's remarks emphasize the desirability of visualizing several curves simultaneously.

Sensitivity Characteristics of a Low-Frequency Bridge Network for Locating Opens in Telephone Circuits

BY P. G. EDWARDS[1] and H. W. HERRINGTON[1]
Associate, A. I. E. E. Non-Member

Synopsis. *The problem of locating opens in telephone cable conductors involves the determination of impedances. A study has been made of the degree of accuracy and sensitivity obtainable in impedance measurements with different frequencies of supply voltage. For long cables the input impedance is a hyperbolic rather than linear function of the characteristic impedance. The error in impedance measurement arising from this functional departure proves to be least for the lower frequencies. On the other hand, the bridge sensitivity is improved by somewhat higher frequencies.*

A mathematical and experimental analysis of the sensitivity of impedance measurements in cable fault location by means of a de Sauty bridge indicates the desirability of using frequencies of the order of four cycles. The sensitivity is further increased by controlling the phase of the field excitation of the bridge galvanometer.

This improved open location method and equipment are sufficiently accurate that in practically all cases a fault in a 60-mile length of cable may be located within a maximum variation of plus or minus one-half the length of a cable section (a section is the length of cable between splices — about 750 ft.), and therefore enables one to select, prior to the opening of the cable, one or the other of the two splices between which the fault lies. This degree of accuracy is very desirable for practical reasons.

* * * * *

An analysis of the variation of sensitivity with change in frequency has been coordinated with a study of the characteristic variation of errors with frequency changes. These studies were made primarily for the purpose of selecting a suitable frequency of testing potential for a more sensitive, accurate, and reliable method of impedance measurement for locating opens in the conductors of telephone cables. The characteristics of these errors and the nature of the impedance measurements are discussed only as an illustration of the method in which a frequency of testing potential was selected to give a suitable sensitivity as well as to reduce certain errors which vary with frequency.

An indication of the location of an open is given by the ratio between an impedance measurement made on the faulty wire and a similar impedance measurement made on a good wire of similar characteristics which follows the same route as the faulty wire. For short cables, the impedance measured to ground may be regarded as identical with the capacitance component of the impedance to ground, but as the length of cable increases, the input impedance can no longer be regarded as equivalent to the capacitance component of this impedance because the input impedance is not proportional to the capacitance but may be expressed as a hyperbolic function,

$$Z_i = Z_0 \coth P\,L \qquad (1)$$

where Z_0 is the characteristic impedance of the line, P is the propagation constant, and L is the length.

A calculation of this hyperbolic deviation or error for different frequencies of testing potential showed that this error decreased with frequency as indicated by the curve of Fig. 1. To minimize this error, the optimum value of frequency obviously should be zero. But the sensitivity of a capacitance bridge network is zero at zero frequency. The problem, then, was one of selecting a frequency which would be low enough to make the hyperbolic errors negligible for all types of conductors and at the same time provide a sensitivity which would be sufficient to permit an accurate balance of a bridge. From this standpoint, it may be observed that for a decreasing frequency of testing potential,

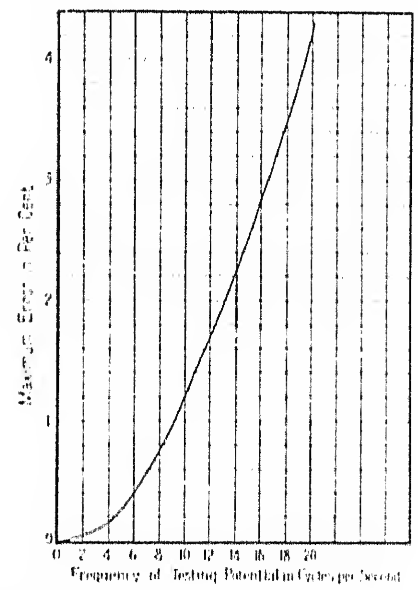

FIG. 1 THE MAXIMUM HYPERBOLIC ERROR FOR VARIOUS FREQUENCIES OF TESTING POTENTIAL

the maximum rate of decrease of hyperbolic error is evident in the neighborhood of four cycles, as shown by Fig. 1. It was shown by a computation of the hyperbolic errors of measurements made on the maximum length of conductors that these errors at four cycles might be neglected as being within the required accuracy of the method. Hence, a computation of the frequency sensitivity characteristics of a bridge network appeared to be the next step in the selection of a suitable frequency of testing potential.

1. Both of the American Tel. and Tel. Co., 195 Broadway, New York, N. Y.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

The sensitivities for several frequencies of testing potential were computed for a modified form of the de Sauty bridge. In this impedance bridge network, shown in Fig. 2, a very sensitive electrodynomameter, or a galvanometer equipped with an electromagnetic field, was used as a detector. The condition for balance in this impedance bridge network is

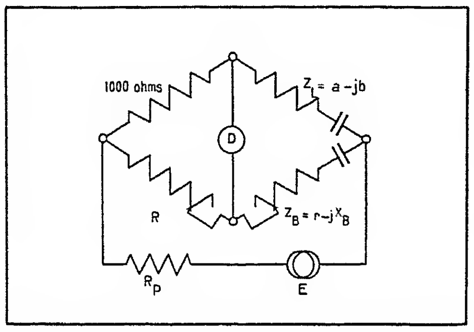

FIG. 2—BRIDGE USED IN THE LOCATION OF OPENS

E represents the low-frequency source, and R_p a protective resistance. The rheostat R and the 1000-ohm resistance may be regarded as the ratio arms of the bridge. The impedance of the line is represented by Z_L, a resistance and capacitance in series. The rheostat r is used in balancing the resistance component of the line impedance, so that the impedance angle of Z_B will equal the impedance angle of Z_L.

$$R\,Z_L = 1000\,Z_B$$

or

$$R\,(a - j\,b) = 1000\,(r - j\,X_B).$$

Collecting reals and imaginaries,

$$R\,a = 1000\,r$$

and

$$R\,b = 1000\,X_B\,.$$

If measurements R_1, r_1 and R_2, r_2 are made on the bad and good wires, respectively,

$$R_1\,a_1 = 1000\,r_1$$

and

$$R_2\,a_2 = 1000\,r_2;$$

also

$$R_1\,b_1 = 1000\,X_B$$

and

$$R_2\,b_2 = 1000\,X_B,$$
$$R_1\,b_1 = R_2\,b_2,$$

or

$$\frac{R_1}{R_2} = \frac{b_2}{b_1}$$

Yet the design of a suitable bridge is not concerned alone with balanced condition, but rather with the sensitivity and ease of balance with slight unbalances present. An indication of the probable sensitivity is afforded by a complete solution of the bridge network to determine the phase and magnitude of the galvanometer unbalance current with respect to the impressed voltage. The following determination of the galvanometer unbalance current was obtained by an application of Kirchoff's law to the bridge network shown in Fig. 3.

$$i_2\,z_1 - i_3\,z_5 - (i_1 - i_2)\,z_4 = 0$$
$$(i_2 + i_3)\,z_2 - (i_1 - i_2 - i_3)\,z_3 + i_3\,z_5 = 0$$
$$(i_1 - i_2)\,z_4 + (i_1 - i_2 - i_3)\,z_3 + i_1\,z_6 = E$$

After collecting current coefficients determinants are used in obtaining an expression for the unbalance current i_3, which is given by equation (2).

Collecting coefficients:

$$-\,i_1\,z_4 + i_2\,(z_1 + z_4) - i_3\,z_5 = 0$$
$$-\,i_1\,z_3 + i_2\,(z_2 + z_3) + i_3\,(z_2 + z_3 + z_5) = 0$$
$$i_1\,(z_3 + z_4 + z_6) - i_2\,(z_3 + z_4) - i_3\,z_3 = E$$

Solving by determinants for i_3:

$$i_3 = \frac{\begin{vmatrix} O & (z_1 + z_4) & -\,z_4 \\ O & (z_2 + z_3) & -\,z_3 \\ E & -\,(z_3 + z_4) & (z_3 + z_4 + z_6) \end{vmatrix}}{\begin{vmatrix} -\,z_5 & (z_1 + z_4) & -\,z_4 \\ (z_2 + z_3 + z_5) & (z_2 + z_3) & -\,z_3 \\ -\,z_3 & -\,(z_3 + z_4) & (z_3 + z_4 + z_6) \end{vmatrix}}$$

$$i_3 = \frac{E\,(z_2\,z_4 - z_1\,z_3)}{\Delta} \qquad (2)$$

where Δ is the denominator of the above determinant. Since the condition for balance is

$$z_1\,z_3 = z_2\,z_4$$

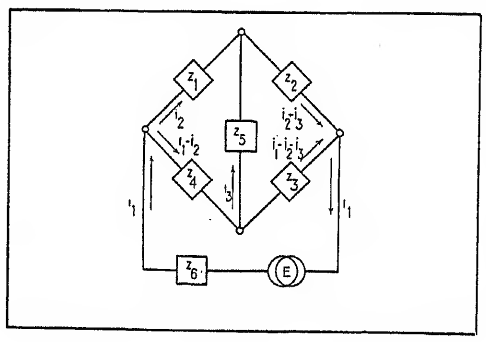

FIG. 3

we have, using the notation of Fig. 2,

$$1000\,(r - j\,X_B) = R\,(a - j\,b)$$

and, equating reals and imaginaries,

$$1000\,r = a\,R \qquad (3)$$
$$1000\,X_B = b\,R \qquad (4)$$

This impedance bridge can be balanced in two ways: by varying r and X_B, keeping R constant, or by varying R and r, keeping X_B constant; see Fig. 2. The effect is essentially the same in either case. When R is varied instead of X_B, the only difference is that the balance of the bridge is disturbed for both the real and imaginary components. This fact necessitates a correction of r each time R is changed in securing a balance of b against X_B. If X_B is varied, the balances of r against a and X_B against b are independent functions. In practise, it is easier to vary R and keep X_B

constant, but for the purpose of theoretical discussion, it lends clarity to consider X_B to be variable from the condition of balance.

From equation (1) above, the impedances of different lengths of line may be computed. A number of impe-

dance values representing different lengths of 19-gage, non-loaded cable up to 60 mi., at three frequencies, *viz.*, 20, 8, and 4 cycles, was selected, and the condition of balance of the impedance bridge calculated for each case

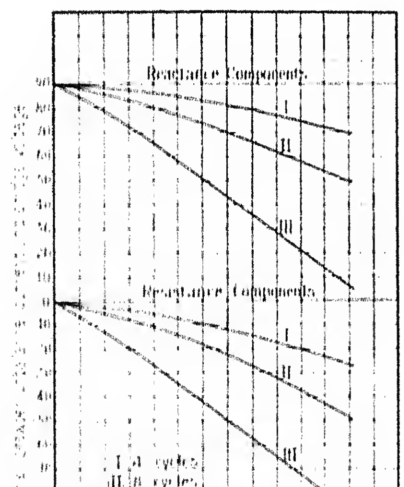

Fig. 5 The Variation of the Angle Between the Bridge Voltage and the Unbalance Current for the Reactance Component and Resistance Component of Non-Loaded 19-Gage Cable in Lengths Varying from Zero to Sixty Miles

The curves represent characteristics for frequencies of four, eight, and twenty cycles.

from equations (3) and (4). Curves of these impedances are shown in Fig. 4, where the reactances and resistances at the three chosen frequencies are plotted.

Since the sensitivity of the bridge network should be a maximum when the unbalance is small, *i. e.*, when a balance is about to be secured, this condition is the one with which the sensitivity calculation is concerned. The capacitance X_B of the bridge network was assumed to vary 10 per cent from the condition of balance and the galvanometer unbalance current, i_3, was then calculated from equation (2) for each length of line at each frequency. Both the magnitude and phase angle were found. Similarly, the resistance r was assumed to vary 10 per cent from the condition of balance, X_B

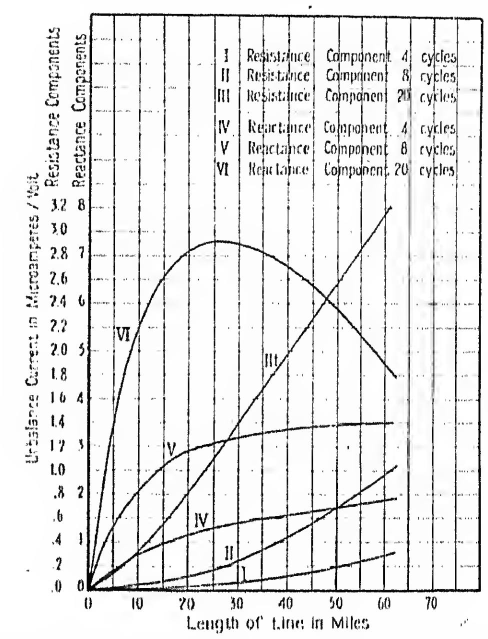

Fig. 6 Magnitude of the Unbalance Current for Measurements on the Impedance of Non-Loaded 19-Gage Cable, at Frequencies of Four, Eight, and Twenty Cycles

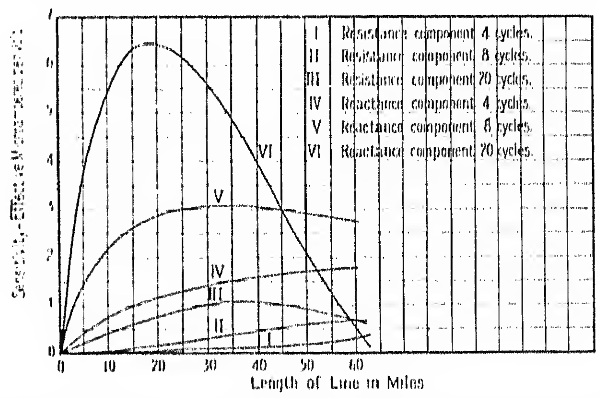

Fig. 7 Sensitivity to Unbalance for the Bridge Network for Impedance Measurements on Lenths of Non-Loaded 19-Gage Cable

These curves represent sensitivities for frequencies of testing potential of four, eight, and twenty cycles

remaining balanced, and another set of galvanometer unbalance currents was determined. Such calculations are particularly tedious, involving successive additions and subtractions, multiplications and divisions of complex quantities. The results of these calculations are shown in Figs. 5, 6, and 7. Figure 5 represents the variation in phase angle of the current i_3 with respect to the bridge potential, Fig. 6 the magnitude i_3, and Fig.

7 the relative sensitivities obtained with different frequencies and different lengths of line. These sensitivities are proportional to i_3, Fig. 6, and to the cosine of the angle between i_3 and the field current of the a-c. galvanometer. In the calculation of the curves

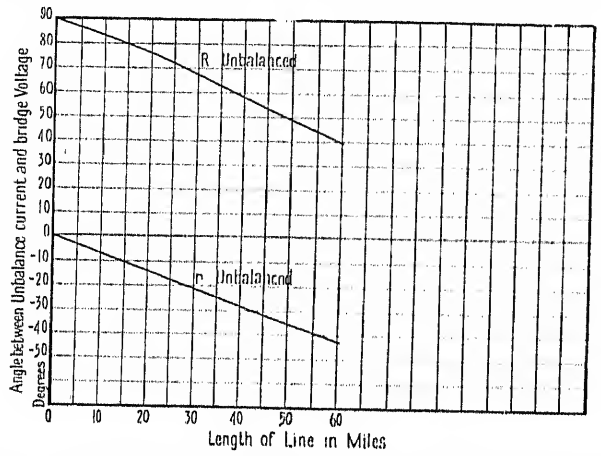

FIG. 8—CALCULATED VARIATION IN THE ANGLE BETWEEN UNBALANCE CURRENT AND BRIDGE VOLTAGE FOR UNBALANCE IN THE CAPACITANCE COMPONENT R AND FOR UNBALANCE IN THE RESISTANCE COMPONENT r OF THE IMPEDANCE OF NON-LOADED 19-GAGE CABLE. TESTING POTENTIAL OF 4-CYCLES

of Fig. 7, the field current of the galvanometer was assumed to be in phase with the bridge potential for the case of an unbalance in r, and leading the bridge potential by 90 deg. for the case of an unbalance in X_B.

Referring to Fig. 5, it is seen that for short lengths of line the unbalance current caused by unbalancing r is almost in phase with the voltage, while the unbalance current due to unbalancing X_B leads the voltage by approximately 90 deg. As the length of line increases, the phase angles tend to lag from these posi-

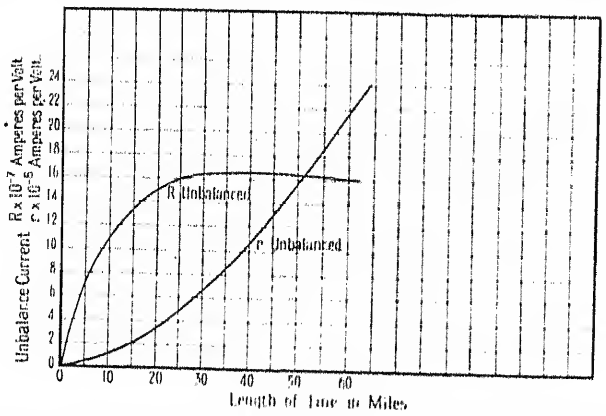

FIG. 9—CALCULATED MAGNITUDE OF THE UNBALANCE CURRENT FOR UNBALANCE IN THE CAPACITANCE COMPONENT R AND UNBALANCE IN THE RESISTANCE COMPONENT r OF THE IMPEDANCE OF NON-LOADED 19-GAGE CABLE. TESTING POTENTIAL 4-CYCLES

tions, due to the effect of the convergent variation of the resistive and reactive components of the line impedance; that is, the resistance increases and the reactance decreases with increase in length of line. This lag is greater for the higher frequencies. The total variation for 60 mi. of cable measured at 20 cycles is practically 90 deg., which means that for a given field current the sensitivity using 20 cycles must approach zero with some length of line between zero and 60 mi. This condition is illustrated in Fig. 7 where the sensitivity for 20 cycles is a maximum at 20 to 30 mi., but falls rapidly toward zero at the longer lengths of line. With the lower frequencies and the setting of

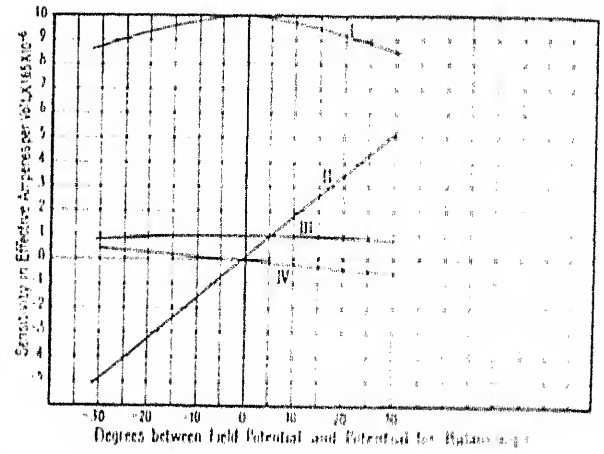

FIG. 10—CALCULATED SENSITIVITY OF THE BRIDGE AT FOUR CYCLES ON A 50-MILE LENGTH OF NON-LOADED 19-GAGE CABLE

Sensitivities for unbalance in the component
I. R with the phase of testing potential applied for balancing R

III. r with the phase of testing potential applied for balancing r
IV. r with the phase of testing potential applied for balancing R

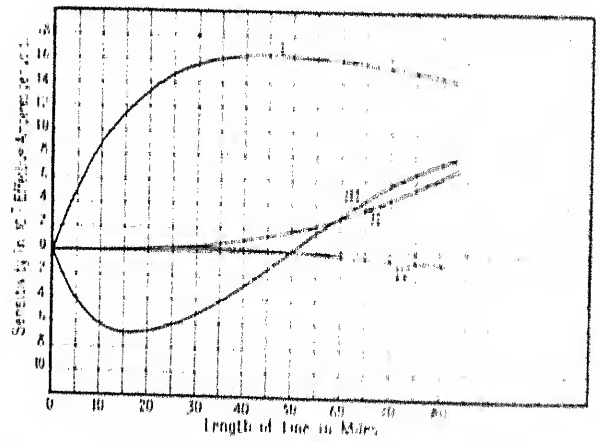

FIG. 11—CALCULATED SENSITIVITY FOR LENGTHS OF NON-LOADED 19-GAGE CONDUCTOR USING THE IMPEDANCE BRIDGE ARRANGEMENT WHICH GAVE THE MAXIMUM SENSITIVITY FOR CURVE I IN FIG. 11

Sensitivity for unbalance in the component
I. R with the phase of testing potential applied for balancing R
II. r with the phase of testing potential applied for balancing r
III. R with the phase of testing potential applied for balancing r
IV. r with the phase of testing potential applied for balancing R

field current used, the general effect is an increase in sensitivity as the length of line increases, and a decrease in sensitivity with decrease in frequency. This decrease is due to the decrease in reactance with increase in length of line; see Fig. 4.

It would appear that provision should be made for

shifting the phase of the field current through 90 deg., its two positions being respectively in phase with the bridge potential and 90 deg. leading. Thus the two components, r and X_B, could be balanced independently except for the shift in phase with different line lengths. This phase shift is small with a frequency of testing potential of four cycles.

A frequency of four cycles was selected as the optimum as regards the size of hyperbolic error discussed above,

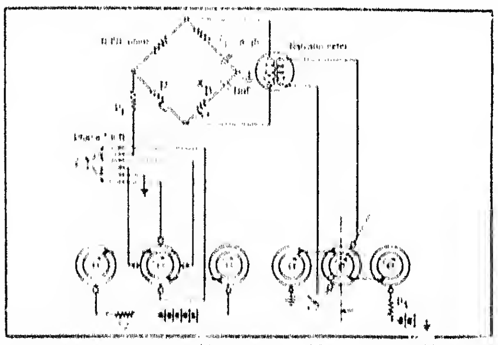

FIG. 12—IMPEDANCE BRIDGE CIRCUIT SHOWING THE ARRANGEMENT USED IN APPLYING 4-CYCLE TESTING POTENTIALS IN QUADRATURE

the sensitivity available, and the amount of phase shift with increase in length of line. The sensitivity at four cycles has the advantage of being sufficient but not excessive. To a large extent, the condition of phase shift, with increase in length of line, governs the ease of securing a balance over the range of line lengths.

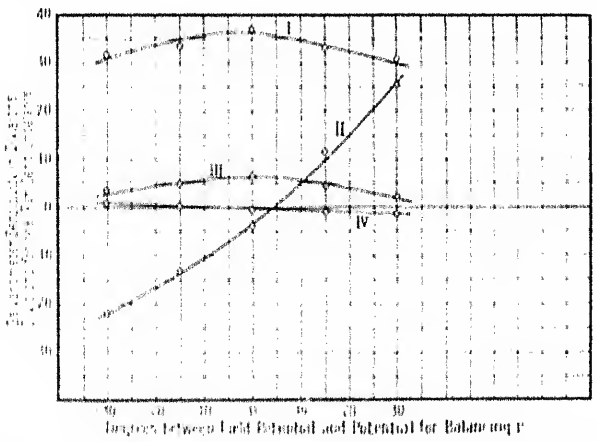

FIG. 13—OBSERVED GALVANOMETER SENSITIVITIES WHICH ARE COMPARABLE TO THE CALCULATED SENSITIVITIES OF FIG. 11

Sensitivity for unbalance in the component:
I. R with the phase of testing potential applied for balancing R
II. R with the phase of testing potential applied for balancing r
III. r with the phase of testing potential applied for balancing r
IV. r with the phase of testing potential applied for balancing R

The ideal arrangement would be one in which the field current could always be placed in phase with the component of the bridge unbalance current it was desired to eliminate. Such a quality is not characteristic of the type of bridge used; however, a desirable approximation of such an arrangement is obtained when a four-cycle frequency of testing potential is used.

In order to check the assumption stated above, that the bridge could also be balanced by keeping X_B constant and varying R and r, without materially changing the conditions of balance, another set of galvanometer unbalance currents was calculated with X_B constant and R and r varied respectively 10 per cent from the condition of balance. The chosen frequency of four cycles was used in this calculation.

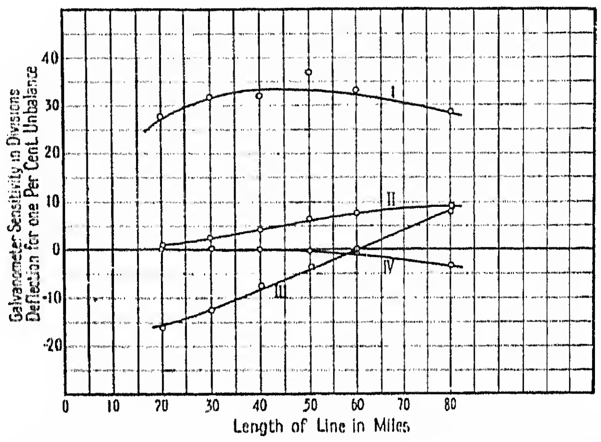

FIG. 14—OBSERVED GALVANOMETER SENSITIVITIES WHICH ARE COMPARABLE TO THE CALCULATED SENSITIVITIES OF FIG. 17

Sensitivity for unbalance in the component:
I. R with the phase of testing potential applied for balancing R
II. r with the phase of testing potential applied for balancing r
III. R with the phase of testing potential applied for balancing r
IV. r with the phase of testing potential applied for balancing R

These curves of phase angle and current magnitude are shown in Figs. 8 and 9, and correspond to those shown in Figs. 5 and 6, calculated by the other method.

Since R increases with increase in length of line, the sensitivity per ohm change in R will be better throughout the range of lengths if the sensitivity for a given change in R is a maximum when R is a maximum.

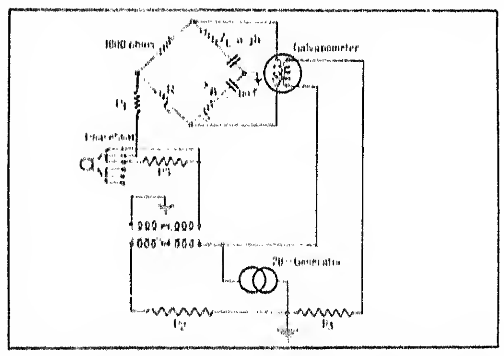

FIG. 15—IMPEDANCE BRIDGE CIRCUIT SHOWING A SIMPLIFIED ARRANGEMENT EMPLOYING 20-CYCLES AS A SOURCE OF TESTING POTENTIAL WITH AN APPROXIMATE METHOD OF SHIFTING PHASE

Taking 50 mi. as the average total length of line, and assuming two bridge potentials 90 deg. apart, a set of sensitivity curves was calculated for this length of line, the phase of the field potential being varied on either side of the bridge testing potential. The lag of the field current from the field voltage calculated from the field inductance and resistance was found to be about 40 deg. The resulting sensitivity curves are shown in Fig. 10, and these indicate a maximum sensi-

tivity for R and r with the field potential in phase with the potential used to balance r.

With the assumed conditions as determined by this calculation, *viz.*, two bridge potentials 90 deg. apart and a field current lagging one bridge potential 40 deg., a complete set of sensitivity curves was calculated for

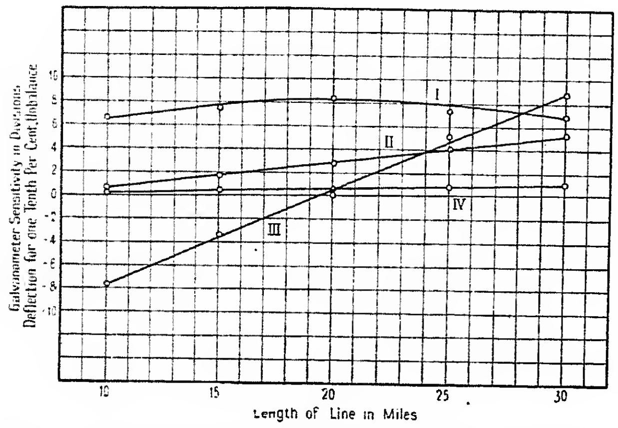

FIG. 16—OBSERVED GALVANOMETER SENSITIVITIES FOR A 20-CYCLE FREQUENCY OF TESTING POTENTIAL. THESE CURVES ARE COMPARABLE WITH THE 4-CYCLE CURVES OF FIG. 14

Sensitivities for unbalance in the component:
I. R with the phase of testing potential applied for balancing R
II. r with the phase of testing potential applied for balancing r
III. R with the phase of testing potential applied for balancing r
IV. r with the phase of testing potential applied for balancing R

different lengths of line from zero to 80 mi. These are shown in Fig. 11. It should be noted that the sensitivity for detecting an unbalance in R is a maximum at the desired length of 50 mi. The sensitivity for an unbalance in r is low at the shorter lengths of line, but increases as the length of line increases. It may be noted that in both Figs. 10 and 11 the sensitivity curve for changes in R passes through zero when the testing potential is applied for balancing r. Likewise, the

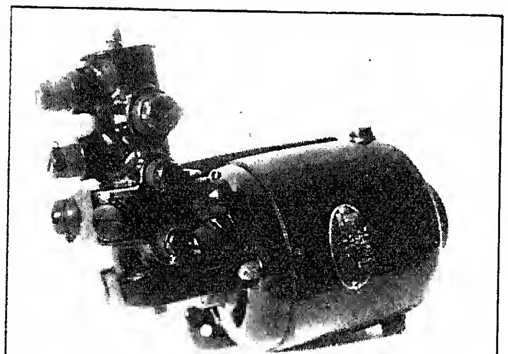

FIG. 17—COMMERCIAL DESIGN OF MOTOR-DRIVEN COMMUTATOR WHICH IS USED TO SUPPLY 4-CYCLE ALTERNATING POTENTIALS FOR THE IMPEDANCE BRIDGE

sensitivity curve for changes in r passes through zero when the testing potential is applied for balancing R. This point is where the field current and galvanometer unbalance current are 90 deg. out of phase. Naturally, this point coincides with the point of maximum sensitivity for the normal potential arrangement. As stated above, it would be ideal if these "reverse sensitivities" could be zero and the "true sensitivities" could be maximum throughout the entire range of lengths. Reference to Fig. 11 will show that the reverse sensitivity for r is practically zero throughout the range of lengths. This fact in itself is significant. Assuming r to be set on zero, R could be varied to

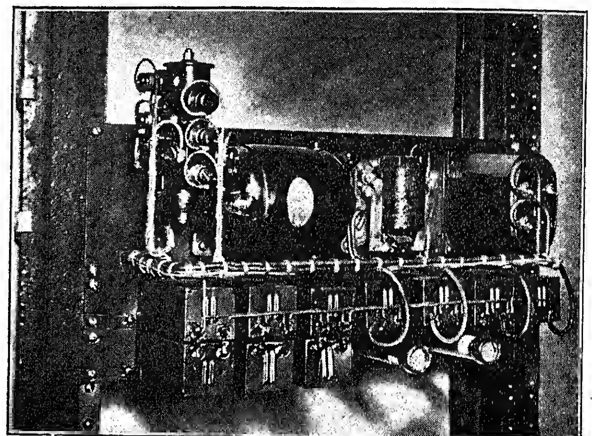

FIG. 18—4-CYCLE MOTOR-DRIVEN COMMUTATOR WITH ASSOCIATED EQUIPMENT

secure an approximate balance, using the proper testing potential. This balance would be fairly accurate since the reverse sensitivity for r is quite low throughout. Shifting bridge potentials 90 deg., r could be adjusted almost to the proper point since R is practically correct. The balance of R and r can then be refined as often as is necessary to secure a perfect balance. Since r is not used in any calculation, and since its effect on R is small once an approximate balance of R and r is obtained, the need for an accurate balance of r is small.

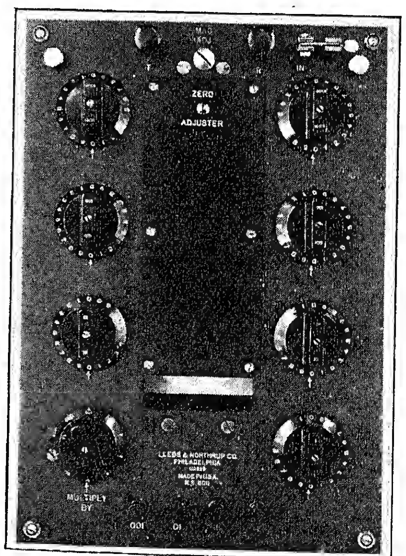

FIG. 19—PANEL ASSEMBLY OF THE IMPEDANCE BRIDGE

A series of observations made with experimental apparatus arranged as shown in Fig. 12 gave the sensitivity curves shown in Figs. 13 and 14. The observed sensitivity characteristics shown by these curves agree

A simplified arrangement for use in certain types of measurement not requiring the accuracy afforded by the four-cycle arrangement of Fig. 12 is shown in Fig. 15. A 20-cycle ringing generator is used as a source of single-phase testing potential. Phase shifting is accomplished by the insertion of a high resistance, PS, in series with the bridge supply. This affords a considerable shift of phase which is not, however, 90 deg., nor is it constant. A transformer is provided for changing the potential when desirable and to afford a non-grounded source of potential in the measurement of mutual capacitances. The 20-cycle generator is normally grounded.

Observed sensitivity curves for this arrangement of 20-cycle equipment are given in Fig. 16. It will be seen that these sensitivities are considerably higher in value than for the four-cycle arrangement because the reactance of a given length of line is less at 20 cycles than at 4 cycles. The range is less with 20 cycles due to the fact that the phase of the galvanometer moving coil current, with respect to the testing potential, changes much more rapidly at 20 cycles than at 4 cycles. Thus the range of line length is lower, unless provision is made for shifting the galvanometer field current. The maximum length of line is limited also by the allowable value of the hyperbolic error. The hyperbolic errors obtained with measurements made at 20 cycles on these short lengths of line are about the same as those obtained in the measurements made at 4 cycles on the longer lengths of line.

In general, the frequency of testing potential of four cycles affords a balance more quickly and easily than does the 20-cycle arrangement. This is because the phase shift with four cycles is exactly 90 deg. while that obtainable with the simplified 20-cycle arrangement is necessarily an approximation, and does not lend itself to regulation either in regard to phase shift or relative position of field current. With four cycles, these relations are more or less flexible and can be adjusted to afford characteristics tending toward an optimum condition.

After having completed an analysis of the problem and demonstrated the practicability of the proposed methods, it remained to develop applications of these methods for practical use. Equipment was designed to develop a low-frequency source of alternating potential by reversing a testing battery. The device developed for this purpose is a four-cycle, motor-driven commutator shown in Fig. 17. The assembly of the four-cycle commutator with associated apparatus is shown in Fig. 18.

The galvanometer and the equipment required in the modified form of the de Sauty bridge have been incorporated in a compact unit which is shown in Fig. 19. This bridge, while being particularly adapted to the four-cycle impedance measurements required for open location tests, is also applicable for d-c. bridge measurements. Assembly details for the bridge arrangement very favorably with the theoretical values shown by the curves of Figs. 10 and 11.

are shown in Fig. 20. The a-c. galvanometer is sufficiently sensitive to be directly actuated by any significant unbalance of the impedance bridge, so that it is unnecessary to use an amplifier, rectifier, or other converting apparatus which may be difficult of adjustment or maintenance.

A few additional features are outlined as some of the significant results of this development of an improved open location method.

It has been shown that the error caused by the deviation from the straight line relation between sending-end admittance and physical length of line, has been reduced to a value which may be neglected as being less than the required accuracy of the open location method.

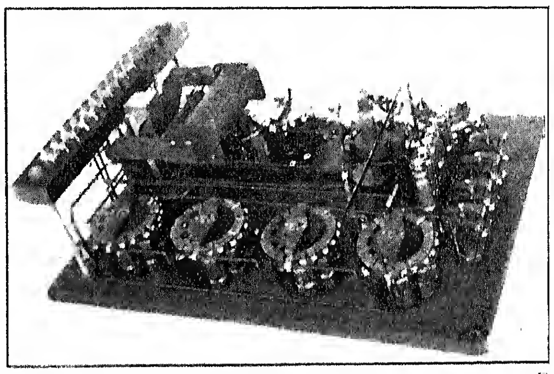

Fig. 20 Internal Assembly of the Impedance Bridge

This impedance bridge arrangement employs several features which are distinct improvements on the methods previously utilized for this purpose. In order that the impedance angles of the impedance networks may be balanced, a variable resistance has been connected in that branch of the bridge which contains the comparison capacitance. This balance of the impedance angles of the impedance network was found to be important in obtaining a steady performance of the a-c. galvanometer. A system has been devised for separately balancing the resistance components as well as the capacitance components of the reactive networks of the impedance bridge. It was found that this arrangement gives a maximum sensitivity to each component and permits of a very rapid balance of the bridge.

Discussion

I. M. Stein: It seems to me that the method and apparatus described accomplish two things. First, the bridge circuit and the type of detector used permit of a great precision of balance; that is, the quantity being measured may be measured precisely enough to give the accuracy desired in locating the open circuit. Then, having a set-up which gives the desired precision, we have two options. One is to chart each long cable by putting "opens" at certain known places and making measurements; the other is to get rid of the non-linear characteristic so that no charting is necessary.

The second method is the one which has been chosen, and the desired result has been accomplished by lowering the frequency enough to give a linear relation between the measured quantity and the length of cable to the "open."

So that there are two steps. First, a precision of setting enabling an accurate measurement of the capacitance; and second, the use of a frequency low enough to eliminate certain errors, thus obtaining a linear relation between capacitance and distance.

I should like to ask if I have a correct understanding of the matter.

B. W. Kendall: The need for the development of this modification of Wheatstone-bridge methods arose in connection with the large growth of toll-cable plant within the last few years. The convenient distance between cable-testing stations is set by the use of telephone repeaters at about a 50-mi. spacing, and it was therefore desirable to be able to locate opens in the cable conductors over distances of this order. Because of the difficulty in getting access to the individual wires along the cable it was important that the location of the fault be as accurate as possible.

The terminal impedance as measured between a defective (open) wire and ground is a hyperbolic function of the distance from the measuring point to the broken end of the defective wire. In this method, the testing frequency is so chosen as to make this relation approach a reciprocal function so that the capacity measured is directly proportional to the distance. This choice is a matter of convenience in testing. It would be possible to use a higher frequency and then by means of tables of hyperbolic functions to determine the distance to the break. In the paper the deviation of the measured capacity from direct proportionality with the distance is spoken of as an "error." This is, of course, an error which would be made if a higher frequency were used for the measurement and it were then assumed that the measured capacity and the distance were in direct proportion. By using so low a measuring frequency the error that would thus be incurred is made negligible and the measuring technique is thereby simplified.

The other notable feature of this paper is the use of bridge and galvanometer currents of different phases for determining the settings of the two adjustable resistances of the bridge. It should be understood that the balance so obtained is correct for any phase of measuring current and that this method is applied simply to obtain a larger deflection of the galvanometer for a given unbalance of the bridge, thereby facilitating the measurement. This method was developed for measuring opens in cable circuits, which have certain definite and uniform characteristics, and I should like to ask Mr. Edwards or Mr. Herrington what experience they have had with the use of the same apparatus in locating faults in open wire in which the impedances would have different characteristics from those of cable circuits.

This paper shows what can be accomplished in the development of a special bridge method for readily making tests of circuits which are uniform in character. At other frequencies and in other arts where a large number of quantities which differ little among themselves are to be measured, the exercise of equal skill and ingenuity can develop methods to simplify and expedite the determinations.

S. P. Shackelton: An important phase of the work of an engineer involves the application to practical everyday problems of the results of pure scientific investigation and research. The contribution of Edwards and Herrington constitutes such a practical application to a problem which has been studied for many years. It occupied the minds of communication engineers before the advent of the telephone. The particular arrangements described do not disclose any new principles but rather represent the utilization of known characteristics of lines and networks to a useful purpose.

The bridge network used was described in 1891. An approximate utilization of transmission-line low-frequency characteristics has been in common use for open locations. Alternating-current galvanometers have been well known although their use as detectors in the balancing of bridge circuits has not been so common. The shifting of the phase in the bridge to assist in obtaining a balance had been treated prior to the work under discussion. The present work, however, affords a convenient tool for the field man whether he be technical or not, to apply technical methods to his common problems of plant maintenance.

Specifically, the problem was one of adapting the technical methods to rather trying limitations imposed by plant conditions. A low-frequency measurement was desired with positive indications of balance and with a minimum adjustment of variables. A method was required which would afford a rather high degree of accuracy considering the precision of the apparatus and the possible errors outside the control of the operator. All this was combined in space limitations which necessitated rather careful detail design.

The authors have not specified any requirements as to wave shape although stressing the phase relations required in the different portions of the bridge network. The effect of phase angle on balance is noted and, of course, for any given length of line and frequency there is a best value of phase shift. It may be interesting to know the relative importance of this and its effect on other lengths of line.

C. R. Fischle: There is one phase of the subject presented by Messrs. Herrington and Edwards that it would seem warrants discussion, and that is the means employed to apply the principles brought out in the paper to practical telephone work.

In order to facilitate the application of these principles by the test-board forces, the Bell System has established routines outlining in a simple and orderly manner the procedures to be followed in determining the location of cable faults in toll cables. The engineering forces, as a rule, prepare in advance for each testing point, data such as temperature correction curves and records giving information as to cable distances, loading, gage of conductors, cable make-up, etc., for the cables to be tested from the respective points. Work sheets are supplied to the test board men on which the results of the electrical tests made at the time of a fault location are entered, together with values selected from the data mentioned above. By following the sequence of calculations set up on this work sheet, the fault location is quickly arrived at. These calculations are of a simple order and do not involve hyperbolics.

By administering the work in this manner the test board men can expeditiously arrive at accurate fault locations, thus materially aiding in the dispatch of repair forces to the fault and in securing the restoration of defective circuits in the least possible time.

P. G. Edwards: One question which has arisen in connection with the low-frequency bridge is that of wave form. A square wave is used with results agreeing very closely with theoretical values based on calculations involving a sinusoidal wave shape. This is made possible by the fact that the bridge network employed is symmetrical. With a square wave and a network involving both inductance and capacitance sinusoidal methods of treatment probably would not be applicable.

A question has been brought up by Mr. Kendall that of errors with frequencies other than 4 cycles. In earlier designs higher frequencies were used and a family of correction curves was plotted for each class of conductors, from which a correction was read for each capacitance ratio. This correction in per cent when applied to the capacitance ratio gave the true length ratio. On toll cables of average length and with a frequency of 8 cycles this correction reached values as high as 1 per cent.

In connection with the subject of correction curves, the question has arisen as to the practicability of plotting curves for individual conductors or classes of conductors. Mr. Stein's analysis of the situation in this respect is quite correct. Due to

the large number of circuits involved, as well as classes of circuits, the number of combinations possible renders this procedure quite unwieldy and expensive. The problem has been treated rather by means of fundamental design. As pointed out by Fischle records of actual measurements, however, are filed and are accessible to the tester.

In regard to phase adjustment, as has been brought out in the paper, there is an optimum phase adjustment for each measurement. In the apparatus as outlined an adjustment has been selected which gives a desirable set of sensitivity characteristics for the type of work for which the apparatus was designed. The equipment arrangements are such that the phase relation of bridge potential and field potential can be adjusted where desirable. This is not done, however, in the normal routine of locating opens.

Mr. Kendall has brought up the question of open-wire impedances. The equipment as outlined has been tried out on exposed aerial lines with success. The chief departure from the problem of locating opens in cables is the presence of a leakance component in the line impedance. Toll cables are almost entirely free from this characteristic. This leakance component happily involves no modification in design, but is observed in the balancing of the bridge as an increase in the value of the resistance component of the condenser arm of the bridge and does not, over a considerable range of leakance, affect the ratio-arm setting, or in consequence, the actual fault location.

Microammeter Indication of High-Frequency Bridge Balance

BY H. M. TURNER[1]

Member, A. I. E. E.

Synopsis. *A visual method of obtaining bridge balance by means of a d-c. microammeter in the plate circuit of an electron tube detector associated with one or more stage of amplification, which gives maximum reading for a state of bridge balance, thereby permitting use of a sensitive meter. A large bridge unbalance reduces the deflection to a low value and as the balance is approached the reading increases. This method overcomes the limitations of the aural method and renders a quantitative determination of the degree of unbalance.*

* * * * *

THE telephone receiver, due to its simplicity, convenience, and sensitivity, has been widely used for determining a-c. bridge balance and, under favorable conditions, is fairly satisfactory. The aural method, however, involving as it does the receiver associated with the ear, has two serious limitations namely, it can be used only where there is very

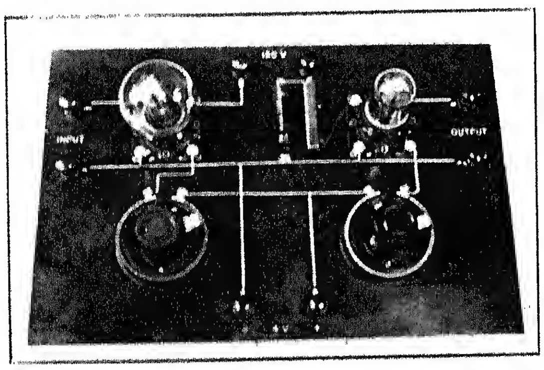

FIG. 1 AMPLIFIER AND DETECTOR UNIT

method in a noisy laboratory, it is unnecessary to point little extraneous noise and for best operation the frequency range is restricted to a band of 200 to 2000 cycles unless a heterodyne scheme is adopted.

For those who have had experience with the aural out the difficulties encountered, other than to say that noise is always a source of annoyance and often makes measurements absolutely impossible.

The combined limitations of the receiver and ear in connection with bridge measurements over a wide frequency range are not so generally appreciated[2]. While the limits of audibility are usually given as 16 to 40,000 cycles, the average person will be unable to hear above 15,000 and it will be impossible to determine even an approximate balance at these extreme frequencies. It is found that above 2000 or 3000 cycles, the sensitivity of the aural method is erratic and usually quite low. There is usually a marked difference in the sensitivity of the right ear and left ear of a given individual and it has been found frequently that the use of both ears is less effective than one alone. Different results are obtained on different days and, of course, there are wide variations among individuals. All of these factors point to the need of a more satisfactory method of determining bridge balance in order that results may be duplicated.

A visual method has been devised in our laboratory, using a d-c. microammeter in the plate circuit of a detector tube, associated with one or more stages of amplification, which has given very satisfactory results.

A reproduction of a photograph of the amplifier and detector unit is shown in Fig. 1 and other details including the plate and grid curves are given in Fig. 2.

1. Associate Professor of Electrical Engineering, Yale University.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

2. Engineers of the Bell Telephone Laboratory are familiar with these matters but have not, so far as I know, published any papers calling specific attention to their bearing on bridge measurements.

Tubes with Gas

It will be observed that the grid-condenser form of detection is used, but without a grid-leak, and operates on the steep straight portion of the plate-current curve and at the sharp bend of the grid-current curve. Due to the current in the plate of the amplifier tube, there is a

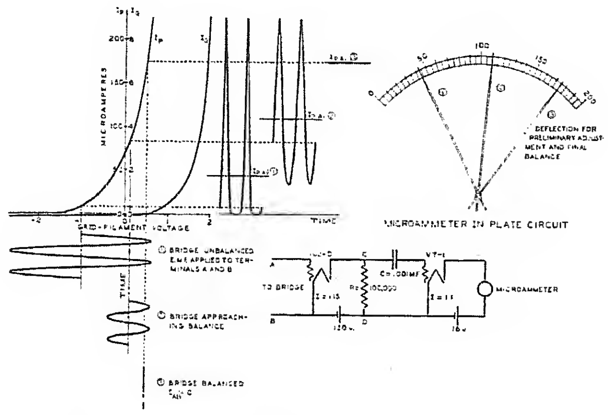

Fig. 2—Visual Bridge Balance Indicator

rather large difference of potential between C and D, that is, across the coupling resistance, C being negative with respect to D. This large negative voltage is impressed upon the grid of the detector tube through the condenser which would naturally reduce the plate current to a low value, but due to the presence of some gas in the tube, there is flow of current in the grid circuit in a counter clockwise direction which charges

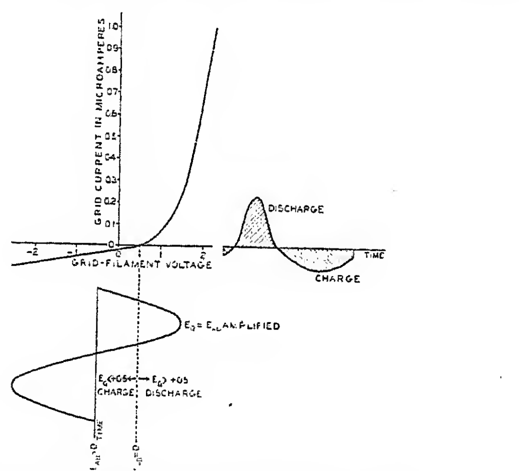

Fig. 3—Action of Grid Condenser with an Alternating E. M. F. of Constant Value Impressed upon Terminals A and B, Fig. 2

the condenser to a potential slightly in excess of that between C and D and, of course, in the opposite direction. The total voltage between grid and filament is about + 0.5 volt. This is the point where the grid current is zero and is changing from negative to positive as shown in Fig. 2. With an alternating electromotive force of constant value impressed upon A B, the charge of the grid condenser is reduced and the grid-filament potential becomes less than +0.5 and, for a large unbalanced bridge, electromotive force may be considerably negative, thus reducing the average plate current to a very small value. Regardless of the voltage impressed, the axis about which it varies moves to the left from the point where the grid current becomes zero, until the average charge on the condenser is constant, that is, until the discharge of the condenser, during the time the impressed electromotive force

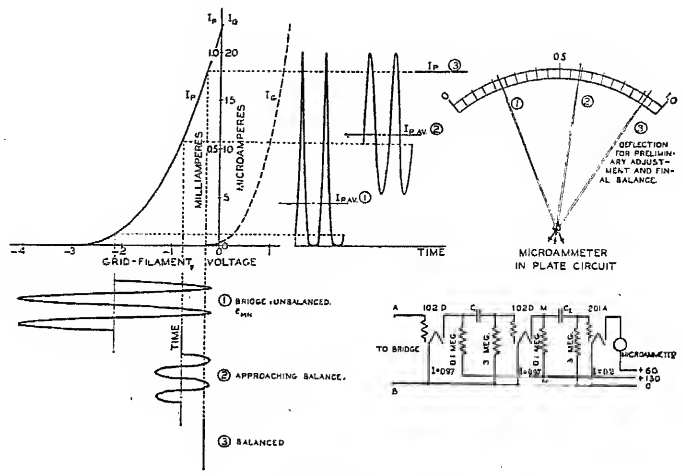

Fig. 3a

makes the grid more than + 0.5 volt, is equal to the charge during the time the grid is less than + 0.5 of a volt, as shown by the shaded areas Fig. 3. Since the negative grid current is very small as compared with the positive values, the grid potential is greater than + 0.5 for a very small part of the cycle as shown.

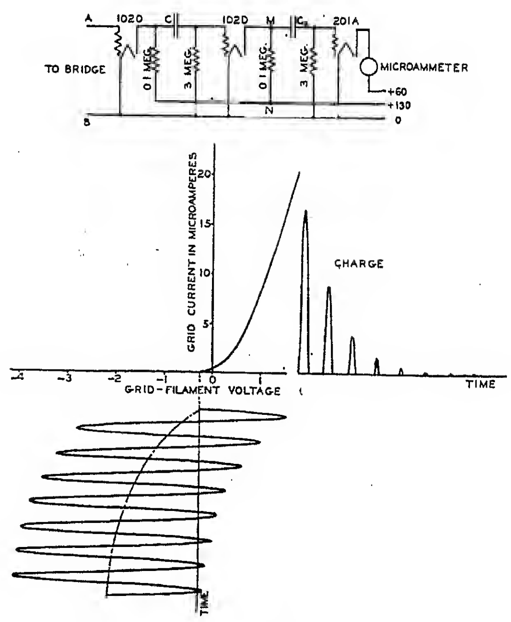

Fig. 3b

By this arrangement, the plate current of the detecting tube is a maximum when the alternating electromotive force impressed upon the terminals A B is zero, which corresponds to a balanced condition of the

bridge, thereby permitting the use of a sensitive meter and at the same time making it fool-proof so far as the meter is concerned after the preliminary adjustment. The maximum current may be predetermined and is

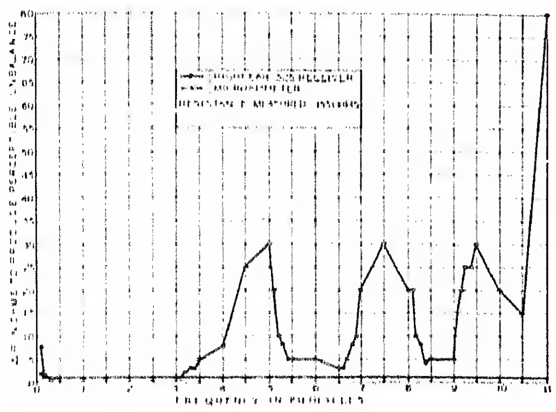

Fig. 1

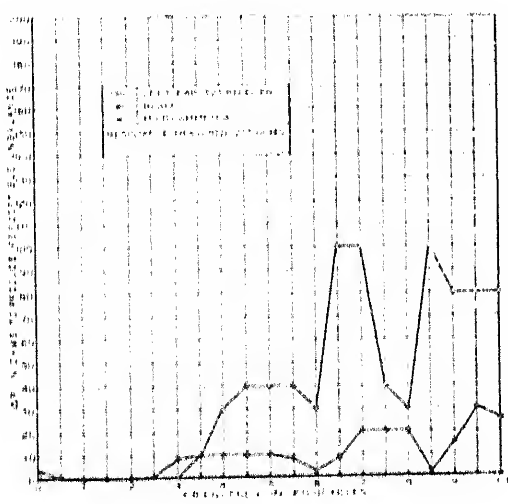

Fig. 5

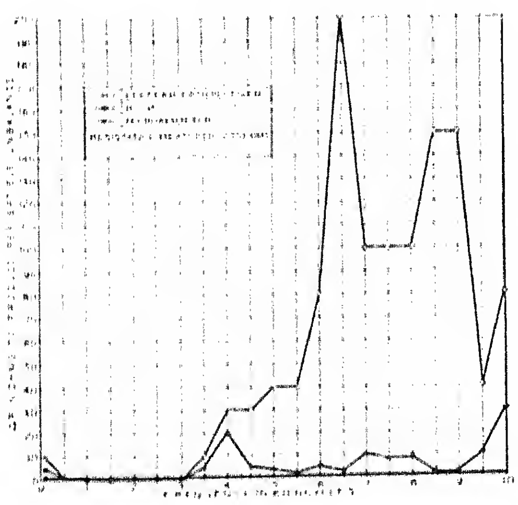

Fig. 6

under the control of the operator. The preliminary adjustment is made by short-circuiting the terminals A B, equivalent to a bridge balance in that there is no impressed electromotive force, and increasing the filament current to give the desired reading which is usually near full scale as shown in Fig. 2. When the bridge is unbalanced, the amplified bridge electromotive force impressed upon the grid filament of the detecting tube results in a marked decrease in the average plate current as indicated by the microammeter, and as the

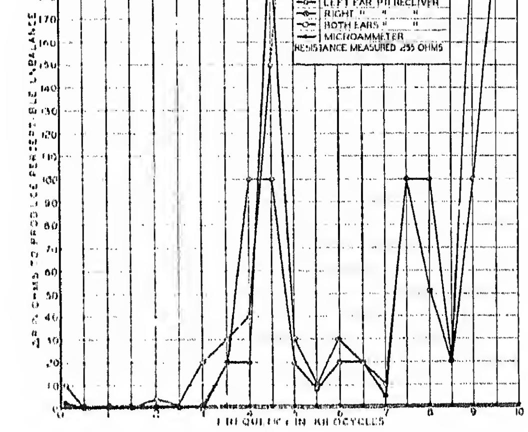

Fig. 7

balanced condition is approached the current gradually increases.

At maximum deflection the meter is extremely sensitive, thus permitting a decidedly sharp balance to be obtained, a slight change in one of the circuit constants being sufficient to cause the indication to decrease several divisions on the scale. It is a simple matter to determine whether the balance is perfect without the

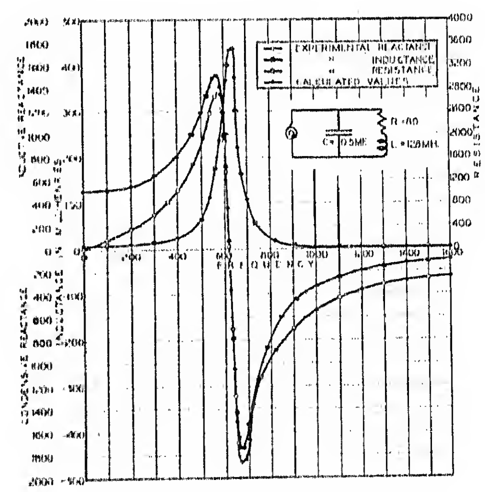

Fig. 8

necessity of remembering the initial maximum current. When the bridge is thought to be in balance, short-circuit the terminals A B, and if there is no change in the meter reading the bridge is balanced. In certain types of circuits, the presence of harmonics in the impressed electromotive force will make it impossible to fulfill

the condition just referred to, in which case it may be desirable to use a multiple-band filter, as shown in Figs. 9 and 10, to eliminate this source of trouble.

High Vacuum Tubes

Where a highly exhausted tube is used for the detector, such as the 201-A, a modification of the circuit is necessary for the reason that the high negative potential between C and D of Fig. 2 would reduce the steady plate current to zero and keep it there. However, by putting the battery in series with the coupling resistance *CD*, *C* becomes positive with respect to *D*, this voltage being quite large, a large positive grid current flows momentarily charging the condenser until the grid-filament voltage of the detector tube is zero or slightly negative which is a satisfactory operating point.

The modified circuit and characteristic curves are shown in Figs. 3A and 3B. With terminal *AB* connected to an unbalanced bridge there will be a constant alternating potential between *M* and the negative filament and for the positive half cycles a grid current flows increasing the charge on the condenser as shown by Fig. 3B. During the negative half cycle there can be no grid current so the charge is constant and the voltages add up in the usual way. At the beginning of the second cycle the operating point is to the left of the initial position due to the increased charge on the condenser. This action continues until the axis has been moved to the left by an amount almost equal to the maximum value of the alternating component. The average plate current is considerably reduced as shown by 1 Fig. 3A. Now as the bridge balance is approached the alternating e. m. f. component decreases but with a perfect grid condenser there would be no change in the plate current and in any event the change would be extremely slow. A leak resistance is provided in order to make the plate meter responsive to changes in the impressed e. m. f. in which case the condenser charge decreases and the average plate current increases until some new position such as 2 is reached. For any bridge unbalance the axis about which the alternating component of grid voltage varies is to the left of the point where the grid current becomes zero by an amount slightly less than the maximum of the alternating voltage, that is, during a small part of each cycle there is a flow of grid current to maintain the average charge on the condenser constant.

As the bridge balance is approached closely the alternating grid voltage becomes less and less and the excess charge on the condenser approaches zero as the charge leaks away and the average plate current is a maximum.

In order to illustrate the points that have been discussed, a number of curves that are more or less self-explanatory will be included. The simplest type of circuit is used in order to make the comparison more easily appreciated. Fig. 4 shows the change in resistance, ΔR, necessary to produce a perceptible unbalance as a function of the frequency. Here are compared the results obtained with the aural and visual methods. With the aural method, the sensitivity was entirely satisfactory from 200 to 3000 cycles but a change of 30 ohms in 155 was required to produce a perceptible unbalance at 5000, 7500, and 9500 cycles and 80 ohms at

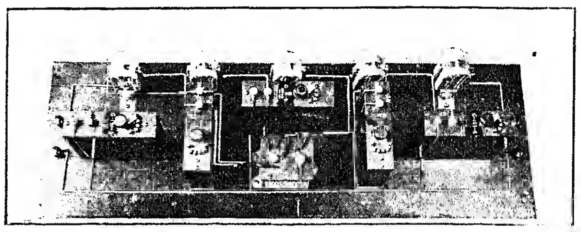

Fig. 9—Multiple Band Filter

11,000 cycles. The visual method gave a sensitivity of one ohm from 200 to 11,000 cycles. On another day, the observer, using the same receiver, obtained better results with the right ear than those shown in Fig. 4 but much poorer with the left ear. These curves are shown in Fig. 5 and a similar set using a different receiver in Fig. 6. At certain frequencies one ear shows a relatively high, and the other a very low, senstivity, and vice versa, suggesting the desirability of using a double receiver, but in Fig. 7 at 4500 cycles and at 9000 the results are not so good as with the right ear alone. These points were checked many times and represent the best data obtainable. These irregularities have been verified recently by other observers. In the different cases there is considerable variation in the frequencies at which the maximum and minimum points occur.

In all cases, the results obtained by the microammeter

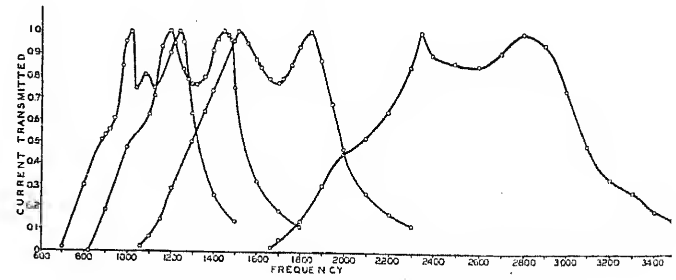

Fig. 10—Multiple Band Pass Filter

were satisfactory throughout the frequency range, although the sensitivity could have been made greater had it been necessary or desirable. There are limits beyond which it is not wise to go, however, for if the sensitivity is too great, the adjustment becomes difficult and unless the indicator set is well shielded, stray field may cause trouble.

In circuits having inductance and capacity in parallel, the apparent resistance and reactance change rapidly

over a relatively few cycles near the resonant frequency and thus afford an opportunity to test the merit of the visual method. Both the experimental and calculated values are given by the curves in Fig. 8 and it will be observed that the results are in satisfactory agreement.

The visual method not only overcomes the limitations of the aural method but makes possible a quantitative determination of the degree of unbalance at any time, which is often a distinct advantage. Observers show a decided preference for the visual method.

Data for the various curves were obtained by the following graduate students in Communication Engineering, Yale University: Lt. Perry Wainer, W. H. Schlasman, and Captain A. M. Gurney.

Mechanical Forces between Electric Currents and Saturated Magnetic Fields

BY VLADIMIR KARAPETOFF[1]

Fellow, A. I. E. E.

Synopsis. *The general case considered is that of N independent electric circuits placed in a medium of variable permeability and subject to saturation, in parts or as a whole. The problem is to determine the component (in a given direction) of the mechanical force acting upon one of the electric circuits, upon a group of circuits, or upon a group of circuits with part of the magnetic medium rigidly attached to them. It is believed that the problem has not been solved in this general form heretofore.*

Use is made of the expression for the stored electromagnetic energy, W, of the system, assuming all the electric circuits to be originally open and then closed one by one. Such a treatment necessitates a number of partial saturation curves, giving the linkages with each individual electric circuit when some of the remaining circuits are closed and the rest are open. A virtual displacement, δs, is then given to the part of the system under consideration, keeping either the linkages or the currents constant, and the mechanical force, F, is determined from a comparison of the work done, $F . \delta s$, with the change in the stored energy, δW.

It is shown that the familiar reciprocal relationship for the mutual inductance, $M_{12} = M_{21}$, which holds true in a medium without saturation, can be generalized to a more involved integral expression for a saturated medium.

In order to connect the general treatment with the simpler cases previously solved in the literature of the subject, some intermediate cases of one and two circuits are considered, especially those of importance in applications. The substance of the general method used was presented before the American Physical Society, at the Philadelphia Meeting, in December, 1926.

INTRODUCTION

CONSIDER a system of stationary linear electric circuits in each of which a steady direct current is maintained by a suitable source of energy. Let these circuits be sufficiently close to each other to influence each other's magnetic fields. For the sake of generality, assume the medium to be of variable permeability; that is, let the permeability at a point be a scalar function of the position of the point. Moreover, let the medium be subject to saturation; that is, let the permeability be a function of the resultant flux density at that point.

Generally speaking, the system can be maintained in its given position only by some external mechanical forces or constraints, preventing the individual circuits from moving into a more stable position in the direction of maximum stored energy. The problem is to find the values of these mechanical forces for any individual circuit or part of the system. Since each circuit may require a force and a couple to hold it stationary, the problem may be formulated thus: To find the magnitude of the projection of the force (or of the turning couple) with which a given circuit tends to move along (or to rotate about) a given axis.

In its most general form, with variable permeability and saturation, the solution of the problem leads to quite complicated equations. Moreover, many less general cases are of greater importance in actual applications, and a physical interpretation of more general cases is facilitated by a previous study of simpler combinations. For these reasons, the treatment in this article follows the order "from specific to general," even though a treatment in the opposite order might have been somewhat shorter. The notation and the units are those used in the writer's "Magnetic Circuit," (McGraw-Hill Book Co.), and the references are to the pages of that book, unless stated otherwise.

IA. A SINGLE CIRCUIT IN A MEDIUM OF CONSTANT PERMEABILITY

Consider the coil shown on page 178. The electromagnetic energy stored in it is expressed by equation **(102a)**, and from this expression, together with the definition

$$W = 0.5\, L\, i^2 \tag{1}$$

follow equations **(105)** and **(106)** for the coefficient of self-inductance. The same expressions hold true, in a medium of constant permeability, for an electric circuit of any form, not necessarily a coil.

Let a circuit, Fig. 1, be of such a shape that its movable part, C, tends to approach the stationary part, H, with a force, F, unless held in place by an external

1. Professor of Electrical Engineering, Cornell University, Ithaca, N. Y.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

force, $-F$. It is shown on page 251, equation (**182**), that

$$F = 0.5\, I^2\, \delta\, L/\delta\, s \tag{2}$$

where s is the distance from an arbitrarily chosen fixed origin Q to some point D on the part C of the circuit. In other words, s is a coordinate which determines the position of C, and s increases when the two parts of the circuit come closer together[2].

If left to itself and not stopped by H, the part C of the circuit will finally come into a position in which $F = O$, and since in this position there is no force tending to move C any farther, the motion will stop. The condition $F = O$ means $\delta\, L/\delta\, s = O$, or $L =$ max. Thus, *a circuit tends to assume a position of maximum inductance, or, with a constant current, that of maximum stored energy.*

With a non-linear deformable conductor, such as a bath of mercury or of molten metal, the mechani-

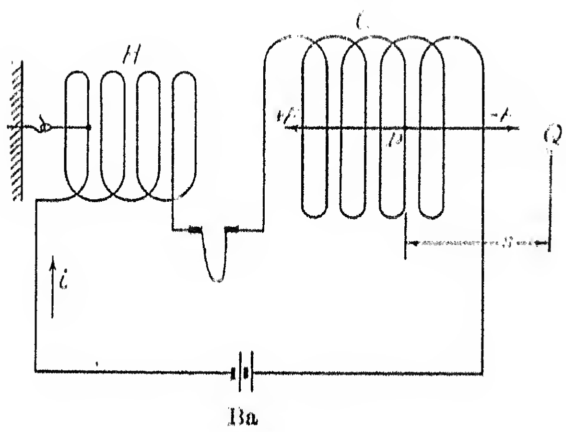

Fig. 1

cal forces tend to modify the shape of the body of the liquid for a maximum of stored electromagnetic energy, consistent with the shape of the container. The tendency is to increase the length and to contract the cross-section[3]. In some cases this tendency for maximum flux linkages results in a continuous motion, as in a homopolar motor. With liquid conductors, such a motion has been utilized for automatically stirring molten metal in an electric furnace[4]. The writer fully recognizes the value of the late Dr. Hering's ingenious experiments and of his work on electric furnaces; he only does not see the necessity for a new "law" to interpret the observed phenomena. As has been pointed out by several persons in the discussion of the above paper, the relationship expressed by eq. (**2**) is sufficient to interpret the observed forces and motions.

---

2. In this investigation, the variation sign δ is used to indicate a change with respect to s. The differential sign d is reserved to indicate a change with respect to the current.

3. For some ingenious experiments illustrating spontaneous adaptation of various circuits to a shape of maximum energy storage, see Carl Hering, TRANS. A. I. E. E., 1923, Vol. 42, p. 321.

4. *Ibid.*, Bibliography on p. 326.

Ib. A Single Circuit in a Medium Whose Permeability Varies from Point to Point, But is Independent of the Flux Density

In such a medium, magnetic lines of force obey the law of refraction (page 119). With the same exciting circuit, the magnetic field has a shape different from that in a medium of constant permeability. Nevertheless, all the flux densities are proportional to the exciting m. m. fs., and the field retains its general shape as the m. m. f. is increased. Consequently, eqs. (**1**) and (**2**) still hold true, but values of L have to be determined for the actual elementary permeances as they enter in eq. (**105**) or (**106**).

As a simple example, consider the lifting magnet shown on page 243. Let the reluctances of all the iron parts be constant and let their sum be denoted by $\mathcal{R}_1$. Then, if the length of the air-gap is a, the total reluctance of the magnetic circuit is

$$\mathcal{R} = \mathcal{P}^{-1} = \mathcal{R}_1 + (a/\mu)(S_1^{-1} + S_2^{-1}) \tag{3}$$

and

$$\delta\,\mathcal{P}/\delta\, s = -\delta\,\mathcal{P}/\delta\, a = -\delta\,\mathcal{R}^{-1}/\delta\, a$$
$$= \mathcal{R}^{-2}(S_1^{-1} + S_2^{-1})/\mu \tag{4}$$

Hence, disregarding the change in the partial linkages, eq. (**2**) gives

$$F = 0.5\, I^2\, n^2\, \mathcal{R}^{-2}(S_1^{-1} + S_2^{-1})/\mu \tag{5}$$

But $I\, n\, \mathcal{R}^{-1}$ is the total flux of complete linkages and $I\, n\, \mathcal{R}^{-1} S_1^{-1}$ is the corresponding flux density in the inner air-gap. Hence, eq. (**5**) may also be written in the form

$$F = 0.5\, B_1^2\, S_1/\mu + 0.5\, B_2^2\, S_2/\mu \tag{6}$$

which agrees with eq. (**169**), and is the usual formula for the supporting force of a lifting magnet.

Ic. A Single Circuit in a Composite Medium, Part of Which is Subject to Saturation

Let now a coil or an electric circuit of any kind be placed in a position where the magnetic lines of force are partly in the air, partly in iron, the latter being somewhat saturated at the assumed values of electric current. To determine the mechanical force F between some two parts of the magnetic circuit, we shall assign to these parts a virtual relative displacement $\delta\, s$ in the desired direction s, and let this displacement occur at a constant current.

If $\delta\, s$ has a component in the direction of the longitudinal tension along the lines of force, the flux and the stored energy will be greater in the final than in the initial position. We then have for the final position:

$$e\, I\, \delta\, t = F\, \delta\, s + \delta\, W \tag{7}$$

where $-e$ is the voltage induced in the circuit during the displacement, and $+e$ is the voltage applied from an external source to keep the current constant; $\delta\, t$ is the interval of time during which the displacement occurs, and $\delta\, W$ is the increase in the stored electromagnetic energy.

In Fig. 2, let $O\,A$ be the saturation curve of the circuit in the initial position and $O\,A'$ that in the final

position. The current, i, is plotted as abscissas and the corresponding flux linkages, ϕ, as ordinates. By ϕ is meant the sum of the fluxes linking with the individual turns. For example, if the circuit consists of three turns, and the actual fluxes linking with these turns are 3, 2.5, and 2.7 kilolines respectively, then $\phi = 8.2$ kilolines. The actual value of the current at which the force F is to be determined is I and the corresponding sum of the linkages is Φ.

Since the magnetic flux is a function of both the current i and the position s, it is necessary to distinguish between two increments of ϕ, which in Fig. 2 are denoted by $d\,\phi$ and $\delta\,\phi$ respectively. The increment $d\,\phi$ is the increase in the linkages, *at a constant* s, when the current increases from i to $i + d\,i$. The increment $\delta\,\phi$ is the increase in the linkages, *at a constant current* i, when s is changed to $s + \delta\,s$. If $d\,\phi$ be called the *differential* of ϕ, then $\delta\,\phi$ is the *variation* of ϕ. In equation (7)

$$e = \delta\,\Phi / \delta\,t \tag{8}$$

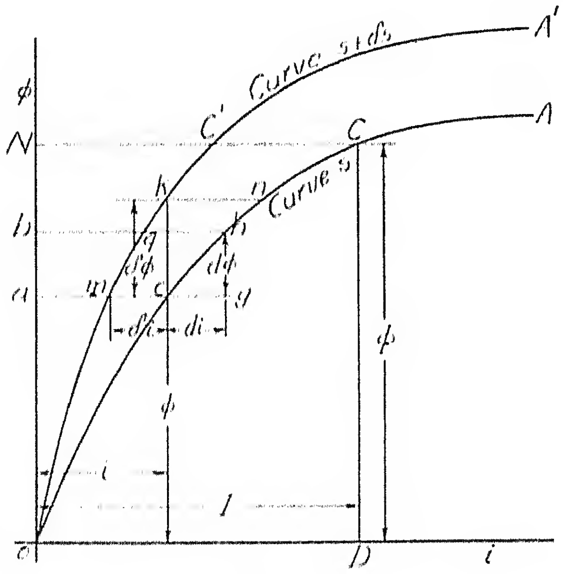

Fig. 2

the symbol δ signifying that the current I is kept constant while s varies.

To find an expression for the stored magnetic energy, it is necessary to compute the electric energy put into the circuit to establish the current I in the position s. During the process of building up the current, let the linkages increase by $d\,\phi$ when the current increases from i to $i + d\,i$. This is shown by the lengths $c\,g$ and $g\,h$ in Fig. 2. The induced voltage is $-d\,\phi/d\,t$ and the electric energy supplied by the external source is

$$i\,(d\,\phi/d\,t)\,d\,t = i\,d\,\phi \tag{9}$$

This energy is represented in Fig. 2 by the strip $a\,b\,h\,c$. The total stored energy in the position s is

$$W = \int_0^I i\,d\,\phi \tag{10}$$

and is proportional to the area $C\,N\,O\,c\,C$. The energy in the position $s + \delta\,s$, at the same current I, differs from W by the amount

$$\delta\,W = \int_0^I i\,\delta\,d\,\phi \tag{11}$$

which is obtained from eq. (10) by partial differentiation with respect to s.

It is permissible in this case to put the variation symbol δ under the integral sign, since the limits of integration are independent of ϕ or i.

Substituting now the expressions (8) and (11) in eq. (7), we get

$$I\,\delta\,\phi = F\,\delta\,s + \int_0^I i\,\delta\,d\,\phi \tag{12}$$

or, solving for F,

$$F = I\,(\delta\,\phi/\delta\,s) - \int_0^I i\,d\,(\delta\,\phi/\delta\,s) \tag{13}$$

In this expression, the symbols δ and d are interchanged under the integral sign, in accordance with the fundamental theorem of the Calculus of Variations; namely, that the variation of a differential is identically equal to the differential of the variation[5]. Using on the right hand side of eq. (13) the familiar transformation

$$\int x\,d\,y = x\,y - \int y\,d\,x \tag{13a}$$

we finally obtain

$$F = \int_0^I (\delta\,\phi/\delta\,s)\,d\,i \tag{14}$$

Equation (14) can also be proved by assuming the virtual displacement to occur at constant linkages, that is, under the condition

$$\delta\,\phi = 0 \tag{14a}$$

With this assumption there is no interchange of energy between the electric source and the magnetic circuit, so that the mechanical work is done at the expense of the stored magnetic energy. We therefore have

$$F\,\delta\,s + \delta\,W = 0$$

or

$$F\,\delta\,s + \int_0^I i\,d\,\delta\,\phi = 0 \tag{14b}$$

Integrating in parts, this becomes

$$F\,\delta\,s + I\,\delta\,\phi - \int_0^I \delta\,\phi\,d\,i = 0 \tag{14c}$$

According to eq. (14a), the middle term is equal to zero. Solving for F, eq. (14) is obtained[6].

The area of the strip $C'\,O\,C$ may be thought of as consisting of elementary parallelograms, such as $m\,q\,h\,c$. The area of this parallelogram is $-\delta\,i\,.\,d\,\phi$, the minus sign being necessary because $\delta\,i$ is a negative quantity. Hence, according to formula (44) in the Appendix, we have

5. In this particular case, the truth of this statement may be seen directly from the fact that $d^2\phi/di\,ds = d^2\phi/ds\,di$, the value of the second derivative being independent of the order of differentiation.

6. See Appendix.

$$F = -\int_0^{\Phi} (\delta\, i/\delta\, s)\, d\, \phi \tag{14d}$$

This is a useful modification of formula (**14**).

If ϕ is given as a function of both i and s, all the operations on the right hand side of eq. (**14**) may be performed, at least approximately, and the value of F determined. When the force is a simple tension in a small air-gap, as in Fig. 58, it is not necessary to use eq. (**14**). The force can be computed according to eq. (**169**) even though the core is saturated. Some inaccuracy is introduced, however, in those lines of force which are not normal to the faces of the air-gap.

When saturation is negligible, eq. (**14**) becomes identical with eq. (**2**) because in this case

$$\phi = i\, L \tag{15}$$

so that

$$\delta\, \phi/\delta\, s = i\, \delta\, L/\delta\, s \tag{16}$$

Thus eq. (**14**) becomes

$$F = \int_0^{I} (\delta\, L/\delta\, s)\, i\, d\, i\, .$$

Without saturation, L is independent of i, so that $\delta\, L/\delta\, s$ may be taken outside the integral sign. The result is

$$F = 0.5\, I^2\, (\delta\, L/\delta\, s) \tag{17}$$

which is identical with eq. (**2**).

IIa. Two Circuits in a Composite Medium with Constant Permeabilities

Let there be two separate circuits, 1 and 2, each supplied with a constant direct current from a separate source. Let the medium be partly air and partly iron, the permeability of the latter being assumed to be constant for all flux densities, from zero to the highest for which the mechanical force is to be computed.

The first step is to determine the magnetic energy stored in the system. Let the circuit 2 be in place, excited with the final value of its current, I_2, and let the circuit 1 be initially open. When the switch of the circuit 1 is closed, let the voltage of the source 2 be so regulated that the current I_2 remains constant while the current in the circuit 1 rises from zero to its final value I_1. Let M_{12} be the sum of the flux linkages in circuit 2, due to one ampere in circuit 1. Then the instantaneous voltage induced in the circuit 2, when the current in circuit 1 increases from some value i_1 to $i_1 + d\, i_1$, is $-\, M_{12}\, d\, i_1/d\, t$. Hence, the total energy furnished by the source 2 to keep the current I_2 constant, is

$$W_{12} = I_2 \int_0^{I} M_{12}\, (d\, i_1/d\, t)\, d\, t = M_{12}\, I_1\, I_2 \tag{18}$$

Therefore, the total stored energy of the system is

$$W = 0.5\, I_1^2\, L_1 + M\, I_1\, I_2 + 0.5\, I_2^2\, L_2 \tag{19}$$

In this expression, the subscript of M has been omitted because $M_{12} = M_{21}$; that is, the coefficient of mutual inductance (or the sum of mutual magnetic linkages per unit current) is the same for both circuits. This follows from the symmetrical form of eq. (**19**). Had we started with the current I_1 at its full value and increased I_2 from zero to its final value, we would have obtained an identical formula, with M_{21} in place of M_{12}. But, without hysteresis, the phenomenon is reversible, and the total stored energy cannot depend on the manner in which the system has been established, so that W is the same in both cases; consequently $M_{12} = M_{21}$, and can be simply denoted by M.

Let now a part of the system be given a virtual displacement $\delta\, s$, while the rest of the system is kept stationary. Both currents are to be kept constant during the motion. The displaced part may include one of the coils and some iron, or only one of these. If a coil and an iron part are moved, they are supposed to be mechanically joined together, and the force F is that necessary to move the combination. Generally speaking, such a displacement will modify the values of L_1, L_2, and M, since the position of the coils with respect to the iron masses will be changed and the flux distribution will be different. The energy furnished by the electrical source 1 during the displacement will be

$$I_1\, (I_1\, \delta\, L_1 + I_2\, \delta\, M),$$

while that furnished by the source 2 will be

$$I_2\, (I_2\, \delta\, L_2 + I_1\, \delta\, M).$$

The increase in the stored energy, according to eq. (**19**), is

$$0.5\, I_1^2\, \delta\, L_1 + I_1\, I_2\, \delta\, M + 0.5\, I_2^2\, \delta\, L_2\, .$$

Hence, we have

$$F\, \delta\, s + (0.5\, I_1^2\, \delta\, L_1 + I_1\, I_2\, \delta\, M + 0.5\, I_2^2\, \delta\, L_2) = I_1\, (I_1\, \delta\, L_1 + I_2\, \delta\, M) + I_2\, (I_2\, \delta\, L_2 + I_1\, \delta\, M) \tag{20}$$

or, after reduction,

$$F = 0.5\, I_1^2\, \delta\, L_1/\delta\, s + I_1\, I_2\, \delta\, M/\delta\, s + 0.5\, I_2^2\, \delta\, L_2/\delta\, s \tag{21}$$

This is a generalized form of Kelvin's law, to the effect that (with constant currents and constant permeabilities) the energy supplied by the electric sources during a displacement is divided into two equal parts. One half is converted into mechanical work; the other half increases the stored magnetic energy of the system. Conversely, if mechanical work is done on the system, pulling it apart, the energy returned to the sources is equal to twice the mechanical work done, the other half coming from the reduction in the stored magnetic energy.

When all media are of the same permeability, a relative motion of the coils does not alter their self-inductances, and the preceding equation is simplified to

$$F = I_1\, I_2\, \delta\, M/\delta\, s \tag{22}$$

which is the one usually given in treatises on physics.[7]

7. See, for example, J. C. Maxwell, *Electricity and Magnetism*, Vol. II, p. 151; J. H. Jeans, *Electricity and Magnetism*, edition of 1920, p. 495; Alex. Russell, *Alternating Currents*, Vol. I, p. 40.

If the coil 1 is displaced without moving the iron parts, the last term in eq. (**21**) is equal to zero. The same is true if an iron part is so moved as to leave the value of L_2 unchanged.

IIb. Two Circuits; Part of the Medium Subject to Saturation

This is an extension of the case treated under **Ic** above. The equations of stored energy, corresponding to eq. (**19**), are

$$W = \int_0^{I_1} i_1\, d\, \phi_{12} + I_2\,(\Phi_{21} - \Phi_{20}) + \int_0^{I_2} i_2\, d\, \phi_{20} \qquad (23)$$

$$W = \int_0^{I_2} i_2\, d\, \phi_{21} + I_1\,(\Phi_{12} - \Phi_{10}) + \int_0^{I_1} i_1\, d\, \phi_{10} \qquad (24)$$

In eq. (**23**), it is assumed that in the circuit 2 the current is first brought up to its full value, I_2, while the circuit 1 is open. The last term on the right-hand side expresses the energy stored in the circuit 2 under these conditions, this term being identical with eq. (**10**). The subscript 20 (read two-o) means "linkages of the circuit 2 when the current in circuit 1 is zero." When the current in the circuit 1 is increased from zero to its final value, I_1, the flux linkages of the circuit 2 are changed from Φ_{20} to Φ_{21}, where the subscript 2 again indicates circuit 2, and the subscripts 0 and 1 indicate the initial and the final values (0 and I_1) of the current in circuit 1. Since the change in the linkages occurs at a constant current I_2, the amount of energy furnished by the source 2 is $I_2\,(\Phi_{21} - \Phi_{20})$. This is the middle term on the right-hand side of eq. (**23**). The energy stored in the circuit 1 is given by the first term on the right-hand side. During the interval of time when the flux linking with this circuit is being built up, the current I_2 remains constant, as indicated by the double subscript 12. Eq. (**24**) is obtained from eq. (**23**) by interchanging the subscripts 1 and 2. On the supposition that the phenomenon is reversible and the value of the total stored energy is the same, no matter which circuit is closed first, the left-hand sides of both equations are denoted by the same symbol W.

Equating the right-hand sides of eqs. (**23**) and (**24**), we obtain the following "reciprocal" relationship:

$$\int_0^{I_1} i_1\, d\, \Delta\, \phi_1 + I_2\, \Delta\, \Phi_2 = \int_0^{I_2} i_2\, d\, \Delta\, \phi_2 + I_1\, \Delta\, \Phi_1 \qquad (25)$$

where

$$\Delta\, \phi_1 = \phi_{12} - \phi_{10} \qquad (26a)$$

and

$$\Delta\, \phi_2 = \phi_{21} - \phi_{20} \qquad (26b)$$

The symbol Δ in application to ϕ_1 stands for the increase in the linkages of circuit 1 due to an increase in the current i_2 from 0 to I_2, the current i_1 remaining constant. In application to ϕ_2 the symbol Δ stands for the increase in the linkages of circuit 2 at a constant current i_2, when i_1 is changed from 0 to I_1.

Applying the transformation (**13a**) to the two integrals in eq. (**25**), we obtain after reduction

$$\int_0^{I_1} \Delta\, \phi_1\, d\, i_1 = \int_0^{I_2} \Delta\, \phi_2\, d\, i_2 \qquad (27)$$

Eq. (**27**) is a generalized form of the relationship $M_{12} = M_{21}$, when saturation is to be taken into consideration. Four saturation curves must be thought of in connection with eqs. (**25**) and (**27**), namely,

between i_1 and ϕ_1 when $i_2 = 0$
between i_1 and ϕ_1 when $i_2 = I_2$
between i_2 and ϕ_2 when $i_1 = 0$
between i_2 and ϕ_2 when $i_1 = I_1$

Eq. (**25**) or (**27**) gives a necessary physical condition which these four curves satisfy.

Without saturation, $\Delta\, \phi_1 = M_{12}\, I_2$, and $\Delta\, \phi_2 = M_{21}\, I_1$. Eq. (**27**) simply becomes: $M_{12}\, I_2\, I_1 = M_{21}\, I_1\, I_2$, or $M_{21} = M_{12}$.

Using the value of $\delta\, W$ from eq. (**23**), the condition expressed by eqs. (**7**) and (**20**) can now be generalized as follows:

$$F\,\delta\, s + \int_0^{I_1} i_1\,\delta\, d\, \phi_{12} + I_2\,(\delta\, \Phi_{21} - \delta\Phi_{20}) + \int_0^{I_2} i_2\,\delta\, d\, \phi_{20} = I_1\,\delta\, \Phi_{12} + I_2\,\delta\, \Phi_{21} \qquad (28)$$

Cancelling $I_2\,\delta\,\Phi_{21}$ on both sides of this equation, and using the transformation (**13a**), we get

$$F = \int_0^{I_1} (\delta\, \phi_{12}/\delta\, s)\, d\, i_1 + \int_0^{I_2} (\delta\, \phi_{20}/\delta\, s)\, d\, i_2 \qquad (29)$$

In eq. (**28**), expression (**23**) for W is used. If eq. (**24**) be used instead, the subscripts 1 and 2 in eq. (**29**) would become interchanged, and we should get

$$F = \int_0^{I_2} (\delta\, \phi_{21}/\delta\, s)\, d\, i_2 + \int_0^{I_1} (\delta\, \phi_{10}/\delta\, s)\, d\, i_1 \qquad (30)$$

Eqs. (**29**) and (**30**) are the general expressions for the mechanical force between two electric circuits in a medium subject to saturation. Since eq. (**30**) may be obtained by combining eqs. (**29**) and (**27**), expressions (**29**) and (**30**) are identical.

As a special case, and as a check on these formulas, consider the condition of no saturation. Then

$$\phi_{12} = L_1\, i_1 + M\, I_2 \qquad (31)$$

and

$$\phi_{20} = i_2\, L_2\,. \qquad (32)$$

Hence,

$$\delta\, \phi_{12}/\delta\, s = i_1\,\delta\, L_1/\delta\, s + I_2\,\delta\, M/\delta\, s \qquad (33)$$

$$\delta\, \phi_{20}/\delta\, s = i_2\,\delta\, L_2/\delta\, s \qquad (34)$$

Substituting these values in eq. (**29**), and remembering that L_1, L_2, M, are independent of i_1 and i_2, we get

$$F = (\delta\, L_1/\delta\, s) \int_0^{I_1} i_1\, d\, i_1 + I_2\,(\delta\, M/\delta\, s) \int_0^{I_1} d\, i_1 + (\delta\, L_2/\delta\, s) \int_0^{I_2} i_2\, d\, i_2 \qquad (35)$$

After integration, this expression becomes identical with eq. (**21**).

In order to perform the operations indicated in eq. (**29**), ϕ_{12} and ϕ_{20} must be given as functions of the distance s and of the currents i_1 and i_2. Such saturation curves, for different values of s, can either be estimated by computation or obtained from test. The value of F can then be determined graphically to a desired degree of accuracy. Or else, ϕ_{12} and ϕ_{20} may be expressed as empirical functions of s, i_1, and i_2, and the integrations performed analytically.

IIIA. N Separate Circuits in a Composite Medium With Constant Permeabilities

This is a generalization of the Case IIA. The first step is to compute the total stored electromagnetic energy. Let the circuit 1 be closed first, then the circuit 2, etc. With two circuits, the total stored energy is expressed by eq. (**19**). When the circuit 3 is closed, its own stored energy, $0.5\, I_3^2\, L_3$, is added, and more energy must be furnished by the sources 1 and 2 in order to keep the corresponding currents constant during the transient period. These latter amounts of energy are equal to $I_1\, I_3\, M_{13}$ and $I_2\, I_3\, M_{23}$ respectively. Thus, the total stored energy of the three circuits is

$$W = 0.5\, I_1^2\, L_1 + 0.5\, I_2^2\, L_2 + 0.5\, I_3^2\, L_3 + M_{12}\, I_1\, I_2 + M_{23}\, I_2\, I_3 + M_{31}\, I_3\, I_1 \qquad \textbf{(35a)}$$

Extending the same process to N circuits, we may write

$$W = 0.5 \sum I_k^2\, L_k + \sum I_k\, I_u\, M_{ku} \qquad \textbf{(36)}$$

In this expression, k and u have all the integer values from 1 to N inclusive, and in the second summation the subscripts correspond to *combinations*, and not to permutations. This means that if, for example, the values of $k = 2$ and $u = 5$ have been used in a term, the values $k = 5$ and $u = 2$ cannot be used any more.

Let now some of the circuits be combined into a subsystem, and be given a common virtual displacement, $\delta\, s$, with respect to the remaining circuits, all the currents being kept constant. For the sake of generality, assume that this displacement causes a change not only in the coefficients of mutual inductance, but in those of self-inductance as well. The energy furnished by the electric source in the kth circuit is

$$\delta\, W_k = I_k\, [I_k\, \delta\, L_k + \sum I_v\, \delta\, M_{kv}] \qquad \textbf{(37)}$$

Here v denotes any circuit except the kth; that is, v has all the integer values from 1 to $k - 1$ and from $k + 1$ to N. Eq. (**20**) becomes

$$F\, \delta\, s + 0.5 \sum I_k^2\, \delta\, L_k + \sum I_k\, I_u\, \delta\, M_{ku} = \sum I_k^2\, \delta\, L_k + \sum \{I_k \sum I_v\, \delta\, M_{kv}\} \qquad \textbf{(38)}$$

The last summation on the right-hand side of this equation contains the same terms as the last summation on the left-hand side, only each term enters twice, because each source of voltage is here considered separately. Thus, we find that Kelvin's law holds true also in this case, and by analogy with eq. (**21**) we may write

$$F = 0.5 \sum I_k^2\, \delta\, L_k / \delta\, s + \sum I_k\, I_u\, \delta\, M_{ku} / \delta\, s \qquad \textbf{(39)}$$

Depending on the particular circuit or circuits for which the force F is sought, the derivatives $\delta\, L / \delta\, s$ and $\delta\, M / \delta\, s$ have different values. Thus, it may be required to determine the mechanical force acting on a winding alone, or on a winding with the corresponding iron core, etc. In each case a virtual displacement must be assumed to take place for the part or parts under consideration, with respect to the rest of the system.

IIIB. N Circuits; Part of the Medium Subject to Saturation

This is an extension of the case treated under IIB. The method is the same, only the subscripts become more numerous and involved. For this reason, it has been deemed sufficient to show the deduction of the final formula in application to three circuits only, since with N circuits each flux ϕ would have a subscript consisting of N numbers of different order. An extension of the reasoning given below to four or more circuits is quite evident, and the final formula for N circuits is written directly.

To compute the stored energy, we shall assume that the circuit 1 is closed first, then circuit 2, and finally circuit 3. By analogy with eq. (**24**), changing somewhat the order of the terms, we may write the following expression for the total stored energy corresponding to the final values of the currents:

$$W = \int_0^{I_1} i_1\, d\, \phi_{100} + \int_0^{I_2} i_2\, d\, \phi_{210} + \int_0^{I_3} i_3\, d\, \phi_{312} + I_1\, (\Phi_{123} - \Phi_{100}) + I_2\, (\Phi_{213} - \Phi_{210}) \qquad \textbf{(40)}$$

In this expression, the first integral represents the energy stored in circuit 1 when $i_2 = i_3 = 0$. The subscript 100 (read one-o-o) means "flux linkages in circuit 1, when the currents in the other two circuits are equal to zero." The second integral represents the energy stored in circuit 2 when the current in the circuit 1 has already reached its full value, while that in circuit 3 is still equal to zero. This is indicated by the subscript 210. The third integral represents the energy stored in circuit 3, and the subscript 312 indicates that the currents i_1 and i_2 have reached their maximum values.

The term $I_1\, (\Phi_{123} - \Phi_{100})$ represents the energy furnished by the source 1 in order to keep the current I_1 constant when the currents in the other two circuits are being increased from zero to their final values. Similarly, the last term gives the energy furnished by the source 2 when the circuit 3 is closed.

Let now a virtual displacement, $\delta\, s$, be allowed to occur in one part of the system with respect to the other, keeping all the currents constant. The energy furnished by the three sources is equal to

$$I_1\, \delta\, \Phi_{123} + I_2\, \delta\, \Phi_{213} + I_3\, \delta\, \Phi_{312}\,.$$

Writing an equation similar to eq. (**28**), and using the transformation (**13a**), we get, by analogy with eq. (**30**) with a reversed order of terms:

$$F = \int_0^{I_1} (\delta\, \phi_{100} / \delta\, s)\, d\, i_1 + \int_0^{I_2} (\delta\, \phi_{210} / \delta\, s)\, d\, i_2$$

I_3

$$+ \int_0 (\delta\, \phi_{312}/\delta\, s)\, d\, i_3 \qquad (41)$$

In order to determine F from this equation, the flux linkages ϕ_{100}, ϕ_{210}, and ϕ_{312} must be given as functions of s and of the corresponding currents. In practical cases, advantage may be taken of certain simplifications due to the arrangement of the circuits or to the particular shape of the saturation curves. Since the total stored energy is independent of the order in which the circuits are closed, certain "reciprocal" relationships must hold true. These may be deduced by analogy with eqs. (25) and (27).

Extending now the formula (41) to N circuits, we get

$$F = \Sigma \int_0^{I_k} (\delta\, \phi_q/\delta\, s)\, d\, i_k \qquad (42)$$

This expression consists of a sum of N integrals corresponding to the values of k from 1 to N. The subscript q is as follows:

$$q = k\,(k-1)\ \ldots\ .\ 21000\ \ldots\ . \qquad (43)$$

This means that for the kth circuit the saturation curve between i_k and ϕ_k, used in eq. (42), must be the one which obtains with the currents I_k, I_{k-1}, I_{k-2}, $\ldots\ I_2$, I_1 at their full values, while the currents i_{k+1}, i_{k+2}, $\ldots\ldots$, i_n, are all equal to zero.

Literature References. Comparatively little has been done on the general theory of mechanical forces in magnetic circuits, especially taking saturation into account. Some recent articles, of applied nature, are listed below. References to earlier contributions will be found in these articles.

Appendix

It is shown in connection with eq. (10) that the magnetic energy stored in a saturated circuit (Fig. 2) is represented by the area $C\,N\,O\,c\,C$. Similarly, the stored magnetic energy, after the displacement, $\delta\, s$, has taken place, is proportional to the area $C'\,N\,O\,m\,C'$. When this displacement occurs at constant linkages Φ, the mechanical work is done entirely at the expense of the stored magnetic energy. Consequently, the curved infinitesimal strip $C'\,O\,C$ represents the work done, $F\,\delta\, s$, so that

$$F = (\text{area of strip } C'\,O\,C)/\delta\, s \qquad (44)$$

This expression permits the visualization of the relations and also the solution of some special cases. Consider, for example, a saturated electromagnet with a small air-gap (a lifting magnet). Within a certain range of small values of air-gap, the lines of force in the gap may be assumed to be straight lines, normal to the iron surfaces, and the flux in the iron parts may be considered to follow the same paths and to have the same leakage, independent of the magnitude of the gap. In other words, within a certain range of gaps, the same saturation curve may be used for the iron, and only the exciting ampere-turns for the air-gap changed. With this limitation, the area of the strip $C'\,O\,C$ may be obtained from the air characteristic alone. For the air-gap we have

$$I\,T = (\Phi/T)\,(s_o - s)/(\mu\, A) \qquad (45)$$

where $I\,T$ are the exciting ampere-turns; s_o and s are some distances whose difference gives the length of the air-gap; A is the cross-section of the magnetic path in the air-gap, and μ the absolute permeability of the air. T being the number of turns, the linkages Φ divided by T give the actual flux. From eq. (45)

$$T\,\delta\, I = -\,(\Phi/T)\,\delta\, s/(\mu\, A) \qquad (46)$$

With the foregoing assumptions, the strip $C'\,O\,C$ becomes a triangle, so that

$$\text{area } C'\,O\,C = -\,0.5\,\delta\, I\,.\,\Phi\,. \qquad (47)$$

The minus sign is necessary because $\delta\, I$ is a negative quantity. Substituting this expression in eq. (44), and using for $\delta\, I$ its value from eq. (46), we get

$$F = 0.5\, A\, B^2/\mu \qquad (48)$$

where B is the flux density in the air-gap. Expression (48) is the usual formula for the lifting force of an electromagnet.

The same result may be obtained from eq. (14d). With the limitations stated above, the saturation curve for the whole electromagnet may be written in the form

$$T\, i = \psi\,(\phi) + (\phi/T)\,(s_o - s)/(\mu\, A) \qquad (49)$$

where the function $\psi\,(\phi)$ is the m. m. f. required for the iron parts. At a constant ϕ,

$$\delta\, i/\delta\, s = -\,(\phi/T^2)/(\mu\, A) \qquad (50)$$

Substituting in eq. (14d) and integrating, will give eq. (48).

Two Cases of Calculation of Mechanical Forces in Electric Circuits

BY H. B. DWIGHT[1]

Fellow, A. I. E. E.

Synopsis. *A formula is derived for the mechanical force in a circle of round wire, due to its own current. A formula, $F = I^2 \operatorname{logh} \frac{a_1}{a_2}$, is also derived for the longitudinal force exerted on a round conductor, due to its own current, where it changes its diameter. Where there is a constriction in a liquid conductor, this force acts in both directions away from the constriction, thus tending to accentuate it. It may be that this has more to do with the rupturing of a liquid conductor by heavy current, than the better known forces acting in a radial direction, which have been usually referred to under the name "pinch effect."*

THE measurement by a laboratory method of mechanical force in circular and rectangular circuits, described in a companion paper by Mr. J. W. Roper[2], lends interest to formulas for calculating such forces. In this paper, formulas are presented for the force acting in a circular circuit and also for the axial force acting in a straight cylindrical conductor where the size of the cross-section changes.

Force in a Wire Circle

The force tending to stretch the wire in a circular circuit is calculated by the well-known method using the differential of the self-inductance of the circuit. The mutual inductance of two coaxial circular filaments is given with a great deal of precision by formulas involving elliptic integrals or by convergent series. Rayleigh and Niven have integrated the expression for this quantity over a circular cross-section, giving the self-inductance of a circle of round wire. Their formula is[3]

$$L = 4\,\pi\,a \left[\operatorname{logh} \frac{8\,a}{\rho} - \frac{7}{4} + \frac{\rho^2}{a^2} \left(\frac{1}{8} \operatorname{logh} \frac{8\,a}{\rho} + \frac{1}{24} \right) \ldots \right] \text{abhenrys} \quad (1)$$

where a is the radius of the circle and ρ is the radius of the wire. The expression logh denotes the hyperbolic or natural logarithm.

When current flows in a circle of wire, one half tends to repel the other half, and a tendency to stretch the wire is exerted at every part of the length of the wire. Let this force be F dynes and let s be the perimeter of the circle. If the current is turned on, and the force F stretches the wire a distance ∂s, the mechanical work done is $F\,\partial s$, since F acts in the direction of s. This can be equated to $\frac{1}{2}\, I^2\, \partial L$ where ∂L is the change in the self-inductance of the circle due to its change in size.

This rather well-known expression can be derived as follows:

The rate of doing mechanical work is $F \frac{\partial s}{\partial t}$. Since the current I is kept constant and the inductance L is varying, a voltage is generated in the circle equal to $I \frac{\partial L}{\partial t}$ and the current I flowing against this voltage supplies energy at the rate $I^2 \frac{\partial L}{\partial t}$. This energy goes to supply the mechanical work and also to increase the stored energy of the magnetic field. The stored energy is $\frac{1}{2}\, L\, I^2$ for inductance[4] equal to L. The rate of change of the stored energy when I is constant and L varies is $\frac{1}{2}\, I^2 \frac{\partial L}{\partial t}$.

Therefore,

$$I^2 \frac{\partial L}{\partial t} = F \frac{\partial s}{\partial t} + \frac{1}{2}\, I^2 \frac{\partial L}{\partial t}$$

Then

$$F\,\partial s = \frac{1}{2}\, I^2\, \partial L$$

and

$$F = \frac{1}{2}\, I^2 \frac{\partial L}{\partial s} \quad (2)$$

This force is in dynes since absolute units are used throughout.

2. J. W. Roper, *Experimental Measurement of Mechanical Forces in Electric Circuits, Jl. A. I. E. E. Sept. 1927, p. 913.*

3. Equation 63, Scientific Paper No. 169 of the Bureau of Standards, 1911, and Rayleigh's collected papers, Vol. II, p. 15.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

4. Principles of Alternating Currents, by R. R. Lawrence, p. 124, equation (14).

The dimension s is the circumference of the circle and is equal to $2\pi a$.

Therefore

$$F = \frac{1}{4\pi} I^2 \frac{\partial L}{\partial a} \tag{3}$$

The differentiation of Rayleigh and Niven's formula **(1)** is quite straightforward and the following formula for force is obtained:

$$\frac{F}{I^2} = \text{logh}\,\frac{8a}{\rho} - \frac{3}{4} - \frac{\rho^2}{a^2}\left(\frac{1}{8}\,\text{logh}\,\frac{8a}{\rho} - \frac{1}{12}\right)\ldots \quad \text{dynes} \tag{4}$$

where I is the current in abamperes.

Example 1. The force in a wire of radius $\rho = 0.1245$ cm. bent into a circle of $a = 20.1$ cm. radius and carrying 100 amperes is

$$10^2\left[\text{logh}\,\frac{8\times 20.1}{0.1245} - 0.75 - \frac{0.1245^2}{20.1^2}\left(\frac{1}{8}\,\text{logh}\,\frac{8\times 20.1}{0.1245} - \frac{1}{12}\right)\right]$$

$= 641$ dynes. (See the calculated curve of Fig. 2 of Mr. Roper's paper.)

Longitudinal Force

The following short formula gives the amount of the longitudinal force; that is, the force acting in the direction of the axis, which is exerted on a round conductor where it changes its diameter:

$$F = I^2\,\text{logh}\,\frac{a_1}{a_2} \quad \text{dynes} \tag{5}$$

where a_1 and a_2 are the larger and smaller radii, respectively, and where I is the current in abamperes.

The force acts parallel to the axis and toward the larger section of conductor, irrespective of the direction of flow of current. The expression involves only the maximum and minimum radii and, as referred to later, the amount of the force is independent of the shape of the conductor while it is changing section, so long as it is round and centered on a straight axis.

Formula **(5)** is useful in calculating the force on a system of round wires in air where there are wires of more than one diameter. It is also of interest in connection with some kinds of electric furnaces where a trough of molten metal carries a heavy electric current. If there is a constriction in the section of the metal, this force produces a flow of metal away from the constriction and so accentuates the constriction. Such an action has been observed.

As is well known, electromagnetic forces also act on all elements of a liquid conductor at right angles to the direction of current flow; that is, in general, toward the axis. This produces greater hydrostatic pressure at the axis than in the outer parts, and, of course, hydrostatic pressure acts equally in all directions.

The hydrostatic pressure in a uniform round conductor, which acts in a radial direction, has been referred to for a number of years under the name, "pinch effect." It has been described as the cause of the phenomenon observed in electric furnaces, that at a certain heavy current a constriction would occur in the liquid conductor, and that this constriction would grow until the circuit was broken.

It is possible that the axial force described and calculated in this paper, which tends to separate the two tapered parts where a constriction occurs in a liquid conductor, is more directly connected with rupturing the conductor at the point of constriction than the radial "pinch effect" force.

The axial force is stronger in the outer parts of the tapered conductor than in the inner parts. In the case of a liquid conductor, unequal forces acting on different parts produce a flow of the liquid, sometimes in short return paths, like local eddies. The amount of this flow

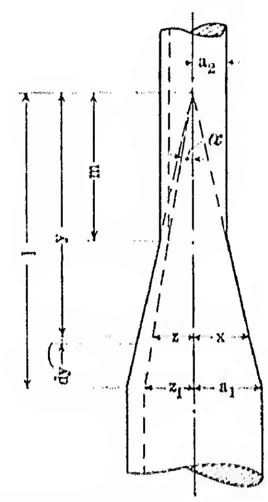

Fig. 1—Conductor with Change in Section

depends on the strength of the electric current and the shape and viscosity of the liquid conductor.

Equation **(5)** is derived by the method of finding the product of the strength of a current and the magnetic field in which it lies, to give the force on the conductor carrying the current.

Assume that the current density is uniform over any cross-section of the wire shown in Fig. 1. Slight departures from this assumption take place where the stream lines do not have abrupt changes in direction, but follow smooth curves. Skin effect also is not considered. The current density at distance y where the radius is x is

$$i = \frac{I}{\pi x^2} \quad \surd$$

The total current inside radius z is

$$\pi i z^2 = I\frac{z^2}{x^2} \quad \surd$$

The flux density at radius z is

$$\frac{2}{z}\ \frac{I z^2}{x^2} = \frac{2 I}{z}\ \frac{z_1^2}{a_1^2}$$

The dotted line at radius z is always at the proportionate distance $\frac{z_1}{a_1}$ along the radius of the wire, and it is almost exactly a line of current flow. A short element of it has a length $\frac{d y}{\cos \alpha}$

where

$$\tan \alpha = \frac{z_1}{l} = \frac{z}{y} \tag{6}$$

A force acts on the short element of the filament carrying current at right angles to its length and proportionate to the current in the filament and the magnetic field in which it lies. This force is

$\frac{2 I}{z}\ \frac{z_1^2}{a_1^2}\ \frac{d y}{\cos \alpha}$ dynes per abampere of current in the filament.

Multiply by $\sin \alpha$ to get the component of force parallel to the axis:

$$\frac{2 I}{z}\ \frac{z_1^2}{a_1^2} \tan \alpha\ d y = 2 I \frac{z_1^2}{a_1^2}\ \frac{d y}{y} \text{ from (6)}$$

Integrate this from $y = m$ to $y = l$. The total force parallel to the axis acting on the filament is

$2 I \frac{z_1^2}{a_1^2} \operatorname{logh} \frac{l}{m}$ dynes per abampere of current in the filament. (7)

If the filament be considered to have a thickness $d z_1$ at the radius z_1 then the total area of all filaments at radius z_1 is

$$2 \pi z_1 d z_1$$

and the total current in them is

$$\frac{I}{\pi a_1^2} 2 \pi z_1 d z_1 = \frac{2 I}{a_1^2} z_1 d z_1$$

The force parallel to the axis acting on the above current is, by (7),

$$2 I \frac{z_1^2}{a_1^2} \left(\operatorname{logh} \frac{l}{m} \right) \frac{2 I}{a_1^2} z_1 d z_1$$

Integrate this from $z_1 = 0$ to $z_1 = a_1$.
The total force parallel to the axis is

$$I^2 \operatorname{logh} \frac{l}{m}$$

$$= I^2 \operatorname{logh} \frac{a_1}{a_2} \text{ which is equation (5).}$$

If the wire tapers from a radius a_1 to a radius a_m, the axial force due to that part will be

$$I^2 \operatorname{logh} \frac{a_1}{a_m}$$

If the wire then tapers at a different rate from radius a_m to radius a_2, the force due to that part will be

$$I^2 \operatorname{logh} \frac{a_m}{a_2}$$

and the total force will be

$$I^2 \operatorname{logh} \frac{a_1}{a_2}$$

This is the same as if the wire had tapered uniformly from radius a_1 to a_2, as in Fig. 1. The change in radius can therefore be made by means of a large number of tapers of different angles, and the total axial force will depend only on the initial and final radii according to eq. (5).

In the above calculation, the value of the flux density at a radius z is dependent on the total current I_1 within the circle of radius z. Since the wire is assumed to be straight and very long, and the return conductor so remote as to be negligible, the magnetic field lies in circles around the axis. The magnetomotive force around the circle of radius z is $4 \pi I_1$. The length of the magnetic path is $2 \pi z$ and the flux density at radius z is $\frac{2 I_1}{z}$. This formula, which is applicable to isolated long, straight, round wires, is seen to be true also when there are changes in section, provided the wire is symmetrical around a straight axis.

In calculating the magnetic field due to a short length of round wire carrying a current, it is often assumed that the field is the same as if all the current were flowing in a small filament at the axis of the round wire. While this is very nearly true, it is exactly true only in the case of an infinitely long wire, and this fact is sometimes of importance in calculations of inductance and of electromagnetic force. The expression for the field at a given point due to a short length of round wire involves elliptic integrals or series equivalent to them.

A case where the current cannot be assumed to be concentrated in a filament at the axis of a conductor is in finding the force on a conductor bent into a quadrant of a circle, for such an assumption makes the calculated force infinitely great. An expression for the force on a quadrant conductor due to its own current must involve the dimensions of the cross-section of the conductor.

The writer desires to make acknowledgment of the assistance of Mr. S. P. Sawyer in preparing numerical examples, etc., in connection with the work of this paper.

Discussion

V. Karapetoff: Professor Dwight's equation (5) may be deduced directly from the general formula (2) for the mechanical force. Let the return conductor be a concentric cylinder of radius b. Let the virtual deformation of the given conductor consist of an axial lengthening of the portion of radius a_2 by an infinitesimal amount $d\,s$ and of a corresponding shortening of the portion of radius a_1 by the same amount $d\,s$. The tapered portion is supposed to move bodily without a change in shape. The inductance of a concentric cable, per unit length, is of the form,

$$L = 0.05 + 0.2 \text{ logh } (b/a) \quad \textbf{(A)}$$

in perms per cm. length[1]

Therefore, the net increase in the inductance is

$$d\,l = 0.2 \,[\text{logh } (b/a_2) - \text{logh } (b/a_1)]\, d\,s \quad \textbf{(B)}$$

Substituting this expression in Dwight's equation (2), his equation (5) is obtained. Therefore, equation (5) is valid so long as equation (**A**) for inductance is valid. The radius b of the return conductor does not enter into the result.

When considering the relationship between an electric current and its magnetic flux, it is safer to start with the universal relationship, which holds true at any point and is expressed by the familiar differential equation $u = \text{curl } H$, where u is the current density.[1] The difference between a solid and a liquid conductor comes in the boundary conditions in the integration of this equation. For a solid conductor, the boundary surface is fixed and the component of the current density normal to it must be equal to zero. With a liquid conductor, the shape of the surface depends upon the magnitude of the total current and its distribution. Because of the pinch effect, the usual hydrostatic conditions must be satisfied at each point within the liquid.

This means that, for each infinitesimal volume taken within the conductor, the forces acting upon it must be in equilibrium. These forces are the resultant pressure exerted by the remainder

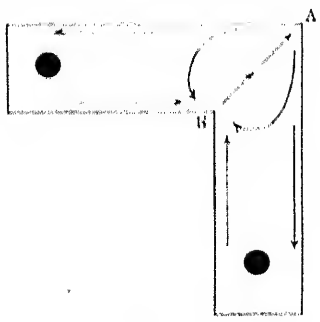

Fig. 1

of the liquid, the weight of the element, and the force between the current and the magnetic field.

E. H. Dodge: I have quite recently performed some experiments concerning forces acting on a liquid conductor with currents as high as 1500 amperes.

When a right-angle trough containing mercury has a current of 1000 amperes flowing, there is a movement in the liquid as shown in the accompanying Fig. 1. The direction of motion is from B to A and the level at A is about ¼ in. higher than the remaining liquid.

If a straight trough with a constriction is used, there is a pronounced flow away from the constriction, as shown in the accompanying Fig. 2. There are also eddies at the constriction. There is a swirling motion at the electrodes accompanied by a marked depression. As the current changes direction by 90 deg., the filaments carrying current stretch out and form this depression. Within the constriction, an interesting phenomenon occurs. With 1000 amperes, the mercury level rises at the center and falls at the edges, as if the mercury were trying to crowd together to form a circular cross-section. Just before the circuit was ruptured with 1450 amperes, the level decreased.

The rise in level would seem to be due to the hydrostatic pressure which acts radially, and has been given by Dr. E. F. Northrup as $p = \dfrac{I^2}{100\,\pi\,R^4}\,(R^2 - r^2)$ dynes per sq. cm. at any point r cm. from the axis of a conductor $2R$ cm. in diameter.

The decrease in level might be explained by the action of the longitudinal thrust or the taper force which tends to drain the mercury from the constriction and thus decrease the level.

The total thrust on a vertical plane omitting the effect of

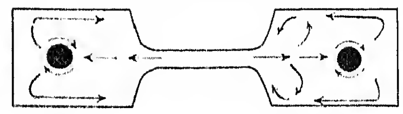

Fig. 2

gravity has been given by Dr. Carl Hering as $T = \dfrac{I^2}{200}$ dynes.

This is obtained by integrating the above expression given by Dr. Northrup. This expression is independent of the size of the conductor: consequently, the thrust on a vertical plane due to the radial force is the same, regardless of the size of cross-section. With this in mind, it seems very reasonable that the rupturing of the circuit is caused by the taper force which has been given by Dr. Dwight as $F = \dfrac{I^2}{100} \text{ logh } \dfrac{R}{r}$ dynes.

A few simple calculations will bring out the differences in pressures. With a conductor carrying 1000 amperes and a cross-section with a radius which varies from 1 cm. to 6 cm., by Northrup's equation, the hydrostatic pressure at the center of the small section = 3180. dynes per sq. cm. which is equivalent to 0.0461 lb. per sq. in. and the pressure at the center of the large section = 89. dynes per sq. cm. which is equivalent to 0.00130 lb. per sq. in.

The total thrust on a vertical section by Hering's equation is $T = 5000$ dynes and equivalent to 0 0112 lb. which is the same for the large section and the small section.

Finally the taper force from Dr. Dwight is

$$F = 17900 \text{ dynes or } 0.0402 \text{ lb.}$$

Thus we see that the taper force is greater and seems to substantiate the assertion that it causes the circuit to rupture. The taper force becomes greater and greater as the small section becomes smaller before the rupture of the liquid conductor.

H. B. Dwight: In my presentation of this paper, I made the statement that equation (5) for a conductor consisting of two long uniform parts of different diameters, joined by a tapered part, can be derived by differentiating the well-known formula for the self-inductance of a long, uniform, round wire. This derivation shows that the two long parts do not need to have the same axis so long as they have parallel axes, and the shape of the tapered part does not matter.

Such a derivation, however, does not apply to the interesting case described by Mr. Dodge, where the two long parts of the conductor have the same diameter and are joined by a double taper, or contraction. Formula (A) of Professor Karapetoff's discussion cannot be applied to the minimum diameter of the contraction, but only to a long uniform conductor. Therefore, in order to show that equation (5) applies to each of the closely adjacent tapers of the contraction, some other derivation, such as the one given in my paper, is necessary.

It has not been shown, and it does not necessarily appear,

1. See, for example G. W. Pierce, Electric Oscillations and Electric Waves, p. 370; M. Abraham, *Theorie der Elektrizitat*, 1912, p. 220.

that any use of the equation u = curl H gives greater safety in calculation than the methods followed in my paper.

While it has not been uncommon for mercury circuits of small cross-section to be broken by electric currents of the order of 100 amperes, the observation in detail of the progressive steps of the phenomenon and the description of the swirling of the liquid which carries an electric current have only rarely been made since Dr. Carl Hering described them. Such observations require a large section of liquid conductor and from 1000 to 1500 amperes. Accordingly, Mr. Dodge's experiments should be of interest to physicists and to designers of electric furnaces. In determining the swirling motion of the liquid, he used heavy floats which extended deep into the liquid, since surface tension prevented the motion from being shown by sprinkling dust on the mercury. When the circuit was broken, it continuously came together and broke at the rate of several times a second.

I agree with the statement in Professor Karapetoff's paper, that Dr. Hering's work on electric furnaces and liquid conductors was of great value, but that his experimental observations are in agreement with the usual methods of calculating the mechanical forces associated with electric currents, and do not require new methods of calculation.

Experimental Measurement of Mechanical Forces in Electric Circuits

BY J. WALTER ROPER[1]

Associate, A. I. E. E.

Synopsis.—*This paper presents a simple laboratory method of measuring the mechanical forces exerted on the parts of a complete circuit due to current flowing in the circuit.*

Tests, using the method, show that the "classic" methods of computing such forces are reliable. Curves are included which show the comparison between the theoretical and measured forces. Tests were made on a rectangular circuit, representing a disconnecting switch, and on a circle of round wire.

Circular Circuits

The expression derived in the companion paper by Dr. H. B. Dwight for the tension acting in a circular circuit has been checked experimentally by the apparatus shown in Fig. 1 and described below. These measurements were made in the Electrical Engineering Department of the Massachusetts Institute of Technology.

A circle of copper wire 0.249 cm. (0.098 in.) in diameter was made, having a centerline diameter of 40.2 cm. (15.81 in.). The circle was divided into two equal parts the upper half of which was fixed by being fastened to a semicircle of wood. The current was led in and out of the circle by means of flexible leads which were clamped at a, about four inches from the terminals T of the circle. An elastic rubber band at e, one inch from T, provided a support for the end of the circle. The other joint of the circle was made at b by means of a slanting or tapered joint. A thin mercury film was used to insure good contact between the halves of the circle. The tapered joint was suggested by the late Dr. Carl Hering, and is a useful device. As shown later, a mercury cup gave approximately the same results as a tapered joint.

The lower half of the circle was braced by a wooden rod d in order to maintain the dimensions of the circuit when current was flowing and to provide a place to attach the measuring device. The motion of the semicircle was limited to 1/16 in. at the joint by a set of stops at s. The upper stop was fitted with a contact which touched a contact on the brace. These contacts were connected by means of very flexible leads with a dry cell and telephone headset. The force was measured by means of a lever arm and scale pan, connected to the brace by a copper rod a little over a yard in length. To offset the weight of the scale pan B, the auxiliary weight W was fastened to the brace as shown in Fig. 1.

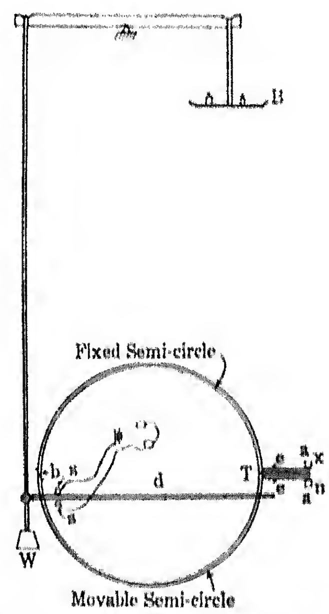

Fig. 1—The Circular Circuit

The vertical support above W was one inch horizontally from b. The moment of the force acting through this support about e was balanced by the moments of the electromagnetic forces at b and T about the same point e. Since the distances $W\,b$ and $T\,e$ were each equal to one inch, the force in the vertical

1. Massachusetts Institute of Technology.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

support was taken equal to the force at b. If the leads $e\ a$ were comparatively stiff so that the semicircle moved about T as a hinge, however, then the observed forces should be multiplied by the ratio of the lever arms which would be about 17 to 16. This may partly account for the fact that the observed forces are less than the calculated values in Fig. 2.

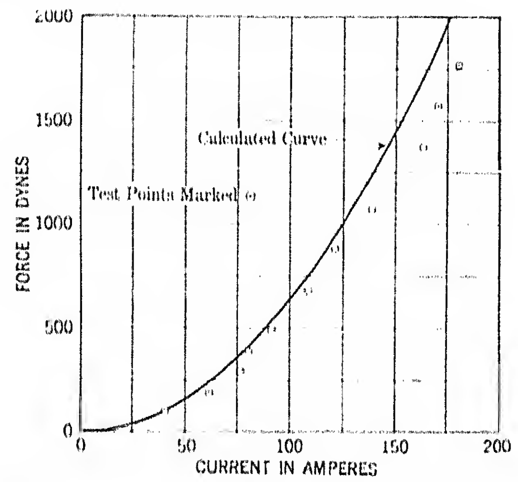

FIG. 2—CURVE SHOWING THE RELATION BETWEEN FORCE AND CURRENT IN THE CIRCUIT OF FIG. 1

The initial position of the lower semicircle was determined by the upper stop which was visually adjusted so that the circuit was circular. In order to have an absolute measurement of the force exerted when current was flowing, it was necessary to determine the

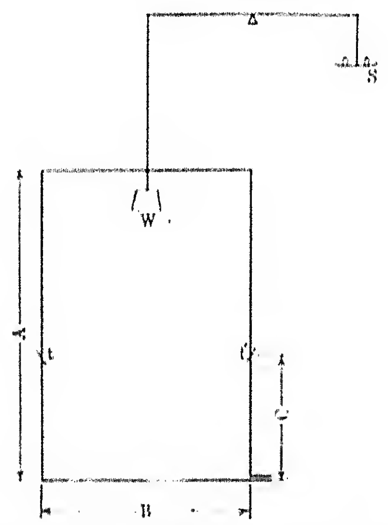

FIG. 3—DIAGRAMMATIC SKETCH OF A RECTANGULAR CIRCUIT

zero of the circuit, that is, the weight on the scale pan B which just held the contacts of the indicating circuit closed. This was done by placing weights on the scale pan B until the removal of a small weight, as carefully as possible, just closed the indicating circuit. If care was taken in placing and removing weights, this determination could be made to within 0.05 gram. The average of several trials gave a good determination of the zero position.

With the zero determined, points were obtained for a curve. The procedure was to add weights by tenths of grams to the scale pan B, and for each increment of weight to send current through the circle. As the current was increased the value of current at which the indicating circuit opened was noted, and as the current was reduced, the value at which it closed was also noted. The average of the two readings was taken as the one which eliminated errors due to friction in the joint and in the flexible leads. Several readings were taken at each point and the results averaged to give the current required for a given force. The curve of Fig. 2 shows the variation of force in dynes against averaged

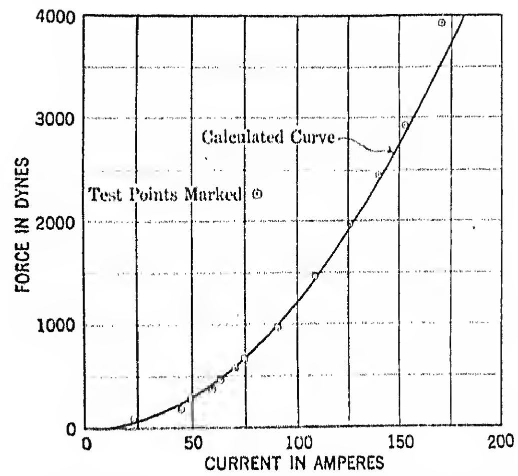

FIG. 4—CURVE SHOWING RELATION BETWEEN FORCE AND CURRENT IN RECTANGULAR CIRCUIT

Length—89.6 cm.
Width—40.0 cm.
Diameter of Wire—0.249 cm.

currents. The maximum value of current which could be used was 180 amperes, for with this current the mercury film blew out, probably due to heating.

The test results were compared, Fig. 2, with the curve calculated from equation (4) of the companion paper which for the dimensions used reduces to

$$F = 0.0641\ I^2 \text{ dynes} \qquad (1)$$

where I is the current in amperes. This comparison indicates an agreement of approximatly 10 per cent. The so called "pinch" effect of the mercury in the joint cannot be reasonably blamed for the divergence. If this were the case, the test curve should lie to the left of the calculated curve, since less current would be required for a given force if "pinch" effect aided the separation. It does not seem reasonable, either, to ascribe the difference to mercury tension or friction because these forces should remain constant over the range taken, and should give a constant error and consequently a continually decreasing percentage error, instead of a percentage error which is practically constant.

RECTANGULAR CIRCUITS

In connection with the tests concerned with the

mechanical forces acting on a conductor due to current flowing in other parts of the same circuit, of which the tests on the circular circuit just described were a part, experiments with rectangular circuits were performed using the same method. A diagrammatic sketch of the set-up is shown in Fig. 3. In this case two separations, at t and t', were made and the force measured in the center of the top cross-piece, thus measuring

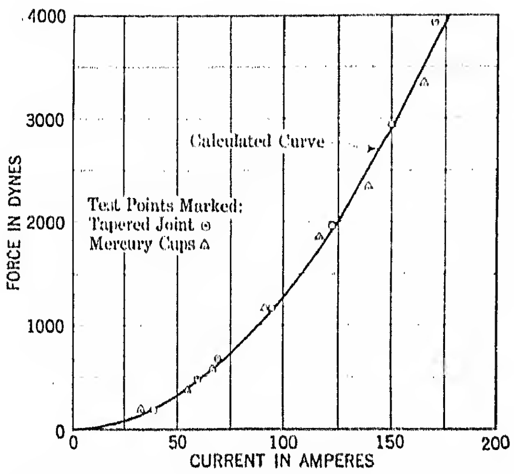

FIG. 5—CURVE SHOWING RELATION BETWEEN FORCE AND CURRENT IN RECTANGULAR CIRCUIT WITH AND WITHOUT MERCURY CUPS

Length—30.0 cm.
Width—40.0 cm.
Diameter of Wire—0.249 cm.

the total force acting. Several different lengths of rectangle were tested and the results for the longest and the shortest are given. According to theory, it should make no difference where the cuts t and t' are made. In the case of the longest rectangle, 89.6 cm. long, the distance from the bottom of the rectangle to the cut was 40 cm. This is dimension C in Fig. 3. In the case of the shortest rectangle, 30.0 cms. long, the distance was 20 cm. At first it was deemed inadvisable to use mercury cups for the joint and the tests were made with the tapered joint previously described. A trial with mercury cups was made later and the results were found to agree quite closely when compared with those obtained by use of the tapered joint. This comparison is shown in Fig. 5.

The results of the tests for the two sizes of rectangle are given in Fig. 4 and Fig. 5. They are compared with curves calculated from formulas (20) and (21) given in a paper, *The Calculation of the Magnetic Force on Disconnecting Switches*, by H. B. Dwight, TRANS. A. I. E. E., 1920, page 1337. This paper has been referred to frequently in several recent articles, but up to the present time there has been no experimental verification of the formulas derived in it. The formulas as given are for a disconnecting switch, of which a diagrammatic sketch is given in Fig. 6. This circuit reduces to a rectangle when S is made equal to A, so that the section $N' P'$ coinciding with $N P$ will cancel the effect of $N P$, as it should for a rectangle, since this part does not exist. The section $T' V'$ cannot be made to coincide with $T V$ since it is necessary to lead current in and out of the rectangle, but the effect of these parts will be reduced to a negligible amount if they are placed very close together. In the disconnecting switch the section $Q R$ was considered to be a flat strap, but in the tests made round wire was used throughout. Another point to be noted is that the disconnecting switch formula gives the force tending to open the blade at Q, and consequently only half the total force acting on $Q R$.

The formulas are given in the form of a convergent series and for convenience will be repeated here. Two cases are considered. Where B is greater than A, the force in dynes acting on the blade of a disconnecting switch is

$$i^2 \Big[\log_h \frac{2A}{r} - \frac{2}{3} + \frac{1}{2}\frac{A}{B} - \frac{1}{6}\frac{c^2}{A^2}$$

$$+ \frac{3}{20}\frac{r^2}{A^2} + \frac{1}{24}\frac{A^3}{B^3} - \frac{1}{24}\frac{A c^2}{B^3} - \frac{B}{S} \Big] \qquad (2)$$

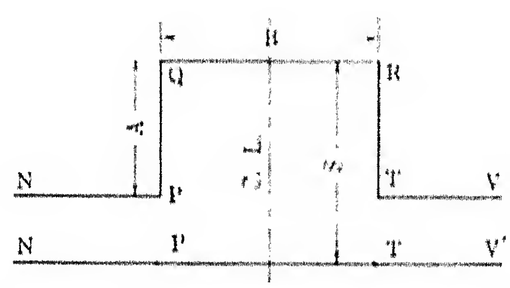

FIG. 6 DIAGRAM OF TYPICAL DISCONNECTING SWITCH

and where A is greater than B, the force is

$$i^2 \Big[\log_h \frac{B}{r} - 1 + \frac{1}{3}\frac{B}{A} - \frac{1}{4}\frac{B^2}{A^2} + \frac{3 r^2}{20 A^2}$$

$$+ \frac{1}{32}\frac{B^4}{A^4} - \frac{B}{S} \Big] \qquad (3)$$

where i is the current in abamperes, r is the radius of the section of wire $Q P$, and $R T$, $2 r$ is the width of the blade and A, B, and S are the dimensions shown in Fig. 6.

Mechanical Forces in Transformers

BY J. E. CLEM[1]

Associate, A. I. E. E.

Synopsis—*In this paper a method of calculating the mechanical forces in transformers, based on mutual reactance between coils, is presented. A formula for the mutual inductance between coaxial solenoids is developed and from this expression the formula for the mechanical force between concentric cylindrical transformer coils is derived. The same method is followed to obtain the formula giving the mechanical force between individual coaxial coils. The method is checked by calculations of reactance of complicated arrangements of coils. Tables are given to facilitate calculations.*

* * * * *

IN the design of transformers it is essential that the mechanical forces set up on short circuit be predetermined so that the bracing structure may be proportioned properly. This feature becomes increasingly important as the size of the transformer and the extent of the power systems increase. In this paper there is developed a method, fundamental and analytical, by means of which the total axial force and the force on separate coils of a transformer having concentric cylindrical windings may be calculated easily and quickly. The method is simple, being based on the fact that the reactance of a transformer may be calculated from formulas of self- and mutual-inductance.

Mutual Inductance of Coaxial Solenoids

This development is similar to other developments of the same problem but the result is given in a form that

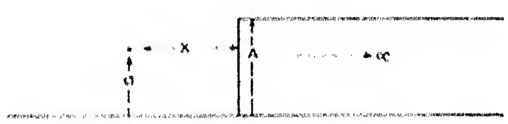

Fig. 1

is more convenient for calculation than heretofore available.

It has been shown elsewhere[2] that the mutual inductance between a circle of radius a and a coaxial solenoid of radius A, Fig. 1, extending to infinity from a point X distant from the plane of the circle is given by an expression which becomes on transformation

$$M = 2\,\pi^2\,a^2\,N\left[1 - \frac{x}{r}\,F\right] \tag{1}$$

$$F = F_0 + \frac{a^2}{r^2}\,F_2 + \frac{a^4}{r^4}\,F_4 + \frac{a^6}{r^6}\,F_6 + \text{etc.}$$

$$F_0 = 1$$

$$F_2 = \frac{3}{8}\;\frac{A^2}{r^2}$$

$$F_4 = \frac{5}{64}\;\frac{A^2}{r^2}\left(7\,\frac{A^2}{r^2} - 4\right)$$

$$F_6 = \frac{35}{1024}\;\frac{A^2}{r^2}\left(33\,\frac{A^4}{r^4} - 36\,\frac{A^2}{r^2} + 8\right)\text{ etc.}$$

$$r = \sqrt{A^2 + x^2}$$

Equation (1) has been transformed from those usually given to obtain a series for the quantity F in which the variables are always less than unity. This makes the calculations easier and extends the working range of the equation by keeping the value of the series for each component part of F down to a small figure throughout the entire range of the variable A^2/r^2.

In this expression M is the number of lines passing through the circle due to the semi-infinite solenoid which has a winding of N turns per cm. The mutual inductance between the finite solenoid, Fig. No. 2, of radius a and length S having n turns per cm. and the semi-infinite solenoid may be obtained by integrating the expression of (1) over the range from $x = x_1$ to $x = x_2$. This gives

$$M = 2\,\pi^2\,a^2\,n\,N\,[x_3 - r_3\,B^{\mathrm{III}} - x_1 + r_1\,B^{\mathrm{I}}] \tag{2}$$

$$B = B_0 - \frac{a^2}{r^2}\,B_2 - \frac{a^4}{r^4}\,B_4 - \frac{a^6}{r^6}\,B_6 - \text{etc.}$$

$$B_0 = 1$$

$$B_2 = \frac{1}{8}\;\frac{A^2}{r^2}$$

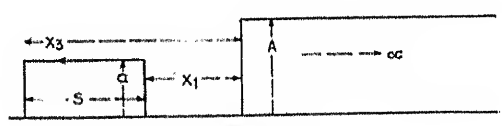

Fig. 2

$$B_4 = \frac{1}{64}\;\frac{A^2}{r^2}\left(5\,\frac{A^2}{r^2} - 4\right)$$

$$B_6 = \frac{5}{1024}\;\frac{A^2}{r^2}\left(21\,\frac{A^4}{r^4} - 28\,\frac{A^2}{r^2} + 8\right)\text{ etc.}$$

By reference to Fig. No. 3 it can be seen that the mutual inductance of the finite solenoid S and a second semi-infinite solenoid extending to infinity but starting P further away from the solenoid S than the the first

1. Central Station Engg. Dept., General Electric Co., Schenectady, N. Y.

2. Bul. No. 169, Bureau of Standards.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

semi-infinite solenoid is given by a similar expression involving x_2 and x_4 in place of x_1 and x_3 as follows:

$$M = 2\pi^2 a^2 n N [x_4 - r_4 B^{IV} - x_2 + r_2 B^{II}] \quad (3)$$

It follows naturally that the mutual inductance of coils S and P with centers x cm. apart as in Fig. No. 4 is the difference between (2) and (3), *i. e.*, (2) − (3) which gives as the final formula for the mutual inductance between two concentric coaxial solenoids

$$M = 2\pi^2 a^2 n N [r_1 B^I - r_2 B^{II} - r_3 B^{III} + r_4 B^{IV}] \quad (4)$$

M = Mutual inductance in centimeters
a = Smaller radius of solenoids in centimeters
A = Larger radius of solenoids in centimeters
S = Length of a solenoid in centimeters
P = Length of A solenoid in centimeters
n = Turns per centimeter of a solenoid
N = Turns per centimeter of A solenoid
r = $\sqrt{x^2 + A^2}$ for each value of x
B = Function of the ratios A^2/r^2 and a^2/r^2 for each value of x as defined in equation (2). Values of B may be taken from Table 3.

$$x_1 = x - \frac{S+P}{2} \qquad x_3 = x + \frac{S-P}{2}$$

$$x_2 = x - \frac{S-P}{2} \qquad x_3 = x + \frac{S+P}{2}$$

Self-Inductance of Solenoids

In order to calculate the net inductance of a pair of solenoids it is necessary to calculate the self-inductance of each. One of the most convenient methods of doing this is that given by Nagaoka as follows:

$$L = 4\pi^2 a^2 n^2 S K \quad (5)$$

which gives the inductance in centimeters. The factor K is a function of the ratio of the diameter to the length of the coil and the values of K are available[3] in any book that treats on inductance.

Axial Force in Two Coaxial Solenoids

When the magnetic centers of two coaxial solenoids coincide there will be no axial force tending to move the coils as a whole. But if the magnetic centers of the coils do not coincide there will be a force tending to

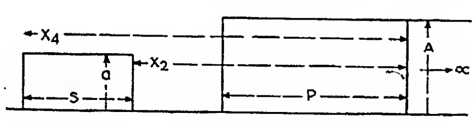

Fig. 3

cause a still greater separation of the magnetic centers. This force will depend upon the stored magnetic energy and the rate at which the energy is changed by the differential motion of the coil, *i. e.*,

$$f = -\frac{dW}{dx}$$

3. Bul. No. 169, Bureau of Standards.

$$W = \frac{1}{2} L I^2$$

W = stored magnetic energy in joules
= 10^7 ergs or dyne-centimeters
L = inductance of circuit in henrys
I = maximum value of currents

$$f = -\frac{10^7}{2} I^2 \frac{dL}{dx} \text{ dynes} \quad (6)$$

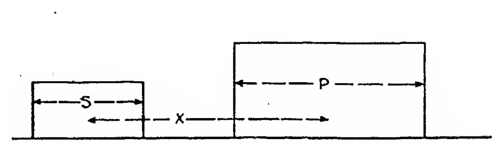

Fig. 4

In the pair of solenoids or transformer coils being considered

$$L = L_p + L_s - 2 M_{ps} \quad (7)$$

L = Net inductance or leakage reactance of transformer
L_p = Self-inductance of primary
L_s = Self-inductance of secondary
M_{ps} = Mutual inductance between primary and secondary

Since the self-inductance of neither the primary nor secondary coil will be affected by any change in their relative position, there results

$$\frac{dL}{dx} = -2\frac{dM}{dx} \quad (8)$$

Since M is given by equation (4), $\frac{dM}{dx}$ is given by the derivative of this equation. Rewriting (4) for inches and henrys;

$$M = 2.54 : \frac{2\pi^2 a^2 n N}{10^9} \sum r B$$

there results

$$\frac{dM}{dx} = 2.54 : \frac{2\pi^2 a^2 n N}{10^9} \sum \frac{x}{r} F$$

and

$$\frac{dL}{dx} = -2.54 \frac{4\pi^2 a^2 n N}{10^9} \sum \frac{x}{r} F \quad (9)$$

When (9) is substituted in (6), the force, after changing from dynes to pounds, is found to be

$$f = 444 I^2 a^2 n N 10^{-9} \sum \frac{x}{r} F$$

In this expression, I is the maximum value of current and to use the usual effective value we must write

$$f = 0.888\, I^2\, a^2\, n\, N\, 10^{-6} \sum \frac{x}{r}\, F \qquad (10)$$

This expression gives the force in pounds when the dimensions are in inches and F is defined as in equation (**1**). The value of F may be taken from Table II.

Force on Individual Coils

To find an expression for the force between a solenoid and a single coil we proceed as above, *i. e.*, integrate to find the mutual inductance between the coil and the solenoid and then differentiate this expression to find the force. The mutual inductance between two circles, Fig. 5, is given by

$$M = 8\, \pi\, \sqrt{a}\, A\, \frac{F - E}{\sqrt{K}} \qquad (11)$$

In this expression F and E are elliptic integrals, available from published data in works on inductance,[4] to the modulus K which is defined as

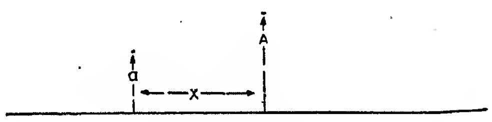

Fig. 5

$$K = \frac{4\, a\, A}{(r_2 + r_1)^2}$$

$$r_2^2 = (A + a)^2 + x^2$$
$$r_1^2 = (A - a)^2 + x^2$$

The mutual inductance between one of the circles and a solenoid is obtained by integrating (**11**) over the range S from $x = x_1$ to $x = x_2$ which gives

$$M = 8\, \pi\, n\, N\, \sqrt{a}\, A \int_{x_1}^{x_2} \frac{F - E}{\sqrt{K}}\, d\, x$$

$$= 8\, \pi\, n\, N\, \frac{\sqrt{a\, A}}{S} \left[\int D \right]_{x_1}^{x_2}$$

Upon differentiating this and substituting in the force equation there results

$$f = 0.698\, n\, N\, \frac{\sqrt{a\, A}}{S}\, [D'' - D'] \qquad (12)$$

f = Force in pounds
n = Turns per inch of solenoidal coil
N = Turns in single coil
a = Radius of solenoid inches
A = Radius of coil inches
S = Length of solenoid inches

Test Application

The method has been checked by the calculation of reactance for complicated arrangements of windings, on the basis that if the voltage can be calculated accurately then the force calculation as based on the differential

of the voltage equation will be established as reliable. This was done because the voltages can be measured much more easily than forces.

In Figs. 6A and 6B are shown diagrams of two transformers for which voltage calculation was made. The agreement of calculated and measured voltage shown in Table I is reasonably close. These are high voltage transformers having extra insulated end turns so that the turns are not distributed uniformly over the high-voltage coils. This has an effect which is greater as the portion of the winding considered is less, but these calculations have been made as for a uniform distribution.

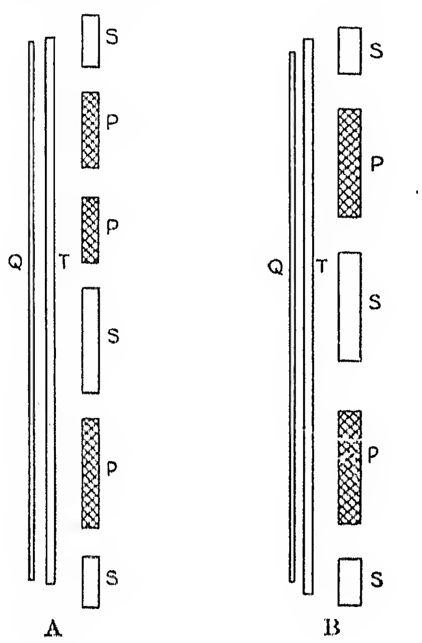

Fig. 6

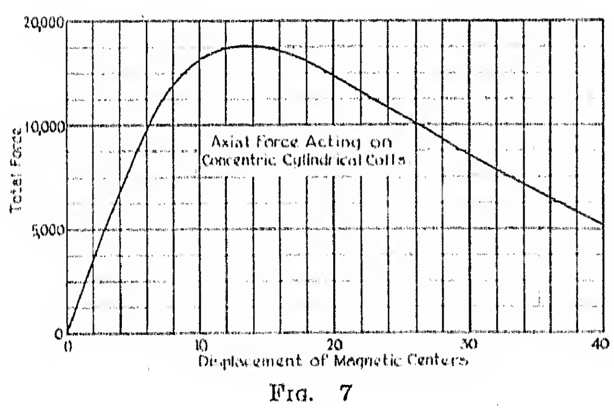

Fig. 7

Forces for a representative transformer have been calculated and the results are shown in Figs. 7 and 8. The coil forces in Fig. 8 are for a displacement of about 14 in. and the sum of the individual coil forces totals to the value on the curve in Fig. 7. In this case the forces are relatively low on account of the rather high reactance of the transformer for which these calculations are made. The displacement which gives the maximum is higher than would ever occur in a well designed transformer.

Discussion

W. S. Moody: The problem of taking care of mechanical forces in transformers became a really difficult one for the practical designing engineer some fifteen or twenty years ago. Previous to that, the power available in case of a short circuit and the size of transformers were not sufficient to require much more than good judgment on the part of the engineer to provide the necessary mechanical support. But with the increase in size, and more particularly with the increase in the available power, the necessity of accurate calculation of these forces arose. Ever since, therefore, we have welcomed most cordially the assistance of the ablest mathematicians and physicists who have shown interest in this difficult problem.

Time and again we have felt that the problem was fully solved, that one's design might be assuredly safe in every respect; but with the ever increasing complexity of transformer designs, now seldom consisting of two simple windings, but with three and even four complex windings, with many taps and the consequent inability to distribute equally the ampere-turns in all cases, new features have arisen showing that the previous study of the subject had not been on a broad enough gage to include all the variables in such complex designs.

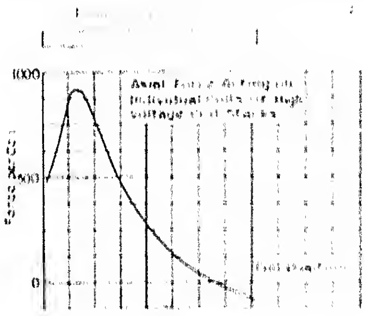

Fig. 8

So we still welcome such assistance as we have so generously received from our mathematical and physical friends.

After formulas have been developed to calculate accurately the mechanical forces resultant from all possible combinations of ampere-turns (if that time ever does come) we shall still have the interesting problem of making those formulas practical for use in "every-day" calculations. Such formulas as have been talked about in this paper are excellent for the general study of transformer design but when it comes to every day designs, which must be produced promptly and cheaply, one can see that these formulas are very burdensome and that there is necessity for short-cut methods giving equal accuracy. For this we must use special mathematical calculating machines, such as specially designed slide-rules and other forms of calculating machinery that make it possible to use the principles of these fundamental formulas in the daily routine of productive design.

F. H. Kierstead: There are often simplifications of difficult circuits that may be made in the calculation of the forces between these circuits. I wish to illustrate such a case.

Many times it is necessary to calculate the forces between two conductors (carrying currents) which have such a form that no standard formula applies. Usually time does not permit of deriving an accurate formula for the special case. Approximate calculations which are generally accurate enough can be made by replacing the actual circuits by equivalent ones to which the standard formula applies. As an example to illustrate this method let us take the case of the forces between a large and a small reactor with parallel but not co-axial axes.

The accompanying figure shows the position of the reactors relative to each other. From the standpoint of forces the reactors can be replaced by the circular filaments *W*, *X*, *Y*, and *Z* and the forces calculated between these filaments are the forces between the reactors. It is, however, difficult to calculate the force between two parallel unequal circles not coaxial. To facilitate this calculation the smaller circle can be replaced by the arcs of circles *G-F* and *H-I* (which are co-axial with the circular filaments of the larger reactor) and the radial lines *G-H* and *F-I*.

Standard formulas are available for calculating the force between co-axial circles and, therefore the forces between the filaments of the large reactor and circles of which arcs *G-F* and *H-I* form a part are easily calculated. The forces between the filaments of the large reactor and arcs *G-F* and *H-I* bear the same relation to the forces between the complete circles that

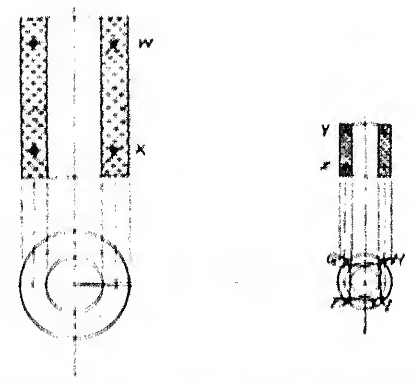

FIG. 1—DIAGRAM REPRESENTING THE EQUIVALENT FILAMENTS USED IN CALCULATING THE FORCES BETWEEN A LARGE AND A SMALL REACTOR

the length of the arcs bear to length of the complete circles. Since that part of the equivalent circuit represented by *G-H* and *F-I* is radial to the filaments of the large reactor, there is no force between it and the filaments of the large reactor. Since the current in the arc *G-F* is in opposite direction to that in arc *F-I* the forces are in opposite directions.

H. B. Dwight: Mr. Clem's paper is an interesting example of a case where it is desirable to have both an inductance formula and a force formula, not only because a knowledge of the inductance is useful, but because the inductance is more easily measured than the force.

Mr. Kierstead's trapezoid solution of the special problem is interesting to me personally. In 1917, I was asked to make an estimate of the force between two air-core reactors which were mounted side-by-side with parallel axes. As I had no formulas that I could use at that time for two circles, I used the device of representing one of the circles by a trapezoid, the same as Mr. Kierstead has described. I had not seen it published before, and perhaps Mr. Kierstead can say if there was a previous announcement of it. My publication of this was in the *Electrical World* of June 16, 1917.

Later, I was able to calculate the repulsion between circular coils with parallel axes, and in the TRANS. A. I. E. E., 1919, page 1678, Fig. 2, there is given a comparison between the circular-coil solution and the trapezoid solution. The curves lie very close together.

There is a formula in Gray's "Absolute Measurements" which may be of interest. If the axes of two coils meet in a point, a calculation is given by which the mutual inductance and repulsion can be obtained.

F. W. Grover: (communicated after adjournment) Mr. Clem has developed a new formula for the mutual inductance of coaxial solenoids, which offers some points of interest.

The Rosa formula for the mutual inductance of a solenoid and coaxial circular filament (*Bull.* Bureau of Standards 3, p. 209; 1907, formula (56) *Sci. Paper*, Bureau of Standards) is made the starting point. This formula, although very convergent for a wide range of cases, involves certain polynomials X_{2n} which, for long solenoids, may assume values so large as to cast doubt upon the degree of convergence. By a simple algebraic substitution Clem eliminates these polynomials, and obtains a transformation of the Rosa equation in which appear as variables only the ratios of the radii to the radius vector from the center of the circle to the circumference of the end turn of the solenoid. Since these variables lie in value between zero and unity as limits, this expression of Clem's is better adapted to tabulation than is that of Rosa. It is worthy of note that, making the proper changes to reduce to the same system of nomenclature, Clem's expression is seen to be identical with that derived by Lorenz, (*Wied. Ann.* 25, p. 1, 1885; also (53) *Sci. Paper* 169, Bureau of Standards).

The derivation of Clem's formula for the mutual inductance of coaxial solenoids from this formula for a solenoid and circle is straightforward and may readily be extended to obtain further terms of the series, if desired. The resulting new expression is readily used, and for practical calculations is much superior to the related formula of Gray, (*Abs. Meas.* 2, Part I, p. 274, or (40) *Sci. Paper* 169, Bureau of Standards) which has heretofore been the only formula available for this case, except the absolute complicated elliptic integral formulas. For example, the solution of Example 41, *Sci. Paper* 169, Bureau of Standards, by Clem's formula gives as a result 1086.2, the true value by the absolute formula being 1086.55. Using Gray's formula directly the result is 1092.3, and to obtain an accuracy equal to Clem's it is necessary to subdivide the coils and to sum the results for the different pairs of sections.

Although Clem's derivation is for the case where the coils are separated axially, it applies also to the case of overlapping coils. For the important case where the coils are *concentric*, only two main terms have to be calculated instead of four. For this case Clem's formula compares very well with the accurate formula of Searle and Airey, (*Lon. Electrician*, 56, p. 318, 1905, or (43) *Sci. Paper* Bur. of Stand.) which is the special form taken by Gray's general formula for the concentric case.

One precaution in using Clem's formula should be mentioned. When the coils are far apart, the main terms $(r_1 + r_4) - (r_2 + r_3)$ give the result as the relatively small difference of two larger numbers. However, these quantities may readily be calculated by a calculating machine to a sufficient number of places. Another obvious method is to expand them in series, but this is advantageous only for very distant coils.

Transformer Tap Changing Under Load

BY L. H. HILL[1]

Associate, A. I. E. E.

Synopsis.—Changing the voltage ratio of transformers under load is now a recognized and established procedure. Methods of changing taps under load are discussed, illustrated, and compared. Equipment for obtaining smooth curve voltage control is discussed, as well as combination voltage and phase-angle control.

* * * * *

Introduction

THE development of reliable equipment for changing the voltage ratio of transformers without disconnecting the load has, in effect, created a new type of apparatus ranking with the induction regulator or synchronous condenser in importance.

Transformers provided with equipment for tap changing under load, however, do not labor under the inherent disadvantages incident to the use of the other two kinds of apparatus. The rapid growth in popularity of this equipment has been due to the fact that for certain applications, a simpler, more compact, more reliable, sturdier, more effective, and cheaper piece of apparatus can be obtained by this than with the older forms of equipment.

The application of transformers provided with equipment for changing taps under load is very wide. Perhaps one of the most important is in connection with transformers used to tie together two large systems or parts of systems. Of next importance are units used for bulk voltage regulation of a secondary bus or to compensate for voltage drop in transmission circuits. Other interesting applications are those involved in the variation of voltage applied to rotary converters and furnace transformers.

Methods of Tap Changing

There have been numerous methods devised and, at least to a limited extent, used to change the voltage ratio of transformers under load. These may be divided into two classes—those changing the ratio in steps and those changing the ratio along a smooth curve.

Changing the Voltage Ratio in Steps

The majority of schemes proposed and used for changing the voltage ratio under load change the ratio in steps. Roughly, these may be divided into two general classes,—(1) those using duplicate paralleled windings in the transformer, each normally carrying one-half of the load, but adapted for carrying the entire load during the time that the taps on the other are being changed; and (2), those using a single winding with a preventive resistance, reactance, or auto-transformer across the taps involved in the transition.

1. Transformer Engg. Dept., Westinghouse Elec. & Mfg. Co. Sharon, Pa.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

The Parallel Winding Method

Fig. 1 indicates schematically a winding arranged to change taps under load by means of the parallel winding method.

Each of the parallel circuits contains a tap changer or ratio adjuster, usually located inside the transformer tank, and a circuit breaker, which is outside of the transformer tank.

When taps are changed, one of the paralleled circuits is opened by means of the circuit breaker in its respective section and the taps are changed while the winding carries no load. During this period the entire load is carried by the other winding. When the first circuit breaker closes, the two sections of the windings

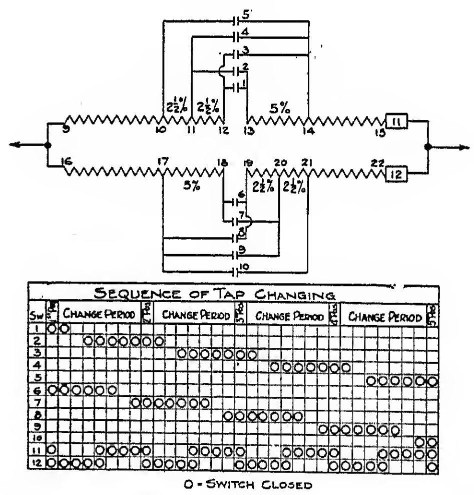

Fig. 1—Schematic Diagram and Sequence Chart of Switch Operations for the Parallel Winding Method

are paralleled with unequal taps and a circulating current exists. This is for a short time only, as the second breaker opens immediately, permitting the taps to be changed at no-load on the second winding, while the first carries the total load. After this, the tap changing operation is completed by closing the breaker on the second winding with the result that the two paralleled sections again operate on equal taps.

During the interval of tap changing, one of the paralleled windings carries double normal current. The windings are ordinarily designed with sufficient capacity to carry this abnormal current during the tap changing operation and differential protection between windings is provided to guard against accidental overloading for a longer period of time.

A transformer designed to change taps under load by means of the parallel winding method is illustrated in Fig. 2.

Single Winding Method

The other methods used in addition to the parallel winding method fall into the class which uses a single winding in the transformer with a preventive coil or some other device to limit the current during the transition period from one tap to the next.

Probably the oldest form of equipment for tap changing under load employed the Stillwell regulator principle, which uses a preventive resistance temporarily bridged across taps to limit the current during the transition period.

Equipments have also been made, to a limited extent, using a preventive reactance in the circuits instead of the resistance used with the original Stillwell scheme.

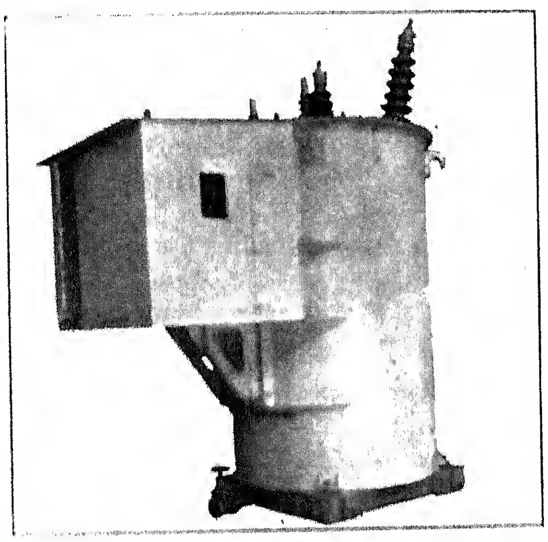

Fig. 2—20,000-Kv-a., 66,000-Volt, 60-Cycle Transformers using Parallel Winding Method

A much simpler scheme than either of these two consists of using a preventive auto-transformer with a mid-point tap, as schematically shown in Fig. 3. A great many units have been built employing this method.

To obtain the full winding of the transformer in the circuit, switches 1 and 6 are closed. The circuit is then through the full transformer winding and divides through the preventive auto-transformer, one-half being through one side of the auto-transformer and one-half being through the other half in the opposite direction. The voltage of the transformer is therefore the voltage induced in the entire winding. To change taps, switch 6 is opened and 2 is closed. This connects the auto-transformer across the two taps and, since the line lead is attached to the center of the preventive auto-transformer, the line voltage becomes the same as it would have been had the line lead been attached to a tap midway between the two actually brought out.

Similarly, to change taps still further, the process is repeated in this manner, (Fig. 3).

In the earlier installations built using this method, the switches and preventive auto-transformers were all mounted separately and apart from the main transformer tank. In later equipments, since the preventive auto-transformer has no moving parts and can be made entirely reliable, it is mounted inside the main tank and supported from the main transformer.

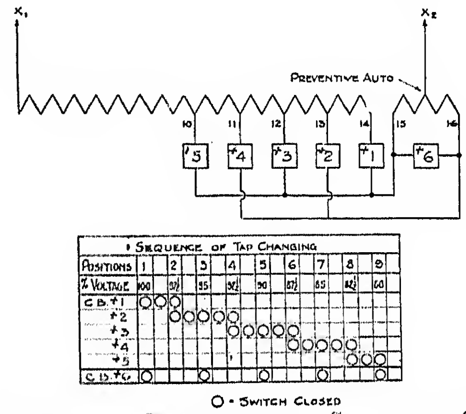

Fig. 3—Schematic Diagram and Sequence Chart of Preventive Auto-Transformer Method

Fig. 4 illustrates an installation of transformers using this type of apparatus. The tap changing equipment is contained in the sheet iron house next to the transformer tank.

The tap leads are all brought through the side of the transformer tank, and are connected to the circuit breakers mounted in the upper portion of the steel house.

The circuit breakers are mechanically connected to the operating mechanism on the floor below.

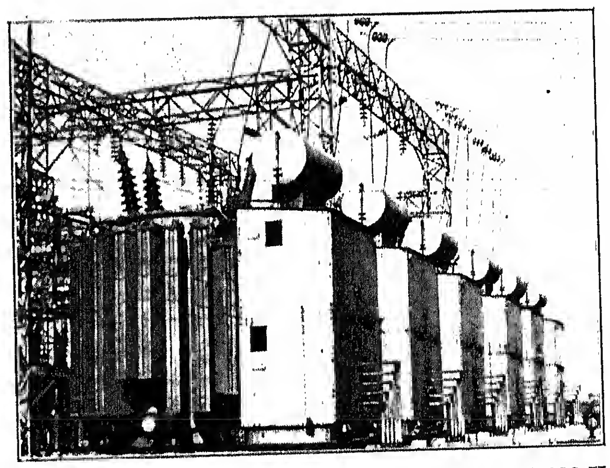

Fig. 4—Installation of 6- 10-, 500-Kv-a., 66,000-Volt, 25-Cycle Transformers using Preventive Auto-Transformer Method

For a short time during the transition period, one-half of the auto-transformer winding carries all of the load current of the transformer, while the other half of the winding is open. The load current is then the magnetizing current, and the voltage across the preventive auto-transformer tends to rise somewhat above normal. To limit this voltage to a low value, the design of the

auto-transformer is such that the core becomes saturated when the voltage reaches a value slightly above normal.

In changing from one voltage to another, two operations are required; namely, the opening of one circuit breaker and the closing of another. Since the circuit breakers are operated mechanically by means of cams on a drive shaft, the correct sequence of operation is assured at all times.

O SWITCH CLOSED

Fig. 5—Schematic Diagram and Sequence Chart of Single-Winding Method using the Simplified Preventive Auto-Transformer

Simplified Preventive Auto-Transformer Method

The preventive auto-transformer method, using a short-circuiting switch across the auto-transformer, has recently been simplified still further by merely the elimination of the short-circuiting switch and the use of an auto-transformer designed to carry the transformer full load current in either half of the winding with the other end disconnected.

Fig. 5 illustrates schematically the winding arrangement when this method is used. To obtain the entire transformer winding in the circuit, switch 1 is closed and the current passes through the transformer winding and one-half of the preventive auto-transformer. This gives a small impedance drop through the auto-transformer which is in series with the transformer. Since the drop is almost entirely reactive, its effect on regulation is practically negligible at power factors above 65 per cent.

To change taps one step, switch 2 is closed, placing the auto-transformer across the two taps, and giving a voltage on the mid-tap of the auto-transformer midway between the two actual tap voltages.

To change taps another step, switch 1 is opened and the conditions become as before, with the other half of the auto-transformer carrying the full current of the transformer.

To change taps still further, the process is continued in the same manner, as may be followed in detail from the sequence chart, Fig. 5.

It may be seen that, by this development, the process of tap changing has apparently reached its utmost simplicity for step-type tap changers with one switch operation to change taps, and in every other tap change, the switch closing instead of opening.

When full load current is passed through one-half of the auto-transformer with the other half open, the full-load current of the main transformer as in the case of the other auto-transformer method becomes the exciting current of the auto-transformer. Under this condition, there are no neutralizing ampere-turns from the other half, so that the transformer becomes a reactor. Air-gaps are provided in the core to give low impedance when operating in this manner which, of course, makes the exciting current, when operating as an auto-transformer across taps, higher than ordinary.

Switches for Tap Changing Service

Circuit-breaker devices for tap changing service have entirely different conditions to meet than the ordinary circuit breaker. The ordinary breaker is designed for relatively infrequent operations with a few operations interrupting many times normal current at line voltage.

The switch for tap changing duty, on the other hand, is called upon to merely transfer current from one circuit to another, and, while it must be insulated for the service voltage, it opens but a small fraction of line voltage and usually not more than twice normal line current. Instead of calling for a few operations with high interrupting capacity, it must be able to stand a great number of operations without losing its adjustment but with very low interrupting capacity required.

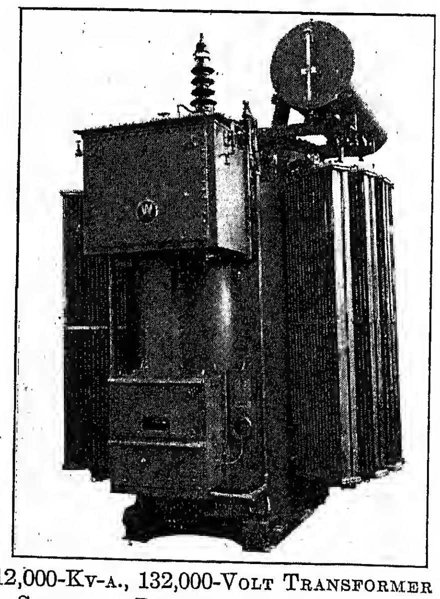

Fig. 6—12,000-Kv-a., 132,000-Volt Transformer using the Simplified Preventive Auto Method

A switch for tap changing service is never called upon to interrupt a short circuit except in the remote possibility of short circuit on the system occurring during a tap changing operation. Even in this case the voltage to be interrupted would be very low but the current would, of course, be considerably higher than normal. In fact, the service required of a switch for tap changing service, approaches that of a heavy duty contactor

switch. Fig. 6 illustrates a transformer provided with equipment for tap changing under load, using a specially designed switch to meet these requirements, a very simple, compact, and sturdy mechanism. The single winding method, using the simplified preventive auto-transformer, was employed.

All mechanical equipment is isolated from the main transformer tank. The switches are contained in a separate oil-filled compartment on the side of the transformer case and the operating mechanism is contained in the housing below with a connecting tube enclosing the drive shaft which enters the upper compartment through an oil tight stuffing box in the bottom.

The general construction of the switch itself may be seen in Fig. 7. Condenser bushings through the side of the transformer tank support the stationary and movable contacts which are arranged to give the rolling action common with heavy-duty contactor switches. The rolling action is such that the arcing is taken at the tips so that the current carrying parts always remain in good condition. Opening and closing is definitely fixed in the proper sequence by the mechanical operation of the cams as in the case of the equipment using circuit breakers. The toggle mechanism assures quick opening, but in case of sticking or contact weld, the cams force the opening.

Control of Tap Changing Equipments

Tap changing equipments are normally arranged for remote electrical control by the operator, with auxiliary arrangements for manual operation in case of failure of motor or control voltage.

The electrical control is such that after the operator has initiated a tap change, auxiliary mechanically operated switches on the equipment assure the completion of the tap changing operation irrespective of the action of the operator. Remote electrically operated position indicators of the dial type or of the indicating lamp type are generally used.

Tap changing equipments may also be built to operate under automatic control. The transformer illustrated in Fig. 6 was arranged to automatically control the voltage at a given point within predetermined limits.

The automatic control is initiated by a rise or fall in the low-voltage potential acting through a long time delay relay.

The use of automatic control with step type tap changers places unusual responsibility on the reliability of the apparatus. On account of the greater number of operations likely to be obtained with equipment responsive to the action of fluctuating line voltages, the time delay relay must be introduced to eliminate unnecessary operations also to prevent the possibility of the tap changer operating during short circuits. Since a short circuit on the system tends to reduce the voltage, there would be a tendency for the tap changer to operate during the short circuit to raise the voltage, which in itself would be undesirable.

With automatic control of step type equipment it is necessary also to design the control equipment to free the motor-actuating circuits from the voltage-responsive circuits as soon as the motor-actuating circuits have become energized.

When transformers are operated as single-phase units in a bank with individual tap changing mechanisms or when two banks are operated in parallel, it is essential that out-of-step operation be guarded against. In all such cases, the automatic equipment is locked out of service and an alarm sounded.

Comparison of Step Type Tap Changing Methods

Satisfactory tap changing equipments have been built using the two fundamental methods of step-type tap changing. There are certain inherent advantages, however, pertaining to each.

The single winding method requires fewer taps in the transformer for a given number of operating positions and gives a simpler transformer winding than the other method. On account of the less number of taps it is easier also to bring all operating parts outside of the

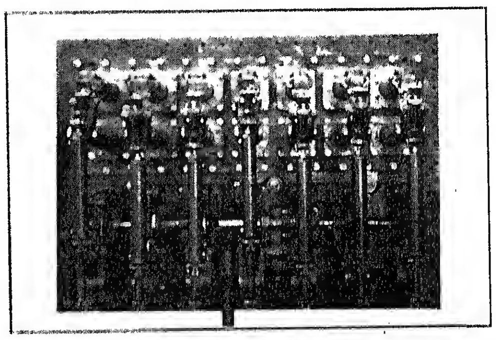

Fig. 7—Special Switch Designed for Tap Changer Service

transformer tank when this method is used. In addition, the fewer number of switch operations give the preventive auto method a decided advantage.

With the parallel winding method, however, when a wide range of taps in small steps is desired, a more compact equipment may usually be obtained by the use of the tap changer inside the main tank. This is particularly advantageous with small three-phase units where space limitations make it difficult to mount all equipments outside the main tank.

Equipment for Changing Transformer Voltage Ratio in Smooth Transition

An interesting modification of the simplified preventive auto-transformer scheme of tap changing is obtained if the two halves of the preventive auto-transformer are replaced by the two sections of a series transformer—in combination with a small induction regulator.

Such a combination is called a step induction regulator and has been used principally for bus regulation and to apply variable voltage in a smooth curve to furnace transformers, testing transformers, and synchronous

converters. It has been applied also to transformers used for interconnecting two systems. Referring to Fig. 8, the switches 1, 2, 3, 4, and 5 are called selector switches while A and B are called transfer switches. The induction regulator may be a standard feeder regulator with the addition of slip-rings to make the rotor suitable for continuous rotation.

Rotation of the induction regulator rotor through 180 deg. changes the voltage in its winding from a maximum in one direction to a maximum in the other

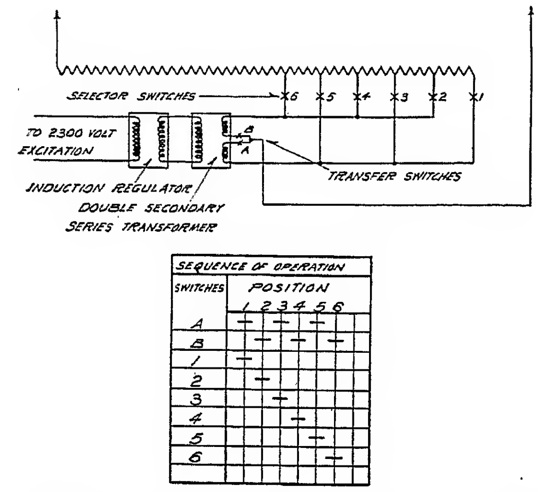

Fig. 8—Schematic Diagram and Sequence Chart for Step Induction Regulator Equipment

direction. In the application to step induction equipment, the voltage of the regulator is added to or subtracted from a transformer tap to provide means for transferring from one tap position to the next and incidentally obtaining an infinite number of operating positions in between.

Referring to Fig. 8, if the entire voltage of the transformer winding is desired, selector switch 1 and transfer switch A would be closed with the regulator rotor in the position of zero buck and boost.

To reduce the effective transformer coil voltage, the regulator is rotated to increase the voltage. At the position of maximum regulator voltage, the series transformer is designed so that the voltage of each half of the series winding is exactly the same as one-half the tap voltage.

At this point, switches 2 and B may be closed, since the half of the series winding connected to switch 1 reduces the effective coil voltage the same amount that the half connected to 2 adds to the voltage up to that point. Since the potential at the two points is the same, they may be connected. Continued rotation of the mechanism opens switches A and 1 and the voltage of the series transformer adds to the coil voltage of switch 2. As the regulator is rotated further, the voltage of the series transformer half decreases to zero when the line voltage becomes equal to the coil voltage up to tap 2. Continued rotation repeats the process to the next tap, as may be followed in detail from the sequence chart of switch operations Fig. 8.

Any of the infinite positions of the induction regulator become operating positions so that an infinite number of steps in voltage may be obtained between the extreme tap position.

It would be possible to eliminate the series transformer with this equipment, by building a special regulator with two sets of secondary coils. The use of the series transformer is desirable, however, not only because it eliminates the necessity of making a special regulator winding, but it isolates the induction regulator from the transformer circuits. The use of the relatively weaker induction regulator, therefore, does not reduce the inherent mechanical and electrical reliability of the main transformer.

When the range of voltage regulation is exceptionally large, it is economical to modify the above scheme by switching the induction regulator along an auxiliary winding, which, in turn, is switched along the main winding at less frequent intervals. The taps are changed on the auxiliary winding in the same manner as described above and the voltage of the auxiliary winding either added to or subtracted from the taps of the main winding.

Assuming that the voltage is to be increased, one of the auxiliary windings is connected to a tap such as tap 1 of the transformer, and the induction regulator switched along the auxiliary winding until the voltage of the double secondary windings is added to the auxiliary winding. The voltage added to tap 1 is then the same as the voltage of the winding between taps 1 and 2

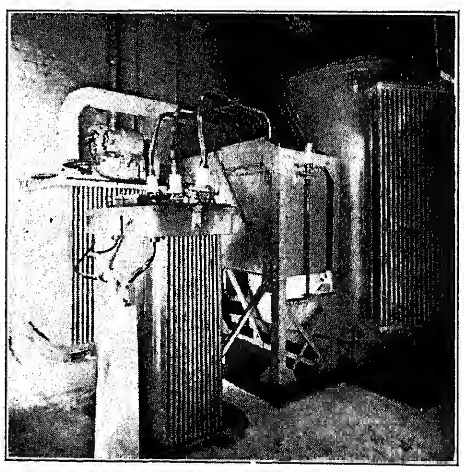

Fig. 9—2500-Kv-a., Step Induction Regulator Equipment

minus the voltage of one winding of the series transformer. There will be no change, therefore, in voltage if the second double secondary winding is connected to tap 2 so that its voltage is subtracted from the tap. The voltage may be increased further by disconnecting the auxiliary winding from tap 1, and rotating the regulator rotor so that the voltage of the second auxiliary winding plus the voltage of one winding of the double

secondary winding is added to tap 2. The connections are then changed as before, so as to subtract the voltage of one winding of the series transformer from tap 3. Further increases of voltage are obtained beyond tap 3 in a similar manner.

An interesting application of the step induction regulator principle is illustrated in Fig. 9, where the voltage applied to a 2500-kv-a., synchronous converter is varied in the ratio of 2 to 1, giving a voltage range of 50 per cent in smooth transitions. By the use of voltage regulating equipment of this kind it is possible to cover a wide voltage range without the use of booster type converters.

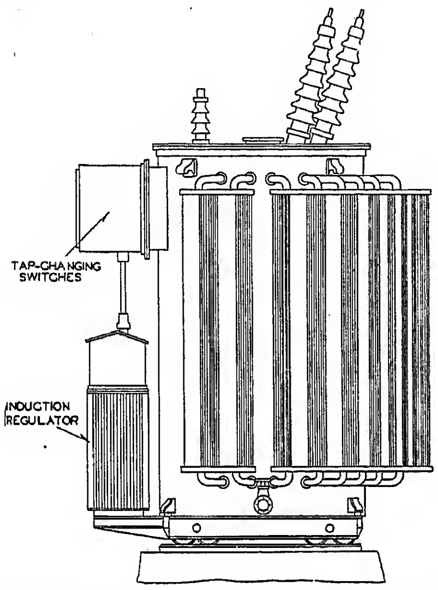

FIG. 10—SKETCH OF TRANSFORMER PROVIDED WITH STEP-INDUCTION REGULATOR EQUIPMENT BUILT INTEGRAL WITH IT

In Fig. 10 is illustrated the possible compact and simple arrangement of step induction regulator equipment with all moving parts external to the main unit but with the series transformer inside the main case. The selector and transfer switches are mechanically operated contactor switches driven by the regulator in the proper sequence.

COMPARISON OF STEP TYPE AND STEP INDUCTION REGULATOR METHODS

The step induction regulator is well adapted for use where bus or transmission circuit voltage is to be controlled, particularly where automatic control is desired. In this case, automatic control merely calls for a voltage actuated relay with time delay, giving a much more simple control equipment than is possible with the step type equipment. When automatic control is used, the number of tap changing operations is usually greater than otherwise so that the step induction regulator units are particularly adaptable on account of the fact that there is no burning of the contacts and therefore less maintenance required.

When the range in taps to be covered is not too large, and if small steps are not required, the step type equipment is more desirable on account of the somewhat simpler equipment.

SEPARATE REGULATING UNITS

The tap changing equipments heretofore considered have been applied directly to the transformer unit. On account of the fact that no additional transformer units are required, this generally gives the cheapest, most efficient, and most compact equipment to change the voltage.

There are applications, however, where modifications of this simple arrangement are desirable.

In general, tap changing mechanisms are so far practicable for direct use in circuits up to 33,000 volts or carrying not more than 1200 amperes. By using these units in the star connection of solidly grounded systems it is possible to apply them to transformers of much higher voltage by placing the tap changer in the grounded end.

In case of delta connections above 33,000 volts or ungrounded star windings of higher voltage, the use of a separate regulating unit becomes desirable at present.

The use of a separate regulating unit may be desirable also from other considerations. For example, if it is desired to obtain voltage control with transformers already installed, the separate regulating unit becomes very useful. In some cases the need for voltage regulation may not be permanent, so that a separate regulating unit may be used with the idea that it may later be transported to some other location.

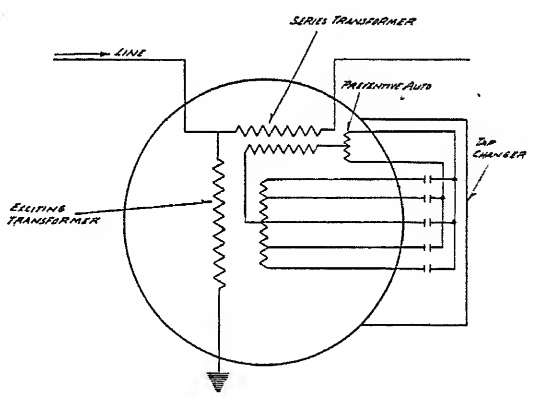

FIG. 11—SCHEMATIC DIAGRAM OF SEPARATE REGULATING UNIT

The use of separate regulating units, however, is accompanied by the requirement of more floor space, lower over-all efficiency on account of the extra transformers required, higher installation cost on account of the interconnections, etc., required between the regulating unit and the main unit.

Fig. 11 illustrates schematically the winding arrangement for a separate regulating unit. By suitably arranging the ratios of the respective series and exciting units, the tap changing equipment may be used to cover a wide range of applications. Both the series and exciting transformers may be mounted in the same case, to reduce the number of bushings and simplify the connections and installations.

In the case of equipment for tap changing under load designed to operate on high-voltage ungrounded units, the auxiliary series and exciting windings may be built into the same unit in such a way as to reduce the number of auxiliary windings and cores and increase the over-all efficiency. Assume, for example, a unit with tap changing under load required on a 120,000-volt delta winding. The series transformer as shown in Fig. 12 may be used but the exciting transformer in the separate regulating equipment may be replaced by a third winding in the transformer as shown.

Combination Voltage and Phase Angle Control

When systems become larger and interconnections become more frequent, cases will arise where phase-angle control, as well as voltage control, may be required to obtain satisfactory results. This condition will exist where a substation is supplied from two sources with interconnecting lines of different impedances.

It appears that the control necessary will be of the order of plus or minus 10 per cent in-phase voltage with a phase-angle control of approximately plus or minus 6 deg. This means that an in-phase component of plus or minus 10 per cent, and a quadrature component of plus or minus 10 per cent, each independently adjustable, should be super-imposed upon one of the lines at some suitable point.

These problems may be worked out, using two induction regulators, two transformers, or by means of a single multi-winding transformer.

Regulation Methods

Under this scheme, taking a 24,000-volt line carrying 25,000 kv-a. as an example, two 1250-kv-a., three-phase, induction regulators, adapted for 5 per cent regulation on 25000 kv-a. and connected in series may be used. The primaries of these regulators are energized by means of a three-phase transformer, 24,000 to 4800 volts, 3300-kv-a. capacity. The output of the two regulators in series may be stepped up by means of a 2500-kv-a. series transformer so as to buck and boost the 24,000-volt line 2400 volts in either direction due to the two 5 per cent windings in series. Because of the fact that a three-phase regulator rotates the voltage vector—that is, it is fixed in magnitude but is variable in phase—the first regulator will add to the line voltage a voltage vector which is equal in magnitude to 5 per cent of the line voltage but whose phase angle with respect to the line voltage (depending upon the relative position of the rotor and stator of the regulator), may swing to any position in a complete circle pivoted upon the end of the line voltage vector. The regulator itself may be supplied with slip-rings so that it is capable of continuous rotation. The terminal voltage of the regulator is therefore represented by a circle of radius 5 per cent. To this, a second regulator is connected in series having an independent control, the terminal voltage of the second regulator describing a 5 per cent circle having its center located on the circle described by the first regulator, with the result that the terminal voltage of the second regulator may be adjusted at any point within a radius equal to 10 per cent and may therefore give a phase angle control of the line voltage of approximately 6 deg. and also a maximum in-phase buck or boost of 10 per cent either way.

Transformer Method

In the second method, two transformers of 2500-volt capacity each may be used with primaries wound for 24,000 volts and secondaries wound for 2400 volts, each rated for 24,000 volts series connection with the line and equipped with tap changing under load covering a range from plus 2400 volts to minus 2400. The first transformer is arranged with its primaries star connected so that the secondary is in phase with the line. The second transformer has a delta-connected primary and by properly selecting the secondary winding, a secondary in quadrature with the line is obtained.

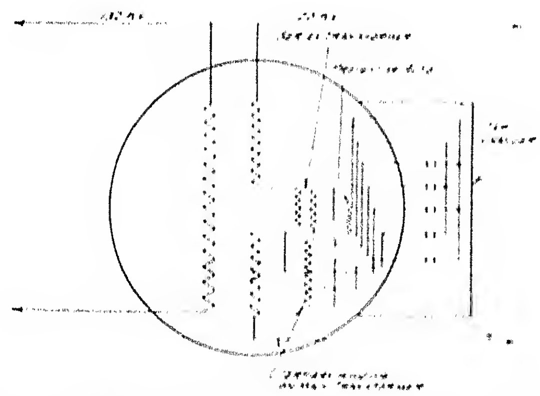

Fig. 12—Schematic Diagram showing Applications of Low-Voltage Tap-Changing Equipment to High-Voltage Transformers

These two windings are placed in series with each other and with the line, and it is therefore possible to impose upon the line an in-phase voltage component of 10 per cent plus or minus and also a quadrature voltage component of 10 per cent plus or minus, each being controlled independently. By a manipulation of the two transformers in effect, it is evident that any degree of in-phase voltage regulation and any degree of phase-angle control within the limit of the apparatus may be obtained.

The losses in the case of the regulator method are approximately double the transformer method.

Multi-Winding Transformer Method

By using a multi-winding transformer, the equipment may be still further simplified. Instead of using two transformers a single three-phase, three-winding transformer may be used. One winding is the exciting winding and the others are connected to give two voltages in series but displaced from each other by 60 deg. This would take the place of the two separate

transformer windings in true quadrature. This arrangement results in a very decided decrease in the size of the transformer tank and also an increase in the over-all efficiency of the transformation, and results in a considerable reduction in cost.

In either of transformer equipments, any of the types of tap changing equipment may obviously be used.

Conclusion

The development of reliable sturdy apparatus for changing transformer voltage ratio under load has opened up a new field with enormous possibilities. While it can be seen that equipment of this nature is not inexpensive, yet it will generally be found that if voltage control of large capacity is desired, the use of transformers arranged for changing taps under load will be found economically desirable.

Discussion

For discussion of this paper see page 599.

Characteristics of Interconnected Power Systems
As Affected by Transformer Ratio Control

BY L. F. BLUME[1]

Associate, A. I. E. E.

Synopsis.—Operating characteristics of interconnected systems in which voltage is maintained constant by varying field of the generators is compared with operating characteristics, when, in addition to the control of generator field, transformers equipped with ratio control are employed. The use of transformers with variable ratio introduces a flexibility in operation which permits the division of wattless currents between generating stations independent of voltage held at the generator busses.

A comparison is made of the use of synchronous condensers for the purpose of improving regulation as compared with the use of transformers equipped with ratio control.

The elementary conditions which govern the current distribution in a loop, L, are determined in terms of impedance characteristics of the net-work. The equipments necessary to control the current distribution and at the same time maintain good regulation in the loop are indicated.

THE steady and rapid growth of the use of variable ratio transformers in connection with interconnected central stations makes it of interest to state the fundamental characteristics of apparatus in systems which make these equipments desirable. In a paper[2] before the Institute two years ago, Mr. Albrecht indicated their field and compared their characteristics with induction regulators and synchronous condensers. The purpose of the present paper is to focus attention on a few of these characteristics in order to indicate how quantitative values may be obtained.

The various kinds of voltage control now being used on power systems are:

1. Voltage control by means of generator field current,
2. Synchronous condensers or phase modifiers by means of which the power factor in transmission lines is improved and thus better regulation obtained,
3. Voltage ratio control, either by means of transformers or induction regulators.

The above methods of voltage control will be considered in connection with specific, typical cases, although in the most practical instances it is admitted that the problem is more complicated than the assumptions of this paper imply. The principles as outlined here, however, are applicable, with proper modifications, to the more complicated ones. The four typical cases to be discussed are:

1. Where two generating systems are connected by means of transmission line and power may flow in either direction,
2. Where two generating systems are connected by means of transmission line but one-way flow of power only is required,
3. A generating system with a synchronous condenser floating on the end of the line,
4. Transmission line loop.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

CASE I: TWO-WAY FLOW OF POWER OVER TRANSMISSION LINE CONNECTING TWO STATIONS

With two central stations connected together by means of an interconnecting transmission line (Fig. 1) the operation of the system involves the control of:

1. The division of energy between the two stations,
2. The division of wattless kilovolt-amperes,
3. The voltage at the two busses.

The controls available are (a) throttle control, (b) field control, (c) voltage ratio control. It is evident that the division of energy between the two stations is not determined by the electrical characteristics but by the characteristics of the prime mover and the throttle control. Field control at the two stations does not affect the energy flow, but determines for each load demand the voltages on the two busses, together with the division of reactive kilovolt-ampere between the stations. But field control cannot independently determine the bus voltages and division of reactive kilovolt-ampere. Either can be controlled, but not both simultaneously; thus the field control may be used to hold the bus voltages equal and constant for all loads, under which condition the division of reactive kilovolt-ampere between the stations is determinable but uncontrollable. Conversely, by means of field adjustments it is possible to control the division of reactive kilovolt-ampere between the stations or what amounts to the same thing, the power factor in the line, but when this is done, voltage control on the two busses is sacrificed. The voltage of one point on the system may be held constant, but the other bus voltage will vary through a range which is equal to the regulation drop between the two busses.

In order to control, independently of each other, the three characteristics, namely, *energy* division, *reactive* kilovolt-ampere division, and *voltage* at both busses, it is necessary to introduce a third independent control. This is readily accomplished by introducing variable voltage ratio between the two busses variable under load.

Thus, by means of the insertion of variable ratio between the two busses, it becomes possible to maintain

both bus voltages constant at all loads, which means that the regulation drop between the two busses is zero, and at the same time, to obtain any desired division of current between the two stations. With the flexibility of operation thus obtained, the bus voltage of the two stations may be maintained constant, and at the same time the division of current between stations may be adjusted so as to obtain either

A. Maximum electrical efficiency,

B. Maximum economy in operation,

C. Maximum utilization of apparatus.

Although all three of the above are desirable aims, it is rarely possible to obtain them simultaneously. For example operating for maximum electrical efficiency is simultaneous with operation for maximum economy only when the cost of energy delivered by station A to the load is equal to the cost of energy delivered by station B to the load. With equal energy cost, the division of current to obtain maximum efficiency depends entirely upon the relative losses in the two branches.

When the cost of energy in branch A and branch B, including the transmission line, differ materially, maximum economy is secured by shifting a portion of the load kilowatts from the station in which the cost of energy is greatest to the other station. This results in a reduction in efficiency but an increase in economy. As the division of reactive kilovolt-ampere for maximum economy is not affected to as great an extent by cost of energy, the currents flowing in the two branches for maximum economy are no longer in phase with the load.

Division of current, to obtain maximum economy in operation, is the desirable operating condition for fractional loads but when the total load demand is equal to, or approaches the full kilovolt-ampere of the system, the rating limitations of the apparatus and line may demand considerable departures from division of currents as determined by the consideration of maximum economy. In order to deliver a maximum

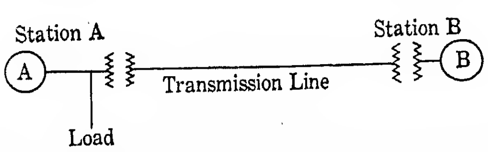

FIG. 1—ELEMENTARY DIAGRAM OF INTERCONNECTED SYSTEMS

output, the division of current must be such as to obtain the maximum utilization of the apparatus.

It is a relatively simple matter to obtain a measure of the extent to which the use of ratio control increases the maximum load which a given system can deliver to a given point without sacrificing constant voltage at the two busses. This may be done by determining quantitatively the limitation which exists when the system is operated in which only throttle and generator field control are employed.

Voltage Relations. We shall assume that the load to be delivered may be concentrated on either bus of the two stations A and B, Fig. 1, and that it is desired to maintain voltages of busses A and B constant and independent of the load demand.

Assuming that the flow of power will sometimes be in one direction and sometimes reversed, the regulation drop in the transmission line and interconnecting transformers should be zero. Therefore, equating

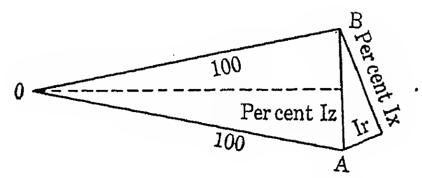

FIG. 2—VOLTAGE RELATIONS IN INTERCONNECTED SYSTEMS
$O\ A$—Equals voltage of bus near load,
$O\ B$—Equals voltage of bus far from load,
θ —Equals phase angle of current in transmission Line

the expression for regulation to zero, we have approximately:

$$(\%\ I\ R) \cos \theta - (\%\ I\ R) \sin \theta = O$$

from which

$$\tan \theta = \frac{\%\ I\ R}{\%\ I\ R} \qquad (1)$$

From this formula it is evident that the maintenance of the two busses at constant voltage at all loads involves the operation of the transmission line at a leading power factor cos θ the value of which is determined from the ratio of resistance and reactance of the line.

A more exact solution can be obtained graphically by plotting the vector diagram of the transmission line voltages, Fig. 2. The premises of the problem make the three voltages an isosceles triangle $O\ A\ B$ in which the impedance drop of the line is the base $A\ B$ and the sides are the bus voltages of the two stations. From this diagram we may write:

$$\sin \alpha = \frac{\%\ I\ Z}{200} \qquad (2)$$

$$\tan (\theta - \alpha) = \frac{\%\ I\ R}{\%\ I\ X} \qquad (3)$$

where

$O\ A$ = Voltage of bus near load,

$O\ B$ = Voltage of bus far from load,

$2\ \alpha$ = Phase angle between voltages $O\ A$ & $O\ B$,

θ = Phase angle of current in transmission line at load end,

$\%\ I\ R$ & $\%\ I\ X$ = Line constants including step-up and step-down transformers.

These equations are plotted in Fig. 4 by means of which it is possible to determine readily the phase

angle θ of current in the interconnecting transmission line when the per cent impedance drop and the ratio of resistance to reactance is known.

Current Relations. The corresponding current relations can be easily derived from the vector diagram, Fig. 3, showing the current relations in terms of the power factor of the load being delivered and the power factor of the transmission line. In this it is assumed that the currents supplied by the two systems to the load are equal,

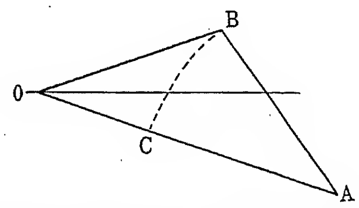

FIG. 3—CURRENT RELATIONS IN INTERCONNECTED SYSTEMS
$O\ B$—Equals current in transmission line,
$B\ A$—Equals current at Station "A",
$O\ A$—Equals load current
Load power factor cos ϕ equals 95 per cent
Angle of lead in transmission line θ equals 20 deg.

under which condition the triangle of current $O\,B\,A$ is isosceles where $O\,A$ is the load current lagging an angle ϕ behind the voltage, $O\,B$ is the current delivered by the transmission line at the angle θ, and $B\,A$ is the current delivered by the local bus. A measure of the effectiveness of the transmission line and distant station in helping out the local station is determined by the ratio $O\,C\,/\,O\,B$, the point C being determined by making $C\,A$ and $B\,A$ equal to each other. This ratio, which may be called the transmission utility

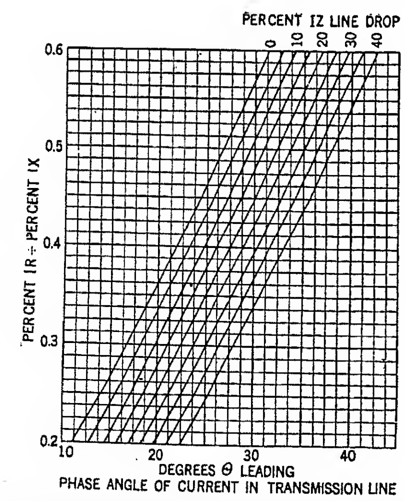

FIG. 4—RELATION BETWEEN TRANSMISSION LINE CHARACTERISTICS AND PHASE ANGLE FOR ZERO-LINE DROP

factor, can be expressed mathematically by the equation derived directly from Fig. 3.

$$T_e = O\,C/O\,B = 2\cos(\theta + \phi) - 1 \qquad (4)$$

This equation is plotted in Fig. 5, from which for various values of phase angles of currents in the transmission line and for various power factors of load, the transmission utility factor can be determined.

By means of Figs. 4 and 5 it is possible to determine the resulting transmission utility factor, when the transmission line constants are known, for any power factor of load. The curves show exactly how much is sacrificed in order to obtain constant potential on the two busses.

Rating of Transmission Line Less than Generating Stations. In the preceding analysis it was assumed

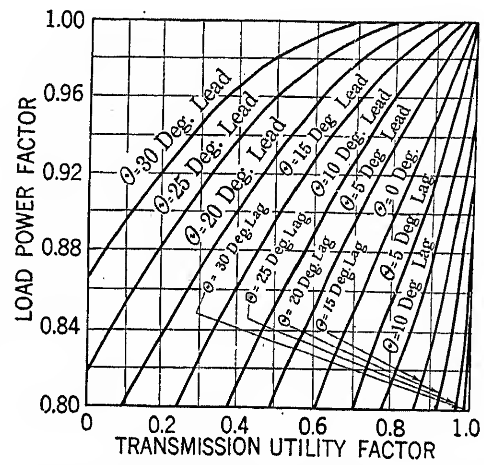

FIG. 5—TRANSMISSION UTILITY FACTOR OF TRANSMISSION SYSTEM AND DISTANT GENERATOR; f = 1.0

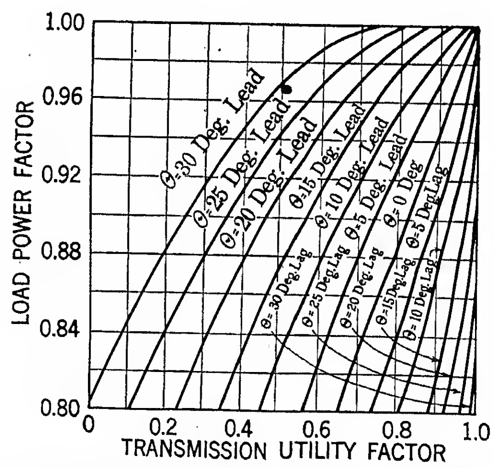

FIG. 6—TRANSMISSION UTILITY FACTOR OF TRANSMISSION SYSTEM AND DISTANT GENERATOR; f = 0.8

that the kilovolt-ampere rating of the transmission line was equal to the kilovolt-ampere rating of the generating stations, and for that reason the current in the transmission line and the current in the local generating station were made equal to each other. It may be, however, that the kilovolt-ampere rating of the transmission line is less than the rating of the stations, and for that reason, it becomes desirable to consider the case in which the division of load between the two stations is unequal. It is desirable, therefore, to have utility factor curves for

various ratios of current in transmission line to current in generator nearest to the load. Let

$$\frac{\text{Current in Transmission Line}}{\text{Current in Generator nearest to Load}} = F$$

The curves, Figs. 5, 6, and 7, correspond to values of $F = 1$, $F = 0.8$ and $F = 0.5$, respectively.

It is of interest to note that in all of these cases, Figs. 5, 6, and 7, that a transmission utility of 100 per cent is obtainable only when the currents in the transmission line and in the generators of both stations are

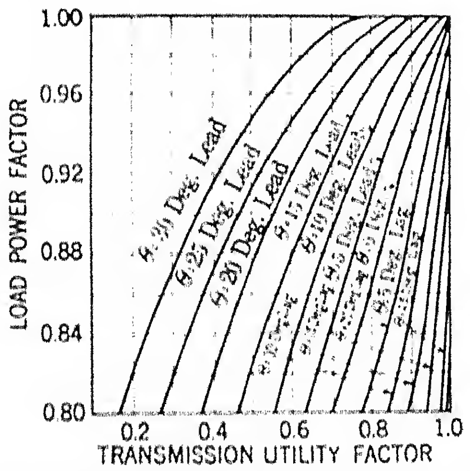

FIG. 7 TRANSMISSION UTILITY FACTOR OF TRANSMISSION SYSTEM AND DISTANT GENERATOR; $f = 0.5$

all in phase with the load current, no matter what the power factor of the load may be, and thus it is evident that the maintenance of constant potential on the two busses cannot be obtained under the conditions assumed without sacrificing the utility factor.

CASE II: ONE-WAY FLOW OF POWER LINE DROP IN INTERCONNECTING LINE MAINTAINED CONSTANT

In case I, a two-way flow of power was assumed; consequently it was necessary to equate the line drop to zero. If the flow of power is in one direction only, it is sufficient that the line drop be maintained constant at all loads. A typical case is to assume 10 per cent line drop. For these assumptions, Fig. 8 has been determined giving the relations between the transmission line constants and phase angle of current in the transmission line. Fig. 8 is to be used in conjunction with transmission economy curves, Figs. 5, 6, and 7.

EXAMPLE FOR CASES I AND II

Transmission utility factors are determined in the following examples, in which constant voltage is maintained at two busses, by field control alone.[3]

3. It should not be inferred that all of the assumed operating conditions in the above examples represent good practise. They are merely cited to show the inherent difficulty of operating with field control alone. In the first example where a transmission factor of 18 per cent is obtained, the power factor in the generator is so poor, about 15 per cent lagging, that it is doubtful whether the generator could deliver its full kilovolt-ampere.

Two stations, A and B, 14 miles apart, interconnected by a 66-kv. transmission line, have a rating of 80,000 kv-a. At this load, the line characteristics including step-up and step-down transformers are:

	Per Cent
Reactance drop	= 32.5
Resistance drop	= 7.5
Impedance drop	= 33.5
r/x	= 0.23
Power factor of load	= 85

To determine the value of using ratio control in connection with the above conditions, it is first necessary to examine the operating conditions or limitations which exist if the two station busses are maintained at constant potential by means of generator field control only, that is, without employing ratio control or other voltage regulating devices. These conditions impose upon the system the necessity of maintaining the current in the transmission line at a definite phase angle, the values of which, as determined from Figs. 4 and 5, are:

For two-way flow of power (Fig. 4) θ = 22-deg. leading
For one-way flow of power (Fig. 8) θ = 4-deg. leading

The values of transmission utility factor for various conditions of operation as determined from Figs. 5, 6, and 7 are given in column 4 of the accompanying table. This value is a measure of the usefulness of the distant station under the conditions assumed. It means that

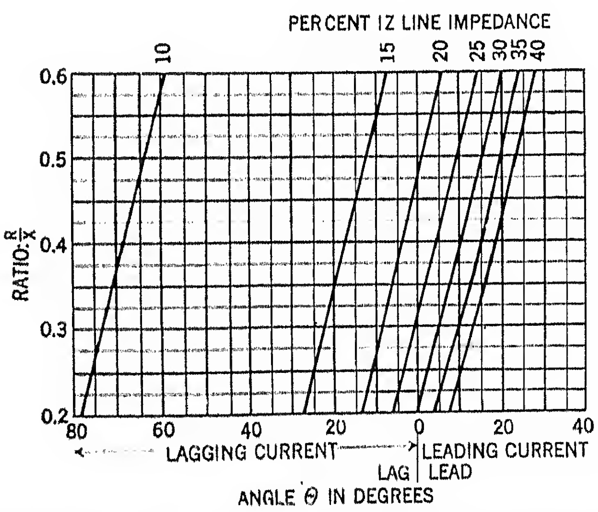

FIG. 8—RELATION BETWEEN TRANSMISSION LINE CHARACTERISTICS AND PHASE ANGLE FOR 10 PER CENT LINE DROP

although in each case the distant generator and transmission line are loaded to the rated kilovolt-ampere of the line, they are effective only to the extent indicated by the percentages given in column 4.

CASE III. COMPARISON OF SYNCHRONOUS CONDENSERS WITH TRANSFORMER RATIO CONTROL EQUIPMENT

Comparison of Ratings. When used for the purpose of enabling the system to hold bus volt-

CASE I: TWO-WAY FLOW OF POWER

Stations A and B Having Equal Ratings, Transmission Line Rating = 80,000 Kv-a.

			Transmission Utility Factor	
	Rating station A and B	Ratio transmission line rating to station ratings	With field control only per cent	With ratio control only per cent
Fig. 5	80,000 kv-a.	1	18	100
Fig. 6	100,000 "	0.8	30	"
Fig. 7	160,000 "	0.5	42	"

CASE II: ONE-WAY FLOW OF POWER

Station B and Transmission Line Rating = 80,000 kv-a.

1	2	3	4	
			Transmission utility factor	
	Rating Station A	Ratio transmission line rating to station ratings	With field control only per cent	With ratio control only per cent
Fig. 5	80,000 kv-a.	1	62	100
Fig. 6	100,000 "	0.8	66	"
Fig. 7	160,000 "	0.5	72	"

ages at both ends of the line constant and independent of load changes, the synchronous condenser must compensate for the regulation of the line and interconnecting transformers. The condenser floating on the end of the line takes an additional wattless load the value of which, expressed in per cent of transmission line rating, is to be determined. The regulation due to the addition of the condenser load must be made equal and opposite to the regulation due to load. Hence

$$\left[\% \, (\text{Kv-a.})_c + \% \, (\text{Kv-a.})_c^1\right] \frac{\% \, I \, X}{100} = \% \, R \qquad (11)$$

where

$\% \, (\text{Kv-a.})_c$ = Rated leading kilovolt-ampere of condenser,

$\% \, (\text{Kv-a.})_c^1$ = Rated lagging kilovolt-ampere of condenser,

$\% \, I \, X$ = Per cent reactance drop of line without condenser,

$\% \, R$ = Per cent regulation of line without condenser,

from which the condenser rating can be determined when the regulation of the line, without condenser, is known.

The rating of load ratio control equipment for the same duty is:

$$\% \, (\text{Kv-a.})_{RC} = \frac{\% \, R}{2} \qquad (12)$$

Combining equations (11) and (12)

$$1/2 \left[\% \, (\text{Kv-a.})_c + \% \, (\text{Kv-a.})_c^1\right] \frac{\% \, I \, X}{100} = \% \, (\text{Kv-a.})_{RC} \qquad (13)$$

which means that line reactance determines the relative size of condenser and ratio control apparatus for the same performance.

In equations (12) and (13) the fraction ½ is inserted assuming that the ratio control equipment has equal plus and minus ranges. This is generally, but not always, the case.

These equations determine the sum of the leading and lagging ratings of the condenser. They also show that as far as voltage control is concerned, it is immaterial how much of the sum is lagging and how much is leading.

Assuming that the first cost per kilovolt-ampere of ratio control equipment is appreciably less than the cost per kilovolt-ampere of synchronous condenser, it becomes evident from equation (13) that the first cost of ratio control equipment is inherently much less than the synchronous condenser.

Increased Output of System Due to Condenser. The costs of the *two* equipments are not directly comparable owing to the fact that the use of the condenser increases

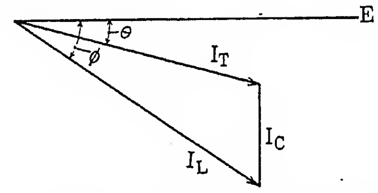

FIG. 9—CURRENT DIAGRAM SHOWING EFFECT OF SYNCHRONOUS CONDENSER ON TRANSMISSION LINE CURRENTS

the output of the system. The amount can be determined from Fig. 9. As the maximum load is increased by the condenser current, the energy remaining constant, we can write:

$$(\text{Kv-a.})_L \cos \phi = (\text{Kv-a.})_T \cos \theta$$

or

$$(\text{Kv-a.})_L = (\text{Kv-a.})_T \frac{\cos \theta}{\cos \phi} \qquad (14)$$

where

$(\text{Kv-a.})_T$ = rating of generating plant,

$(\text{Kv-a.})_L$ = Kv-a. delivered to load,

which means that the ratio of the power factor of the load to the power factor of the line determines the increase in kilovolt-ampere of system on account of the condenser.

Perhaps the best way of obtaining an equable cost comparison between the use of a condenser and ratio control equipment is to determine the extra cost involved when ratio control is used to increase the system kilovolt-ampere by the ratio $\cos \theta / \cos \phi$. Ordinarily this merely involves providing the generators and interconnecting transformers with a correspondingly greater current carrying capacity. The increase in current in the overhead transmission line does not necessarily involve an increase in copper since the only

practical effect of the increased current is greater line losses and increased regulation drop. An exception to this should be noted in the case of underground cables where the consideration of operating temperatures may make it undesirable to increase the maximum current. In this case the saving in cable equipment secured by employing the synchronous condensers may more than off-set its greater first cost.

Saving in Line Losses Obtained by Means of Synchronous Condenser. Consideration must also be given to the fact that the synchronous condenser, by improving the power factor of the line currents, decreases the copper losses in the line. The ratio of line copper losses with and without using the condenser is given by the expression:

$$\text{Loss ratio} = \left(\frac{\cos\phi}{\cos\theta}\right)^2 \qquad \textbf{(15)}$$

Improving, by condenser, the power factor from 80 per cent to 95 per cent, for example, reduces the line loss 25 per cent. Where poor power factor of load is combined with inherently large line losses, the saving in losses at full load due to the use of condensers is considerable.

The actual saving in loss, however, is less than may

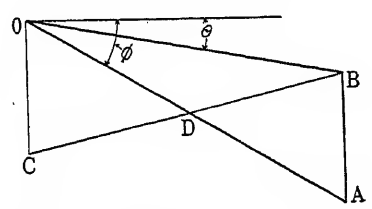

Fig. 10—Current Diagram for Fractional Loads showing Effect of Synchronous Condenser with Maximum Lagging Current Equal to Maximum Leading Current

be inferred from the above, on account of the fact that under usual operating conditions the load factor is considerably less than unity. At fractional loads, the saving in losses resulting from the condenser is very much reduced, and at light loads, when the condenser is operating lagging, the line losses are actually increased by the condenser. It is reasonable to expect, therefore, that under normal conditions of load, the actual net saving in line losses is much less than the value obtained for full load conditions.

From this it appears that the saving in line losses is very much affected by (a) the load factor and (b) the ratio of leading and lagging rating of the synchronous condenser.

Losses in Condenser vs. Losses in Ratio Control Apparatus. Furthermore, the net line losses saved by condenser are off-set partially by the fact that the transformer ratio control apparatus is inherently considerably more efficient than synchronous condensers, for several reasons:

1. On account of the smaller kilovolt-ampere rating of transformers,

2. On account of the inherently higher efficiency of transformers,

3. On account of the fact that in transformer ratio control, both the core and copper losses may be variable. The core loss varies from maximum to minimum when voltage ratio is shifted from maximum value to unity and the copper losses vary from maximum to minimum with changes in load.

To form a correct comparison between the two equipments, the actual values of the various losses just cited must be carefully estimated and capitalized.

Example Illustrating Case III

Assuming the following conditions:

	Per Cent
Line reactance drop	29
Line resistance drop	7
Power factor of load	86

it is desired to compare the use of ratio control equipment with a synchronous condenser when used to maintain voltage at both ends of line constant. Under these conditions the line regulation without the condenser is 22.7 per cent. By equation **(12)** the rating of ratio control equipment necessary to maintain voltage constant is 11.3 per cent of the kilovolt-ampere of the load.

By equation **(13)** the rating of the condenser is per cent $(\text{kv-a.})_c$ + per cent $(\text{kv-a.})_c{}^1$ = 70 per cent

The synchronous condenser performance depends upon the ratio of the leading and lagging rating of the condenser. Assuming equal leading and lagging ratings, in other words, per cent $(\text{kv-a.})_c$ = per cent $(\text{kv-a.})_c{}^1$ = 35 per cent, current relations are obtained as shown in Fig. 10. At full load the addition of the condenser brings the line power factor up to 99 per cent. The ratio of line power factor to load power factor is 1.14, which means that the system rating has been increased by 14 per cent, equation **(14)**. The full load line losses by equation **(15)** are 77 per cent of what they would be without the condenser. The triangle $O\,B\,D$ in Fig. 10 gives the current relations for full load; $O\,C$ is the condenser current at no load; and the line $C\,D\,B$ is the locus of the line current as the load increases from no-load to full load. At the intersect D corresponding to half load for Fig. 10, the condenser is not contributing. For less than half load the condenser is increasing the line losses, and for loads greater than half load the line losses are decreased by the condenser.

The current diagram, Fig. 11, corresponds to the assumption that the leading rating of the condenser is 46.5 per cent and the lagging rating is 23.5 per cent. The chief difference between Figs. 10 and 11 is the position of the intersect D, which now occurs at 33 per cent load. It is evident that operation, in accordance with the assumption upon which Fig. 11 is based, means a greater saving in line losses for a given load factor

than operation in accordance with conditions assumed for Fig. 10.

CASE IV. TRANSMISSION LINE LOOP

Under cases I and II it was shown that by the help of one voltage control equipment constant voltage can be maintained at two points and at the same time any desired current relation obtained. The principle can be extended to any number of stations operating on a line so that with N stations and $N - 1$ voltage control equipments it is possible to maintain the bus voltage constant at N stations and at the same time secure any desired division of current in each portion of the line.

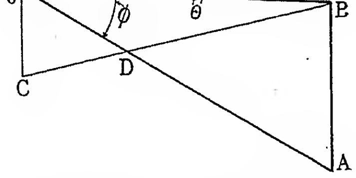

FIG. 11—CURRENT DIAGRAM FOR FRACTIONAL LOAD, SHOWING THE EFFECT OF SYNCHRONOUS CONDENSER WITH MAXIMUM LAGGING CURRENT 50 PER CENT OF MAXIMUM LEADING CURRENT

At each station voltage control may be inserted between high and low voltage of the power transformers as shown in Fig. 12, or the variable voltage may be inserted in series with the line as shown in Fig. 13. In the former case the over-all regulation of the line is unaffected, whereas in the latter case the variable voltage being inserted in the line itself, not only the station bus voltage but also the line voltage, is affected.

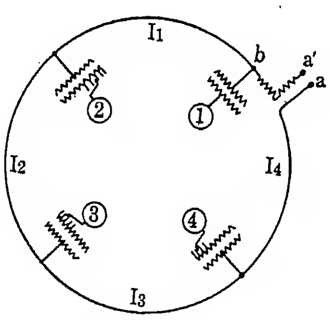

FIG. 12—TRANSMISSION LINE LOOP PROVIDED WITH IN-PHASE AND QUADRATURE VOLTAGE CONTROL

When the two ends of the lines a and b, in either Fig. 12 or 13, are connected together forming a loop, it is desirable to know whether complete current flexibility is still obtainable. It is evident for example, that if the currents in the four portions of the line, in Figs. 12 and 13, are to be independently variable, a variable voltage exists between a and b which is the resultant of the impedance drops in the four lines. This voltage (e) varies in value and in phase from time to time depending upon how much the currents are changing in the line. We may write for the voltage between a and b for Fig. 12

$$e = I_1 Z_1 + I_2 Z_2 + I_3 Z_3 + I_4 Z_4$$

where

$I_1\, I_2\, I_3\, I_4$ are the currents desired in the lines;

$Z_1\, Z_2\, Z_3\, Z_4$ are the corresponding line impedances.

For Fig. 13 the expression becomes:

$$e = I_1 Z_1 + I_2 Z_2 + I_3 Z_3 + I_4 Z_4 - e_2 - e_3 - e_4$$

where

e_2, e_3, e_4 are the control voltages inserted in the line at stations 2, 3, and 4.

If the loop is formed by connecting a and b without inserting any control equipment, the voltage (e), as given in the above equations, is short-circuited and a circulating current flows throughout the loop, the value of which is given by the expression,

$$I_c = e/(Z_1 + Z_2 + Z_3 + Z_4)$$

The line currents have now become

$$I_1 + I_c$$
$$I_2 + I_c$$
$$I_3 + I_c$$
$$I_4 + I_c$$

It is evident that the desired currents, I_1, I_2, I_3, I_4, can

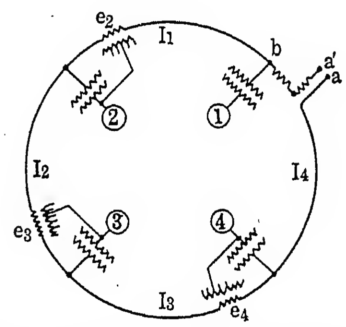

FIG. 13—TRANSMISSION LINE LOOP PROVIDED WITH IN-PHASE AND QUADRATURE VOLTAGE CONTROL

be obtained only in the remote coincidence that these currents happen to be of such values as to make the resultant voltage (e) zero. The alternative is to introduce into the line a voltage which is always equal and opposite to (e). Therefore, if the ends a and b are to be connected without interfering with current flexibility, it is necessary to bridge the points a and b with a voltage which is equal to, and in phase with, the vector sum of the impedance drops in the lines.

The insertion of such a low impedance voltage bridge between points a and b in which the voltage and also the phase angle are independently controllable can be accomplished by two ratio control equipments, one providing the proper in-phase voltage and the other providing the proper quadrature voltage. (See note following.)

In general, a transmission line loop in which a maximum current flexibility is desired together with N points

maintained at constant potential, requires N voltage ratio controls and one quadrature control.

Although two independent controls, consisting of an in-phase and a quadrature control, are necessary to obtain complete flexibility, nevertheless, under particular conditions of load variation, one ratio control equipment is sufficient for loop control.[4]

For example, when the currents I_1, I_2, I_3, I_4 vary during the load cycle in such a manner that the resultant voltage (e) changes in value but not in phase, it is then only necessary to determine the phase angle of (e) with reference to the line voltage, and to design loop control equipment having this angle.

Loop control may be needed to prevent excessive current flowing in portions of circuit as, for example, when underground cables are used having a limited current rating, or it may be desired in order to be able at all loads to obtain a minimum of energy loss in the loop. In the latter case the exact setting of the control equipment can be calculated readily.

Current Distribution with Reference to Obtaining Minimum Energy Losses in Loop. At the end of this paper, equations are developed which give the condition for current distribution so as to obtain minimum energy losses in the loop. These equations show that the criterion for minimum losses is the condition that the vector sum of the resistance voltage drops around the loop should be zero. This criterion can always be met by means of two control equipments if they are so adjusted as to allow a circulating current to flow through the loop in accordance with

$$R I_c + \Sigma r I = 0$$

where

I_c is the circulating current,

R is the total resistance of the loop,

$\Sigma r I$ is the vector sum of the resistance drops (not including the drop due to circulating current).

To obtain this current distribution, the control equipments must introduce the following voltages into the line: An in-phase voltage equal to

$$e = j_1 x_1 + j_2 x_2 + j_3 x_3 + \text{etc.}$$

and a quadrature voltage equal to

$$j e = i_1 x_1 + i_2 x_2 + i_3 x_3 + \text{etc.}$$

An important particular case is when the ratio of resistance to reactance in each portion of the line is equal; that is, when

$$\frac{x_1}{r_1} = \frac{x_2}{r_2} = \frac{x_3}{r_3} = \frac{X}{R}$$

where R and X are the total resistance and reactance of the loop. Then

$$x_1 = \frac{r_1}{R} X \quad x_2 = \frac{r_2}{R} X \quad x_3 = \frac{r_3}{R} X$$

When these values are substituted in the equations for e and $j\,e$, they reduce to the following simple form:

$$j\,e = \sum r\,i \frac{X}{R}$$

$$e = \sum j\,r \frac{X}{R}$$

But by the conditions of the problem $\Sigma i\,r = 0$ and $\Sigma j\,r = 0$. It therefore follows that both e and $j\,e$ are zero. The important conclusion follows that when the ratios of resistance to reactance in each portion of the loop are all equal to each other, the currents distribute in the loop so as to obtain minimum copper loss, when the loop is closed without voltage inserted. Loop control equipment is therefore necessary only by virtue of the fact that the various portions of line have different ratios of resistance to reactance.

Acknowledgment is hereby made to Raymond Bailey, P. J. Walton, W. W. Lewis, H. O. Woods and M. B. Mallett for their assistance in the preparation of this paper.

An appendix with equations to find the current distribution in a loop with reference to obtaining minimum energy losses in a loop is included in the complete paper.

Appendix

To find the current distribution in a loop with reference to obtaining minimum energy losses in loop. Copper losses in loop for any current distribution such as shown in Fig. 12 can be written

$$L = r_1 i_1^2 + r_2 i_2^2 + r_3 i_3^2 + \text{etc.}$$
$$+ r_1 j_1^2 + r_2 j_2^2 + r_3 j_3^2 + \text{etc.}$$

With a circulating current $i_c + j_c$, the copper losses become

$$L = r_1 (i_1 + i_c)^2 + r_2 (i_2 + i_c)^2 + r_3 (i_3 + i_c)^2 + \text{etc.}$$
$$+ r_1 (j_1 + j_c)^2 + r_2 (j_2 + j_c)^2 + r_3 (j_3 + j_c)^2 + \text{etc.}$$

Expanding:

$$L = r_1 i_1^2 + r_2 i_2^2 + r_3 i_3^2 + \text{etc.}$$
$$+ R i_c^2 + 2(r_1 i_1 + r_2 i_2 + r_3 i_3 + \text{etc.})\, i_c$$
$$+ r_1 j_1^2 + r_2 j_2^2 + r_3 j_3^2 + \text{etc.}$$
$$+ R j_c^2 + 2\,(r_1 j_1 + r_2 j_2 + r_3 j_3 + \text{etc.})\, i_c$$

where $R \doteq$ total resistance of loop.

4. Loop control can also be obtained by means of two polyphase inductive regulators, the series windings being mounted in the line and connected in series with each other. Each regulator inserts in the line a constant voltage with phase angle variable from zero to 360 deg. By adjusting their phase angles, the combined voltage introduced into the line can be made any desired value and any angle.

To find circulating current for minimum loss:

$$\frac{d\,L}{d\,i_c} = 2\,R\,i_c + 2(r_1\,i_1 + r_2\,i_2 + r_3\,i_3 + \text{etc.}) = 0$$

$$\frac{d\,L}{d\,j_c} = 2\,R\,j_c + 2\,(r_1 j_1 + r_2 j_2 + r_3 j_3 + \text{etc.}) = 0$$

Therefore

$$i_c = -\frac{r_1\,i_1 + r_2\,i_2 + r_3\,i_3 + \text{etc.}}{R}$$

$$j_c = -\frac{r_1 j_1 + r_2 j_2 + r_3 j_3 + \text{etc.}}{R}$$

are the in-phase and quadrature components of circulating current which, added to currents $i_1 + j_1$, $i_2 + j_2$, $i_3 + j_3$, etc., result in a minimum loop loss. These equations may be written:

$$i_c = -\frac{\Sigma\,r\,i}{R} \tag{1}$$

$$j_c = -\frac{\Sigma\,r\,j}{R} \tag{2}$$

These equations mean that minimum losses are obtained in a loop when a circulating current is allowed to flow equal to the vector sum of the resistance drops due to the original currents, divided by the total resistance of the loop.

These equations may also be written:

$$R\,i_c + \Sigma\,r\,i = 0 \tag{3}$$

$$R\,j_c + \Sigma\,r\,j = 0 \tag{4}$$

or

$$\Sigma\,r\,(i + i_c) = 0 \tag{5}$$

$$\Sigma\,r\,(j + j_c) = 0 \tag{6}$$

From the last equation it is evident that the condition for minimum loss in a loop is a current distribution in which the vector sum of the resistance drop is zero. It is evident from these equations that in a d-c. loop or in an inductance less a-c. loop, the currents naturally divide so as to give the minimum copper loss.

In a loop with inductance, it is necessary to determine the summation of inductance drops under the conditions of minimum loss as given by equations (5) and (6). The summation of reactance volts when circulating current i_c flows is for the in-phase currents:

$$j\,e = (i_1 + i_c)\,X_1 + (i_2 + i_c)\,X_2 + (i_3 + i_c)\,X_3 + \text{etc.}$$

and for the quadrature currents

$$e = (j_1 + j_c)\,X_1 + (j_2 + j_c)\,X_2 + (j_3 + j_c)\,X_3 + \text{etc.}$$

Substituting equations (1) and (2)

$$j\,e = \left(i_1 - \frac{\Sigma\,i\,r}{R}\right)X_1 + \left(i_2 - \frac{\Sigma\,i\,r}{R}\right)X_2 + \left(i_3 - \frac{\Sigma\,i\,r}{R}\right)X_3 + \text{etc.} \tag{7}$$

$$e = \left(j_1 - \frac{\Sigma\,j\,r}{R}\right)X_1 + \left(j_2 - \frac{\Sigma\,j\,r}{R}\right)X_2 + \left(j_3 - \frac{\Sigma\,j\,r}{R}\right)X_3 + \text{etc.} \tag{8}$$

which gives the resultant or unneutralized voltage $(e + j\,e)$. In order to maintain this distribution of current, a voltage equal and opposite to $e + j\,e$ must be inserted in the loop.

In the particular case when

$$\frac{x_1}{r_1} = \frac{x_2}{r_2} = \frac{x_3}{r_3} = \frac{X}{R}$$

where

X = total inductance of loop,

R = total resistance of loop,

then

$$x_1 = \frac{r_1}{R}X$$

$$x_2 = \frac{r_2}{R}X$$

$$x_3 = \frac{r_3}{R}X \text{ etc.}$$

Substituting the above in equations (7) and (8), both e and $j\,e$ reduce to zero from which the important conclusion follows that if ratio inductance to resistance in all portions of the loop is equal, current distribution for minimum loss naturally occurs and therefore loop control is unnecessary.

Discussion

CHANGING TAPS ON TRANSFORMERS UNDER LOAD

(HILL)

CHARACTERISTICS OF INTERCONNECTED POWER SYSTEMS AS AFFECTED BY TRANSFORMER RATIO CONTROL

(BLUME)

E. F. Gehrkens: The subject of voltage control is an exceedingly important one and it was so recognized as far back as 1882, at which time an automatic generator voltage regulator for d-c. machines was developed.

When the a-c. system was introduced and large generating units were built, two types of *feeder* voltage regulators were developed,—the switch or step type and the induction type.

Each design has its advantages and disadvantages, and in order to eliminate the disadvantages so far as possible, as long ago as 1898, a combination of the two was designed and built for the control of electric furnaces.[3]

This combination is justified only in case large regulating units are required, and the delay in the development in this design was due partly to the lack of sufficient demand to warrant the expense and to difficulties of design; for although the theory and connection diagram are simple, the mechanical design is extremely difficult. Previous to 1898 induction regulators having capacities of 700 kw. were also built for the same purpose and while the latter was the more simple in design and operation, the former was less expensive and more efficient with a better power factor.

For lighting systems requiring relatively small regulators, the induction type is the recognized standard because of its simplicity and low cost, but for power and interconnecting lines requiring large regulators, the selection of the regulator depends upon the requirements and the cost. In design, the induction type is limited to approximately 13,000 volts, and for use on higher-voltage systems it requires an exciting and a series insulating transformer. This increases the cost and the losses. The switch type can be built for use in much higher voltage circuits and therefore has the advantage.

In the combination of the switch and induction types, the switch element may be used in a high-voltage circuit, but the induction element requires the insulating transformers or transformer windings. The choice between the switch and the combination type of regulator depends again upon the requirements. On long single lines, or even on long multiple interconnections, it would seem that the switch type should be satisfactory because of the high resistance and reactance of such lines, but for short lines or a combination of short and long lines, a more uniform voltage change may be required. In case the regulators are operated by hand or motor, a finer adjustment can be obtained by the combination type, but in case this type is operated automatically, about as close a regulation as can be obtained is one per cent either way from normal; that is, the combination type of regulator corresponds to the switch type having one per cent steps, and on this basis the deciding factor is probably the price.

The switch or step type is certainly the simpler in construction and has a higher efficiency and should therefore be used wherever conditions warrant.

Mention was made of the desirability of in-phase and out-of-phase control for parallel connecting lines. The results obtainable by the use of two polyphase induction regulators were fully illustrated and described in the London *Electrician* of Nov. 6, 1914, but the system has not been generally adopted by operating companies because of the cost and the difficulty of making this arrangement automatic. However, as the multiplying of lines increases and the necessity of controlling both the wattless and the power current in such lines is recognized, this arrangement will undoubtedly be more generally used.

F. F. Brand: Mr. Hill has outlined very well in his paper the different methods in use for changing transformer taps under load, and he has brought out the difference between the two principal schemes—the one of using parallel circuits, and the other of using the preventive reactance or auto-transformer.

I am inclined to take issue with him on the application of two different schemes, as I would consider that the scheme of using the preventive auto-transformer to derive mid-voltage between taps is more applicable to small transformers, and the other scheme of using parallel circuits is better adapted to large transformers.

For a 20,000-kv-a. transformer with taps 5 per cent apart, and with a preventive reactance used to derive the mid-point, the nominal size of the reactor is approximately 1000 kv-a., and the losses in the reactor would be of the order of 10 to 20 kilowatts. Furthermore, on this scheme in those positions in which the preventive auto-transformer is used to derive the mid-voltage, there exists a circulating current which is constant irrespective of load conditions, and the losses in the reactor and that portion of the winding through which the circulating current flows must be considered a part of the light-load transformer loss.

Also the use of the preventive auto-transformer to derive the mid-point does not give equal voltage steps, and a difference in the voltage derived from the true mid-point is greater the lower the power factor. For instance, at 80 per cent power factor and full load, the voltage actually derived is of the order of 1¾ per cent from one tap and 3¼ per cent from the other tap instead of 2½ per cent from each.

Better conditions of obtaining the true voltage required are obtained if the circulating current is increased, but this obviously increases the losses in the tap portion of the transformer, the size of the tap portion, and the size and losses of the auto-transformer.

It is quite true that the preventive auto-transformer scheme enables a slightly simpler winding to be used than parallel circuits, although it should be understood that it is not necessary in the parallel-circuit scheme to provide two complete parallel paths throughout the total winding. It is necessary to parallel only a portion of the winding to obtain sufficient reactance between these portions to limit the circulating current to a reasonable value in the transfer position. In fact, modern practise is to use a single-circuit winding including the tap portion and a parallel-circuit portion sufficient to obtain necessary reactance between these parallel portions. There are, therefore, only nine taps on a winding designed to give nine voltages, each tap being carried through two ratio adjusters respectively connected in circuit with the parallel portions.

When it is considered that in order to obtain the necessary reactance control, paralleling portions of the winding is undesirable, the preventive reactance, or auto-transformer, connected externally to the transformer winding, may be used. Ratio adjusters are used to select the taps, and the normal operating position is with both ratio adjusters on one tap. The current then divides in the halves of the preventive reactance, and the ampere-turns neutralize one another; therefore, the voltage drop is practically negligible. This scheme cuts the size of the preventive reactor to half that of when the reactor is used to derive the mid-voltage between taps. The losses are therefore less, and circulating current exists only at the time of transfer.

The question of whether or not it is desirable to reduce the number of operations depends principally upon the reliability of the apparatus to accomplish the tap changing. To my mind, the elimination of circulating-current losses at periods of light load, and the fact that one obtains an exactly equal division in voltages by the plan when the normal operating position is always at both ratio adjusters on one tap, far outweighs the slightly more complicated operating mechanism.

Referring to Mr. Blume's paper—it seems to me there is a good

3. See *Electrical World*, Janua;y 7, 1899.

opportunity for the combination of load-ratio control transformers and synchronous condensers on transmission-line work. As he has pointed out, there are certain advantages in each type of control. The synchronous condenser has the advantage of controlling power factor, and therefore the possibility of reducing the losses. If used in combination with variable-ratio transformers, it is quite possible to reduce the losses under certain operating conditions; for instance, on the light-load condition, a synchronous condenser, if used to control the voltage draws lagging current, increases the line current and line losses, and the losses in the condenser of course increase as the current increases. When using a variable-ratio transformer, it should be quite possible to do away with lagging requirements of a condenser, except, perhaps, when it is necessary to hold down voltage on a long, lightly loaded, high-voltage line, when the voltage increases due to capacity charging current.

With a variable-ratio transformer it is possible to reduce leading kv-a. requirements of the condenser. That is, in the case of lines of very poor regulation it is not necessary to raise the power factor to unity or to leading in order to maintain proper voltage regulation. The combination of these two, that is condenser and variable-ratio transformer, may easily result in both cheaper equipment and very much lower losses over the average operating conditions.

H. O. Stephens: At first thought, one would be inclined to question why so many different methods of changing transformer voltage under load are used and if it would not be better and more economical in the long run to standardize upon one method? This is a perfectly logical question, but the very nature of the object to be accomplished makes it difficult to standardize upon one scheme that would be universally applicable. The variations in voltage and current are so great that one type of circuit-interrupting device can hardly be used throughout the range and if the voltage as well as the current to be interrupted is high, it is desirable to keep the number of circuit-interrupting devices as small as possible for the sake of economy and size.

Additional complications, such as auto-transformer connections, tertiary windings, etc., that may be introduced into the transformer, demand that the designer be given considerable latitude in his choice of equipment. However, it is very desirable to standardize upon as few methods as possible and considerable help in this direction can be given by the users of the apparatus by slightly modifying their requirements to meet the exigencies of design.

There is a tendency among certain operators to demand extremely small voltage steps on transformers equipped with load-ratio control which I believe, in most cases, is not justified. Even when automatic operation is specified, taps in steps less than $2\frac{1}{2}$ per cent can hardly be considered necessary. It should be remembered that with $2\frac{1}{2}$ per cent taps, the voltage can be adjusted to within $1\frac{1}{4}$ per cent of the desired value.

An induction regulator, which is generally considered to be a very satisfactory voltage-regulating device, requires at least a plus or minus variation of 1 per cent from the desired voltage for the contact-making voltmeters to function, and usually this difference is $1\frac{1}{2}$ to 2 per cent, so that the transformer with $2\frac{1}{2}$ per cent taps can be operated to give virtually as good regulation of voltage as an induction regulator. For this reason I believe the extreme refinement supposedly accomplished by the use of the so-called "step induction regulator" with a transformer with taps is an unnecessary refinement. When desired, a very small percentage in tap variation can readily be accomplished by the multiple winding scheme of transformer operation.

W. M. Dann: I think Mr. Stephens has hit the nail very squarely on the head when he talks about standardization of tap-changing-under-load equipment. Of course, this field of tap-changing under load is really in its infancy in spite of the pioneer equipments that have been in use for several years. The trend in the design has been very much toward simplification and standardization. I am very much in sympathy with Mr. Stephens' remarks about the demands of the industry itself. If we can get the operators to simplify some of those demands and make use of equipment that has already been designed and installed, it will help very materially towards that ideal of standardization.

K. A. Oplinger: It is unfortunate that no standard terminology exists upon the general subject of changing taps on transformers under load. Equipment for this purpose is usually called a tap changer but at other times the term "ratio adjustor" is used. The N. E. L. A. has started to collect data on equipment for controlling the voltage ratio of transformers under load and already a number of reports has been published covering these data. Although this equipment has developed very rapidly during the past two years, it is now fairly well standardized and a uniform terminology would be very desirable.

For example, the single-winding method, as described in the reports mentioned above, appears under the title of "multiple-switch method." This method has also been called the "preventive-auto-transformer method" because a preventive auto-transformer or protective reactance is switched along the transformer taps. This method was one of the first employed to change transformer taps under load.

The term "single-winding method" appears to be most appropriate for this particular scheme as it is comparable with the term "double-circuit method" which requires double windings on the transformer.

With reference to the automatic control of tap changers, an interesting application is under consideration at the present time in which the tap changer will automatically control the flow of wattless kv-a. between two generating stations in inverse proportion to the load on the two stations. A transformer with equipment for changing taps under load is to be used as a tie-in between the two stations and as the load on one station is increased the tap changer will automatically operate to transfer the wattless kv-a. to the other station. This same control might also be arranged to regulate the wattless kv-a. in direct proportion to the load of the two stations.

Other methods of automatic control may be arranged to have the tap changer limit the exchange of wattless kv-a. between stations or to have the tap changer responsive to changes in power factor.

J. S. Lennox: Mr. Hill brought out one point that I think is a very good one, and that is that with the parallel-winding method, the transformer must be protected against an accidental stoppage of the mechanism leaving a load on one-half of the winding. It is for that reason, I think, that the parallel circuit method has developed into what Mr. Hill calls a single-winding method, but distinguished from the arrangement that Mr. Hill has described in his paper by the fact that the circuits are broken in a separate device from the one that changes the tap connections, and by so doing, it is possible to place inside the transformer adjacent to the windings, a tap device of such simple and sturdy design that it involves no maintenance problem, and permits the use of small steps. Therefore, there is low deterioration of the contacts in the contact-making device placed outside the transformer tank and easily accessible for renewal of contacts.

L. H. Hill: Mr. Brand made a comparison of the two methods employed, the single-winding method and parallel-winding method, and he mentioned the increase in loss by the use of the preventive auto-transformer. It is obviously true that additional loss will be introduced by the introduction of additional apparatus. However, with the parallel winding method, additional loss is also introduced in a more indirect manner. Reactance is required to effect the tap change regardless of the method used, so that if the parallel winding method is used the windings must be so arranged and so interlaced that sufficient reactance will be obtained between them to limit the current to a reasonable value during the transition period. That

ordinarily means making the core of the main transformer larger and naturally introduces additional loss, although as a general thing it is true that it is not as large as would be obtained by means of the preventive auto-transformer.

He also mentioned that in the single-winding method using the simplified preventive auto-transformer, unequal steps were obtained. Naturally, when the equipment is operating with one-half of the preventive auto-transformer in series with the line, it acts as a small series reactor. Since the drop is almost entirely reactive it is subtracted from the theoretical tap voltage at right angles, which at the higher power factors does not cause any appreciable unequality in tap voltages. The difference in reactance obtained on the two different operating positions of the preventive auto-transformer must be taken into account, however, under certain conditions of paralleling.

For example, assume a transformer with four per cent impedance, and with a two-one-half per cent tap, or five per cent in voltage across the whole winding of the preventive auto-transformer. The impedance volts at full load through one-half the auto-transformer in series with the line would be about one per cent or an increase in reactance from four to five per cent on alternate taps, which would not give good paralleling conditions with a transformer which did not use the preventive auto-transformer. However, with a transformer with eight per cent impedance, the change from eight to nine per cent impedance would be proportionally less, and can be compensated for by making the impedance of the main transformer winding midway between the two values, giving good paralleling conditions.

In cases where very close paralleling is required or even assuming conditions where the transformers are to be operated at very low power factor, when the impedance drops and unequality of steps might be of some importance, it becomes a simple matter to use the short-circuiting switch shown in Fig. 3 of my paper. In that case, the series impedance drop is eliminated entirely.

These things are merely a matter of detail design, and we feel the same as Mr. Lennox, that the two methods, single- or parallel-winding, could be changed from one to the other at will. The point is that the method using a preventive auto-transformer is fundamentally a single-winding method as distinguished from a parallel-winding method. A number of variations of the single-winding method is possible. For conditions of ordinary design, the range in taps to be obtained is generally not more than 20 or possibly 25 per cent in steps which ordinarily would not require more than 6 circuit breakers.

If it is desired to cover a very wide range, for example, 100 per cent range by this method, it is true it would not be desirable to add 5 or 6 more switches, as it would make a large and expensive mechanism. In this case, the switches in each tap lead may be contactors or some sort of ratio adjustors with auxiliary circuit breakers in the two end connections to the preventive auto-transformer to open and close the circuits. Even with this type of equipment the few taps required by the single-winding method make it possible to place all switches outside of the main tank, so that all moving parts are external to the main case.

In all the equipment which we have built with the exception of the early installation using the parallel-winding method, all switches were outside of the tank, and our policy in now building the single-winding method exclusively is based on experience with both types. We have built these 20,000-kv-a. single-phase units, which are large units, with the parallel-winding method, and we have built units up to 25,000 kv-a. with a single-winding method, and we are now building some 33,000 kv-a. single-phase units using the single-winding method.

A comparison of the parallel-winding method and single-winding method when used to obtain a typical range of eight, two one-half per cent taps may be of interest.

With the single-winding method five taps and five switches are required. With the parallel-winding method, nine taps are required in each winding or a total of 18, making almost four times as many taps and switches.

The measure of the inherent reliability of equipment for a certain performance is based on the amount of apparatus and moving parts required and the amount of operations of that equipment, and the amount of circuit interruptions of that equipment are a measure of the maintenance required and performance to be expected over a long period of time. To change taps by means of the parallel-winding method there are required at least six switch operations, whereas but one is required with the single-winding method, or in case the short-circuiting switch is used, there are but two.

In the case of the parallel-winding method there are two circuit interruptions per tap change. In the case of the single-winding method a circuit is closed instead of opened on every alternate tap change giving the equivalent of one-half a circuit interruption per tap change over the whole range.

With the parallel-winding method, it is not commercially practical to build each of the windings capable of carrying the whole load current continuously. Each winding is overloaded during the tap-changing operation and a protective system is needed to protect the windings in case of accidental stoppage of the equipment during a tap-changing operation. With the single-winding method no winding is overloaded during the tap-changing operation.

The few taps and switches needed with the single-winding method permit mounting all moving parts outside of the main tank, which is desirable from the standpoints of maintenance, operation, and safety.

The equipment developed for use with the single-winding method is very simple. Proper sequence of all switch operations is assured by positive mechanical drive using simple gears and linkages.

In the parallel-winding method, there is a great amount of mechanism needed inside the tank which must be connected to the operating mechanism outside, in order to assure proper sequence of operations between the internal switches and the external circuit breakers.

The statement has been made that the parallel-winding method is more applicable to large units. I have already mentioned some of the large units which have been built using the single-winding method. We recently built some three-winding units rated at 20,000 kv-a. water-cooled (25,000 kv-a. forced-cooled), single-phase on each winding. They were arranged to change taps under load on two windings, one 66-kv. and the other 132-kv. solidly grounded. To change taps with the single-winding method, five switches are used in the grounded end of each winding. The transformer has but few taps in it, a single winding, (no complicated interlacing of paralleled sections) and the two preventive auto-transformers are mounted at each end of the core, making a very simple arrangement for handling one of the largest and most complicated cases of tap changing under load likely to be encountered.

With the parallel-winding method a very complicated transformer with a great number of taps would result which would be very difficult to bring out. It would be necessary to interlace two 132,000-volt windings and two 66,000-volt windings, giving the equivalent of a 5-winding transformer, which is a simple 3-winding transformer when the single-winding method is used.

The separate regulating unit has been proposed as being desirable for such cases and that is undoubtedly true if the parallel-winding method is used, because it is very undesirable, in fact impracticable, to build such a transformer with the parallel-winding method while it is entirely practicable and simple to do it with the single-winding method. The single-winding method can be applied to any size and rating of transformer by the use of the series transformer for very high-voltage applications.

The separate regulating unit has certain definite fields of

application, for example, where it is desired to use the voltage-control equipment on different parts of the system, or where the main units are already installed and additional control is desired. However, in the ordinary installation of single-phase units the tap changers can be put on each of these units including the spare, giving a very simple, reliable, and efficient form of installation.

It is true that when the spare transformer is used there are four separate mechanisms to operate with each bank. If a separate three-phase regulating transformer is used, as was mentioned, it is necessary to install underground or overhead structures to connect to the main units which, of course, increases the installation costs and space required and introduces far more losses than the preventive auto-transformer introduces with the single-winding method on the main transformers. The separate regulating unit generally has two cores, an exciting transformer and a series transformer, which obviously are much larger than in the auto-transformer used with the single-winding method, and naturally introduce a very considerable operating loss.

The regulating unit has the advantage that it does keep all the moving parts outside of the main transformer case, which is very desirable. But, the same thing is done with the single-winding method on the main units. The three-phase regulating unit has the additional drawback, that no spare tap-changing equipment is available as is the case when four single-phase transformers or seven single-phase units are used. Spare tap-changing equipment is becoming almost as important as spare capacity for the transformer.

There is one other place where the separate regulating unit might be desirable. In case the three-winding unit first mentioned had been arranged with an ungrounded neutral, so that it would be necessary to use the series transformer, in order to keep the tap-changer voltage down to a low value, then it would require two series transformers, in each winding. The series transformers are ordinarily placed inside the tank, along with the preventive auto-transformer and that would make quite a large number of transformers all in one tank. In the case of such a very special application it might be desirable to use a separate regulating unit, but even then, the single-phase regulating unit for the reasons just mentioned, has some advantage over the three-phase unit. Single-phase units of that type are now being built.

Mr. Stephens mentioned that on account of the steps required, it seems hardly necessary to use the step induction-regulator equipment. That is true perhaps in many cases from that point of view, although on account of the fact that no circuit interruptions are required for a tap change it is very good from a maintenance point of view, since it may be operated very frequently without any deterioration on the contacts or oil as would be the case with any step type of equipment; for this reason it is well suited for electric furnace operations or in synchronous-converter or certain automatic-substation applications.

L. F. Blume: In the paper by Mr. Hill, mention is made of the use of a preventive auto-transformer bridging across adjacent transformer taps. This auto-transformer is described as being physically of a relatively small size, but designed to operate at high-flux density. Operating with one contactor open, with the entire load current flowing in one winding of the auto-transformer, the saturation of the iron in the reactor prevents excessive voltage drop.

I am inclined to believe that this method of operation is open to the objection that the saturation of the iron in apparatus connected in series with a circuit introduces serious wave distortion in the line voltage.

Before coming to the conclusion that the arrangement having the fewer number of taps is to be preferred to the one using a greater number, consideration must be given to a number of advantages which are obtainable by the use of more taps. First, by increasing the number of taps, it becomes possible to reduce the voltage short-circuited and also makes it possible to avoid having a circulating current in an operating position, both of which materially add to the electrical efficiency.

Second, increasing the number of taps reduces the energy which must be ruptured, and on this account both the wear on contacts and the deterioration of oil are effectively reduced. The result of this is that contacts and oil must be changed less often when more taps are employed.

Although these arguments are negligible when ratio control is used for relatively small kv-a., in the larger equipment they become very appreciable and cannot be ignored.

P. H. Thomas: The tap-changing transformer is in many ways a substitute for the synchronous condenser. It is a simple, cheap, and effective method of accomplishing the same results under certain conditions. The great value of our synchronous type of apparatus, however, is its automatic quality. We can set it in a system with the proper regulators and then changes that have to be made due to changes in load and accidental conditions will occur automatically. In the most modern apparatus or in apparatus which is to be built hereafter, they occur sufficiently quickly to prevent synchronous apparatus dropping out of step.

This is an entirely different thing from adjusting conditions by hand to reduce power factor or to get a satisfactory voltage for customer circuits.

To have the tap-changing outfit the equivalent of the synchronous condenser for this sort of work, it is necessary that it be able to operate quickly enough to produce the necessary changes before the loss of synchronism and other things which we fear when sudden load conditions occur. That is one of the sides of the question that must be studied very carefully, the speed of action and the automatic control of the tap changes. It may be in response to voltage; it may be in response to power transmitted over some circuit; it may be in response to power factor; it may take account of positive and negative power factor; it may be dependent upon circuit-breaker operations, or many other conditions,—according to the particular place in which the tap changing is to be used.

Take, for example, a tie line between two large systems which must pass current backward and forward, according to the variations of load, perhaps at different times of the day. That is an exceedingly exacting duty on a transmission line and transformers and calls either for a wide change of power factor if the voltage is to be maintained constant at the two ends with a change in direction of the load, or a change of tap ratios.

If the large systems are to operate successfully in parallel, relying on the use of tap changers to control the interchange of power backward and forward, without disturbing voltages, they must act very rapidly, and they must act under the control of the necessary factor to produce such a result.

I don't know just how successful the present apparatus will be in that sort of thing, and I wonder if some of the authors could give us a little information as to what extent the tap-changing operations can be counted upon to meet accidental and automatically controlled changes in load.

L. H. Hill: Many types of automatic control to meet more or less steady-state conditions have been developed. The only installations in service that I know of are responsive only to voltage changes. The six 12,000-kv-a. units, illustrated in Fig. 6 of my paper, are operating under automatic control and maintain the bus pressure approximately constant. Under automatic control the tap-changing equipment is of course subjected to considerably more severe duty than would be met with under ordinary manual control. Under manual control, the tap-changing equipments in operation generally average not more than five operations a day, whereas under automatic control they may operate ten times as many.

To eliminate unnecessary operations and avoid hunting it is

desirable to insert some time delay, the length depending on the application.

It is also perfectly feasible to work out automatic control to transfer the power at a constant power factor.

Mr. Oplinger mentioned a case where the tap changer will automatically control the flow of wattless kv-a. between two generating stations in inverse proportion to the load on the two stations. There is almost an infinite number of arrangements that can be used for automatic control under these more or less steady-state conditions. However, for the purpose of using tap-changing equipment to effect the stability of a system under transient conditions, the present equipment is hardly adequate, because the ordinary tap-changing operation requires a matter of seconds. With our equipment, it requires about four sec. to change one tap. It would be entirely practicable to increase this speed perhaps to one sec., which would even then be hardly short enough to do much good under transient conditions.

Mr. Blume in his later discussion mentioned that when the auto-transformer is connected in series with the line it might give trouble, due to harmonics. I think Mr. Blume is confusing some of the earlier auto-transformers which we used and which were provided with the short-circuiting switch. When the short-circuiting switch is used the auto-transformer can be used working high on a saturation curve, so that it saturates under double-load conditions but in that case it is short-circuited when in series with the line, so there is no voltage available to put harmonics on the line.

When the auto-transformer is used in this manner without a short-circuit switch, then as mentioned on the third page of my paper, the auto-transformer is provided with air-gaps in its core, so that the core does not saturate and a straight-line characteristic is obtained.

L. F. Blume: I wonder whether Mr. Thomas in his discussion did not have in mind more particularly the longer high-voltage lines. As far as I know, the use of tap-changing equipments has been applied for the most part to the shorter lines, by which stations not so very far apart are interconnected, where the power to be transmitted is large, and where the reactance between stations is not great, as it is in very long-distance transmission lines.

In long-distance transmission, the effect of capacitance and of line reactance introduces problems which were not considered in the paper. It was assumed that line capacitance could be neglected, and that the amount of line reactance was insufficient to introduce the question of stability.

In the longer lines, where the reactance is high, the paper shows that the higher reactance means that the kv-a. required for a synchronous condenser to maintain constant voltage is proportionally smaller than ratio-control equipments. For example, comparing a low-reactance line with a high-reactance line, the size of the synchronous condenser required to maintain constant voltage with increasing reactance does not increase in kv-a., but the size of the ratio-control apparatus is directly proportional to the reactance.

So, for the longer lines, ratio-control apparatus is not only relatively more costly, but also on account of other considerations, such as stability, is probably unsuitable.

Studies on Sparking in Air

BY A. PEN-TUNG SAH*

Associate, A. I. E. E.

Synopsis.—*Sparking voltages and gradients in air between spheres of unequal diameters and between two cylinders placed with their axes perpendicular to each other in space (called cross-cylinders) have been determined. Complete tables giving the coefficients of gradient corresponding to any given spacing and radii, have been tabulated, the formulas used being those of Kirchhoff and Russell. For cross-cylinders, an approximate formula has been developed.*

In the theoretical discussions, the more definite form of the theory of ionization by collision as given by Bergen Davis has been extended to the sphere-gap and a relation has been deduced to account for the variation of the sparking gradient as investigated in the first part of this work, which is in substantial agreement with those found by F. W. Peek, A. Russell, and others.

* * * * *

INTRODUCTION

SPARKING voltages and gradients between needle-points and spheres have been measured by many investigators. It has been theoretically shown[1] that the relation between the sparking voltage and the spacing, when the spacing is so large that corona precedes a spark-over, should conform to a linear law. Such is, in fact, the case for the needle-gap, as shown by F. W. Peek[2] and others. For spheres, it has also been shown by Peek[3] and A. Russell[4] that for large spacings under twice the radius of the spheres, the results seem to indicate a constant sparking gradient for a given size of spheres when both of them are insulated and are at equal and opposite potentials, the middle of the high voltage winding of the transformer being connected to earth. As for the case when one of the spheres is grounded with the high potential applied to the other insulated sphere, all experimental data seem to contradict this view.[3-12] In this case, the sparking gradient decreases rapidly at first and then gradually increases with the spacing.

The existing theory to explain these phenomena is mainly due to Peek, who assumes that air has a constant dielectric strength, an assumption fairly well borne out by the corona measurements on concentric cylinders and parallel wires. Inasmuch as this theory was extended from the phenomenon of corona, it seems advisable to study the problem of sparking in air by using different kinds of electrodes, namely, two spheres of unequal diameters and two cylinders placed with their axes perpendicular to each other in space (called cross-cylinders, for brevity) to see if similar relations exist and to derive a law for sparking based on the more definite form of the theory of ionization as first formulated by J. S. Townsend and later extended by Bergen Davis to the corona measurements on concentric cylinders and parallel wires. It is thus seen that the present investigation falls into two parts: namely, the determination of the sparking voltages and gradients for the above types of electrodes, and the formulation of a theory to explain the more or less empirical relation of Peek and Russell based on the known laws of ionization by collision.

Part I

SPARKING VOLTAGES AND GRADIENTS BETWEEN UNEQUAL SPHERES AND BETWEEN CROSS-CYLINDERS

Formulas and Tables for the Calculation of the Maximum Gradients between Unequal Spheres and Cross-Cylinders. The case of two conducting spheres is of classical interest, being among the problems first successfully solved by Poisson by using his famous integral. Clerk Maxwell[13] also gave a solution but it was too complicated to be of any service in a numerical work. The first workable formula was given by Kirchhoff[14]. It was put into a manageable form by A. Russell[15], who proved the case for two equal spheres by the method of an infinite series of images, while G. R. Dean[16] solved the same problem by using hyperbolic functions and zonal harmonics. In the appendix to follow, it will be shown how Russell's reasoning can be extended to the general case of two spheres of unequal diameters. From the proof it will be seen that the gradient at the surface of the spheres on the line of centers may be calculated from the following relations:

$$G_1 = V_1 F_{11}/X - V_2 F_{21}/X$$

and

$$G_2 = V_2 F_{22}/X - V_1 F_{12}/X$$

in which X = spacing between the spheres, G_1 = the gradient at the surface of the smaller sphere, V_1 = the voltage on the smaller sphere, and G_2 and V_2, the corresponding values for the larger sphere. The different F's will be called *coefficients of gradient*. The double subscript adopted is similar to the notation used in electrostatics for the coefficients of capacity, or of induction, or of potential. By giving appropriate values to the different V's, these general formulas will be found to be applicable to the different arrangements that are investigated: namely, when $V_1 = -V_2 = V/2$, the case when both spheres are at equal and opposite potentials, V being the potential difference between them; and when $V_1 = O$ or when $V_2 = O$, the two cases when one of the spheres is grounded. Thus for the case when both spheres are insulated and

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

are at equal and opposite potentials, the two coefficients of gradient may be taken as:

$$F_1 = (F_{11} + F_{21})/2, \text{ and } F_2 = (F_{22} + F_{12})/2,$$

respectively.

The various F's are expressed in convergent series, the arguments of which are functions of the ratios b to a, ratio of radii, and X to a, ratio of spacing to the smaller radius. The values for these when $b = a$, *i. e.*, when the spheres are equal, have been given by other investigators[illegible]. In the following tables only F_{11} and F_{21} are given; the values for F_{22} and F_{12}, except for the case when one sphere has infinite radius, can be made to depend on those of F_{11} and F_{21} by a reciprocal relation which will be discussed fully in the mathematical appendix.

For ready reference and interpolations, Figs. 1, 2, 3, and 4 giving values of F_{11}, F_{21}, F_{22}, and F_{12} are herein attached.

For the case of cross-cylinders, because of the lack of symmetry, it is not possible to obtain an exact solution of the problem by using known methods of mathematical analysis. In Appendix II, an attempt has been made at an approximate solution, the basic principle of which is quite similar to that employed by Dean[18] in deriving an approximate solution for two equal spheres. It will be seen that for the case in which both equal cylinders are insulated and are at equal and opposite potentials, the coefficients of gradient F are given by the following table of values, using which the values of the maximum gradient can be calculated from the relation:

$$G = \sqrt{2}\, V F / X$$

where G is the gradient, V the effective potential difference, and X the spacing.

Apparatus, Method of Measurement, Etc. Five sizes of spheres were used in the investigation, their diameters as measured by calipers being 25.0 cm., 20.2 cm., 15.0 cm., 10.0 cm., and 5.05 cm. They were made by soldering together two hemispherical bowls that were spun from copper. Their shape was quite satisfactory, as measurements of the curvature by means of a spherometer did not vary more than one per cent. The shanks were brass tubes, projecting 60 cm. from the spherical surface, each tube having a diameter about one-eighth of that of the sphere to which it was fitted. For the determination of sparking between a sphere and a plane, sphere of infinite radius, two sizes of plane surfaces were used, one being about 50 cm. in diameter and the other 150 cm. At short spacings, it was found that the determinations were practically the same, using either plate. Only when the spacing became large, about one-sixth of the diameter of the plate, did deviations begin to appear. From this, it was concluded that with the 150-cm. plate, the sparking voltages as measured might be assumed to be independent of the diameter of the disk for spacings smaller than 25 cm., which was the upper limit contemplated in the investigation. The small disk, 50 cm., was a cast iron plate with the surface carefully scraped. The larger circular plane, 150 cm., was made of galvanized sheet iron with a ¾-in. (2-cm.) lead tubing soldered all around the edge.

Three pairs of cross-cylinders were used: one pair with 25-cm. in diameter being 48 in. (122 cm.) long excluding the hemispherical ends, and the other two pairs, both 5 in. (12.7 cm.) in diameter, being in two different lengths, namely, 24 in. (61 cm.) and 48 in. (122 cm.), respectively. They were supported horizontally at the ends at about four feet (120 cm.) from ground.

The method of voltage measurement was by comparison with a pair of standard 25-cm. spheres, the sparking curves being those given by the A. I. E. E. standards. Two transformers, both having the center of the high voltage winding grounded, were first calibrated against the 25-cm. sphere-gap to determine their ratios of transformation. Knowing these, the sparking voltages on unequal spheres and cross-cylinders were determined from the readings on the low voltage side of the transformer. The voltage ranges of the transformers were approximately 150 kv. between terminals for the smaller unit and either 250 kv. or 500 kv. between terminals for the larger unit, according to whether the low voltage side was connected in series or in parallel. The wave shape of the low voltage supply was very nearly sinusoidal. The frequency was 60 cycles.

In all of the determinations, the atmospheric density was corrected for. The correction factor was taken to be simply $3.92B/(273 + t)$ to reduce all observations to the standard condition of 76 cm. Hg and 25 deg. cent., B being the barometric reading in cm. Hg and t the temperature in degrees centigrade.

Experimental Data and Results. In the following tables, the coefficients of gradient have not been entered, their values being interpolated from the curves constructed from the tables of values already given, Figs. 1, 2, 3, 4. Calculations for the gradients were made only for cases in which the spacing was under twice the radius of the smaller sphere, as beyond this spacing there was good reason to suspect the formation of corona before a spark-over so that similar computations would become meaningless.

Each value is the average of five consecutive readings. Unless otherwise indicated, deviation from this average is small and negligible.

The symbols at the head of each column are:

a and b = radii of spheres, in cm.,

X = spacing between the spheres, in cm.,

V = sparking voltage when both spheres are insulated and are at equal and opposite potentials, in kv. eff.,

V_1 = sparking voltage when small sphere is insulated and the large one grounded, in kv. eff.,

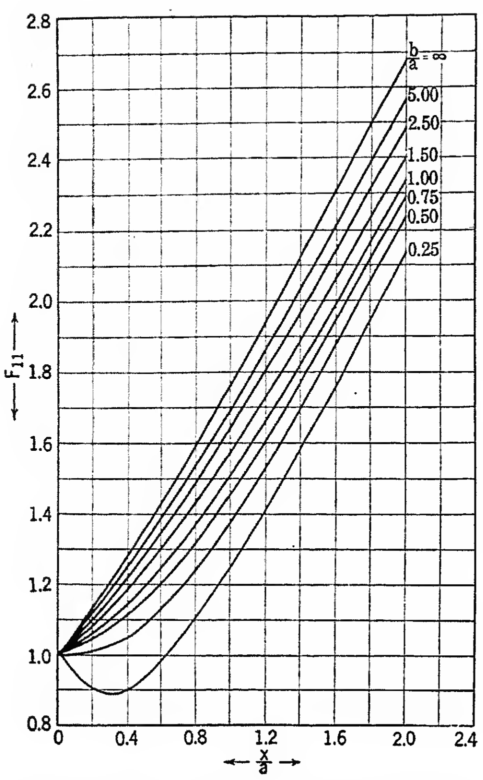

FIG. 1—COEFFICIENT OF GRADIENT FOR TWO SPHERES.

VALUES OF $F_{11}\left(\frac{x}{a}, \frac{b}{a}\right)$

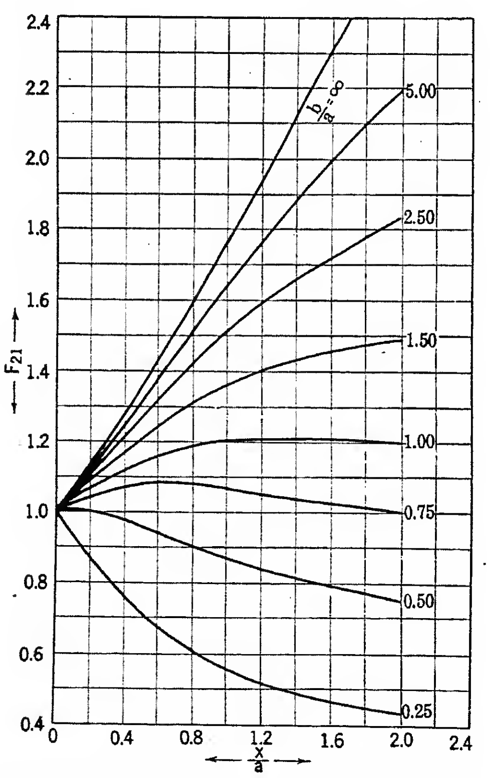

FIG. 2—COEFFICIENT OF GRADIENT FOR TWO SPHERES.

VALUES OF $F_{21}\left(\frac{x}{a}, \frac{b}{a}\right)$

V_2 = sparking voltage when large sphere is insulated and the small one grounded, in kv. eff.,

$G_1 = \sqrt{2}\, V F_1/X$; $G_{11} = \sqrt{2}\, V_1 F_{11}/X$; and $G_{21} = \sqrt{2}\, V_2 F_{21}/X$ are the maximum gradients at the surface of the small sphere corresponding to the three arrangements, in crest kv. per cm.,

$G_2 = \sqrt{2}\, V F_1/X$; $G_{12} = \sqrt{2}\, V_1 F_{12}/X$; and

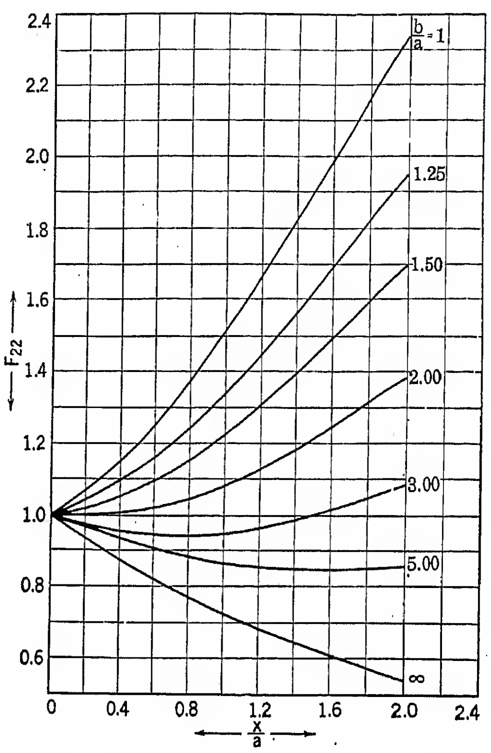

FIG. 3—COEFFICIENT OF GRADIENT FOR TWO SPHERES.

VALUE OF $F_{22}\left(\frac{x}{a}, \frac{b}{a}\right)$

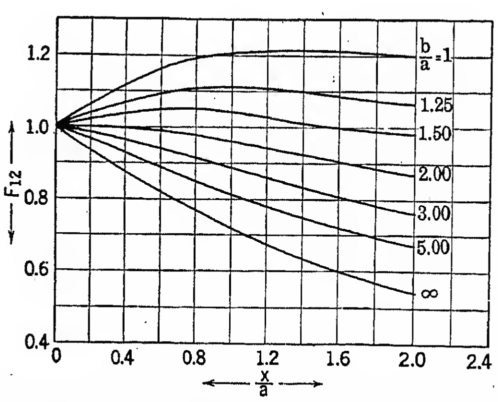

FIG. 4—COEFFICIENT OF GRADIENT FOR TWO SPHERES.

VALUES OF $F_{12}\left(\frac{x}{a}, \frac{b}{a}\right)$

$G_{22} = \sqrt{2}\, V_2 F_{22}/X$ are the corresponding maximum gradients at the large sphere, in crest kv. per cm.

Summary of Results. Part of the above data has been plotted into several sets of characteristic curves. From these (Figs. 5, 6, 7, 8) the following points may be inferred:

1. Unstable Part of the Curves. There is a part in each sparking curve where the sparking voltage is not definite. These parts have been shown as dotted lines. The irregularities at these portions are presumably due to the formation of excessive corona and begin at a separation somewhere around three or four times the diameter of the smaller sphere.

2. General Character of Curves of Series I, Both Spheres Insulated, and Series II, Small Sphere Insulated. These two series as shown by Figs. 5 and 6, show that the more nearly equal are the diameters of the spheres the higher is the sparking curve. Thus the highest curve is the one for equal spheres as interpolated from the data of the A. I. E. E. standards while the lowest curve is the one between a sphere and a plane.

3. General Character of Curves of Series III, Large Sphere Insulated and Small One Grounded. The same

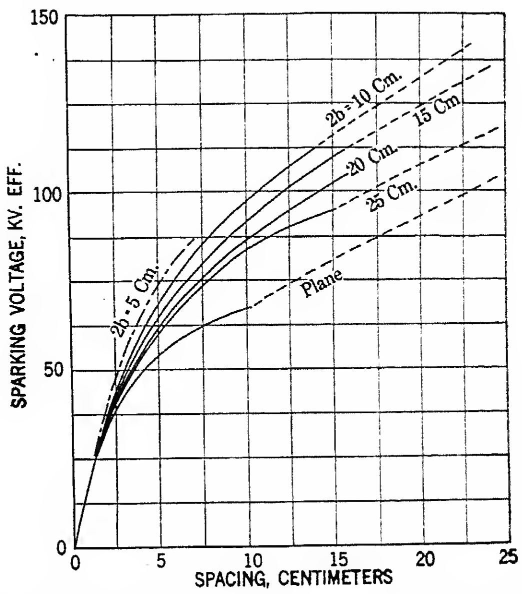

FIG. 5—SPARKING VOLTAGES V BETWEEN UNEQUAL SPHERES

Diameter of small sphere = 5.05 cm.
Diameter of large sphere = $2b$, as indicated
Both spheres insulated

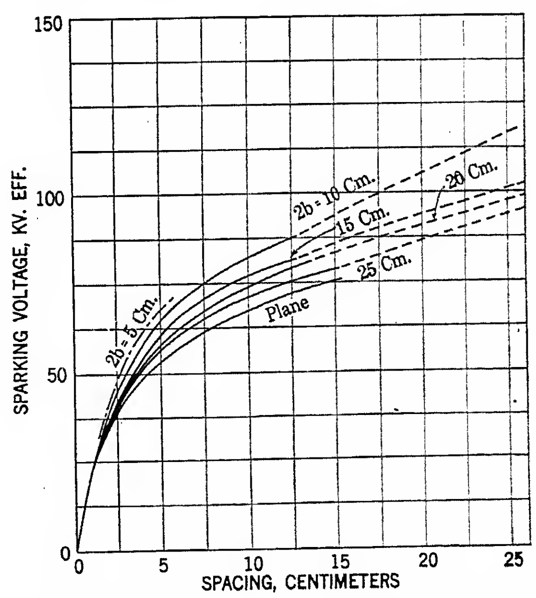

FIG. 6—SPARKING VOLTAGES V_1 BETWEEN UNEQUAL SPHERES

Diameter of small sphere = 5.05 cm.
Diameter of large sphere = $2b$, as indicated
Small sphere insulated; large one grounded

conclusions cannot be reached in this case as in the previous two cases, Fig. 7. When the diameters of the spheres do not differ greatly, the sparking curve bends over much more than the corresponding curves in the other two series. A probable reason for this will be

given when the sparking gradients are studied. It will also be seen that the sparking curve between a plane and a sphere is again lowest.

4. Sparking Gradients for Series I. From the tables,

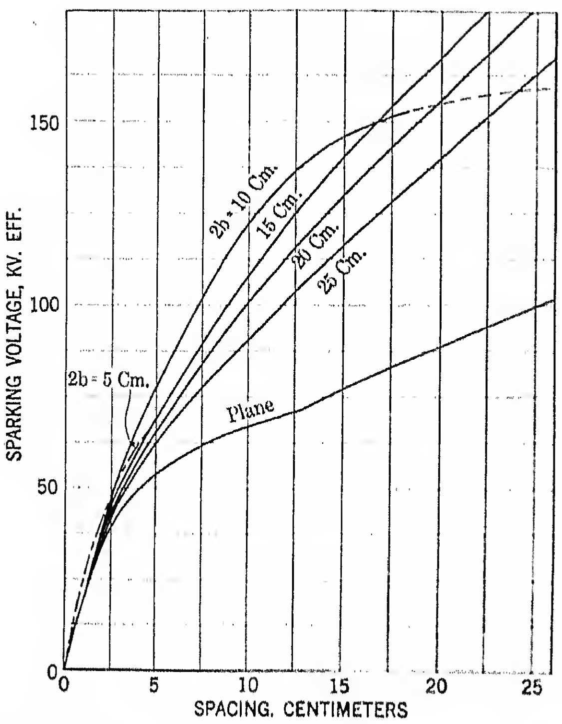

FIG. 7—SPARKING VOLTAGES V_2 BETWEEN UNEQUAL SPHERES

Diameter of small sphere = 5.05 cm.
Diameter of large sphere = 2 b, as indicated
Small sphere grounded; large one insulated

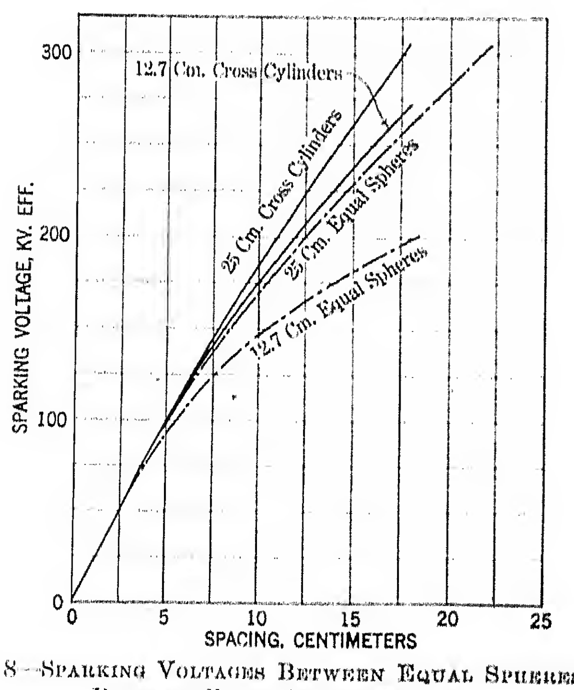

FIG. 8—SPARKING VOLTAGES BETWEEN EQUAL SPHERES AND BETWEEN EQUAL CROSS-CYLINDERS

Both electrodes insulated

it is seen that the sparking gradients G_1 at the smaller sphere are very nearly constant for a given size of the smaller sphere within the range of the spacings investigated. The general relation is: *the smaller the radius, the higher the sparking gradient.*

5. Sparking Gradients for Series II. The values for G_{11}, *t*. ., when the smaller sphere is insulated, will be seen to increase somewhat with the spacing. This increase seems to be greater as the ratio of the radii,

25.40	206	145*	203						

b/a, is more nearly unity. Thus for equal spheres, this increase will be found to be greatest and for a plane and a sphere, it is almost entirely negligible.

6. Influence of G_2 and G_{12}. For the two series above discussed, the influence of the gradients at the surface of the larger sphere, *i. e.*, of G_2 and G_{12}, seems to be negligible since they vary between wide limits. It is probable that they do not have any primary effect in

causing the sparking, which, as already pointed out, seems to be mainly governed by the gradients G_1 and G_{11} at the smaller sphere.

7. Sparking Gradients for Series III. For the third series, namely, that in which the smaller sphere was grounded with the high voltage applied to the large sphere, the sparking gradient G_{21} at the surface of the smaller sphere sometimes increases and sometimes decreases with the spacing while the values of G_{22}, *i. e.*, the gradient at the larger sphere, are not always smaller than G_{21}. In fact, for the cases in which the sparking curves in the third series bend over and intersect the others as noted in (3) above, the gradient G_{22} increases and finally becomes larger than G_{21}; see Tables VIII and XI. In these cases it is probable

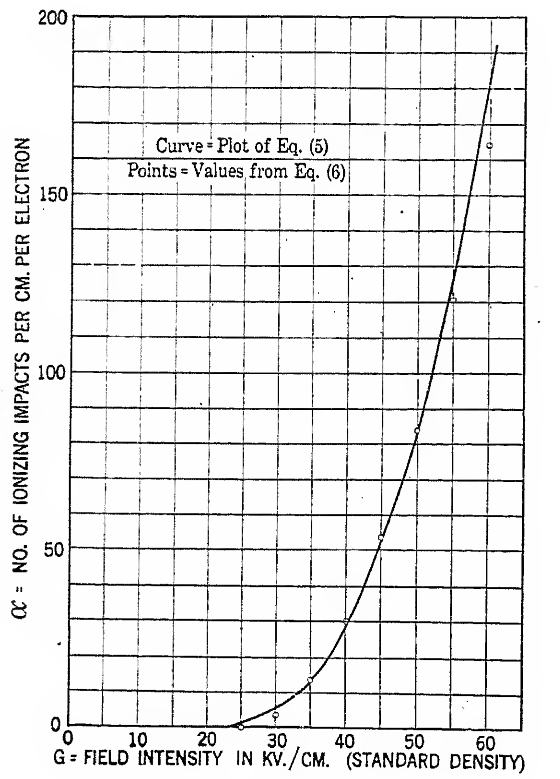

Fig. 9

that the law of sparking should be formulated to take account of the influence of both G_{22} and G_{21}. This is a probable explanation why the curves in this series bend over much more than the corresponding curves of the other two series.

8. Comparison of Curves for the Three Series. When the same pair of spheres is used, it will be seen that the sparking curve is highest when the smaller sphere is grounded and lowest when it is insulated, with the case when both spheres are insulated and are at equal and opposite potentials falling in between the two. For the arrangement when one sphere has infinite radius, i. e., a plane, all three curves are practically the same.

9. Data on Cross-Cylinders. The general relation that the smaller the radius, the higher the sparking gradient, has been found to be also true in the case of cross-cylinders. When the electrodes are at equal and opposite potentials, this gradient seems to be a constant for the spacings considered. As no mathematical calculation has been made to determine the sparking gradient when one cylinder is grounded, nothing can be inferred about this arrangement. Measurements of the sparking voltages in this latter arrangement showed, however, that the sparking voltages were not far different from those determined for the former case of both insulated electrodes. Because of the flux distribution, it will be noted that the sparking curve for cross-cylinders lies higher than the corresponding curve for spheres with the same radius, Fig. 8. It should also be noted, however, that the sparking gradient in the case of cross-cylinders is *smaller* than the corresponding value for equal spheres having the same radius.

From the data on the two lengths of the 12.7-cm. cylinders, it will be seen that when the spacing was below one-sixth of the net length of the cylinder, no appreciable difference in the sparking voltage was observed by using either pair of electrodes.

Part II

Theoretical Considerations

Before proceeding to a discussion of the Davis theory of the corona, from which it will be shown how to derive the relation between the sparking gradient and the radius of the sphere, it would be advisable to give a brief account of Peek's theory of the sphere-gap so as to afford a ready comparison of the two. Peek[19] assumes that air has a constant dielectric strength G_0. But to cause rupture, energy as well as gradient is necessary. Thus corona or sparking does not occur when the gradient at the surface of the electrode equals G_0, because energy has not yet been supplied sufficiently. It is only after the gradient at a certain distance away from the surface of the electrode equals G_0 and hence that at the electrode *exceeds* G_0, that the energy supplied is great enough to cause a rupture. Thus due to curvature of the electrodes, the sparking gradient at the electrode with the radius a should satisfy a relation:

$$G_a = G_0 \left(1 + A/\sqrt{a} \right) \quad (1)$$

in which A is a constant, G_0 the constant dielectric strength of air, and a the radius. From his results on concentric cylinders, parallel wires, and spheres, Peek finds that the values for G_0 vary somewhat for the three arrangements. He attributes this variation to the unbalancing of the field and claims that the dielectric strength of air is probably given by the value 31 kv. per cm. as obtained from the determinations on concentric cylinders where the field distribution is the same on all sides. In the case of parallel wires, there is some unbalancing so that G_0 becomes less, being only 29.8 kv. per cm., while for spheres, the unbalancing is

greatest, in consequence of which the value of G_0 is also lowest, being only 27.2 kv. per cm.

Besides this difficulty and the rather indefinite magnitude of the rupturing energy required by Peek's theory, it is also necessary to account for the variation of the sparking gradients in the cases when one of the spheres is grounded. Although arguments have been advanced to explain this variation, they are not at all convincing[20]. As Bergen Davis has demonstrated how the theory of ionization by collision can be applied to the corona formation around cylindrical conductors, it appears best to extend this to the case of the sphere-gap since our present knowledge and confidence in the electron theory is far greater than at the time of the deductions of Davis.

In order to extend this theory, it is necessary to note the main assumptions as follows:[21]

1. On the Agency of Ionization. Under the conditions of sparking that are being dealt with, ionization of the gas molecules is primarily due to the collisions with electrons. The ionizations caused by positive ions and photoelectric effects are very small and may be neglected.

2. On the Energy Required for Ionization. When an electron collides with a molecule, ionization will follow only when the normal component of the kinetic energy of the electron equals or exceeds a certain least value, which value is a constant characteristic of the gas. Thus for a given density, the number of ionizing impacts depends on the field intensity. By statistical considerations, it can be shown how the number of ionizing impacts and the gradient are related. For practical purpose, a gradient at which ionization begins to be appreciable may be assumed to correspond with the value G_0 of Peek's formula (1), *but not equal to it.*

3. On the Physical Process of Sparking or Corona Formation in an Alternating Electric Field. Consider two concentric spheres for the sake of simplicity. Let the rupturing potential difference be applied. Suppose the inner sphere is passing through the crest value of the positive half of the voltage wave. Imagine a concentric sphere M to be the surface at which the gradient is G_0, *i. e.*, the value at which ionization by collision is appreciable under the given density conditions. As the inner sphere is at the positive half of the wave, free electrons will be moving towards it. When these free electrons pass inside of the region within the sphere M, ions and electrons multiply due to collision. Thus, if there are originally N_0 electrons at the surface of M, the number arriving at the inner sphere will be greater than N_0, say N_{01}. As the voltage wave decreases and finally becomes negative, some of these N_{01} electrons will move outward while a number of them will disappear, being taken up by the conductor as convection current. Those that move outward will again cause ionization by collision and will at the same time recombine with the positive ions that they overtake in their course. The net result of this is that at the next half-cycle, when the inner electrode is positive, the number of electrons at the surface of the imaginary sphere M is greater than N_0, the original number due to the natural ionization of the atmosphere. Call this N_1. These N_1 electrons will again produce ionization when they are within the sphere M and the number that reaches the inner electrode will be greater than N_1, say N_{11}. Of these, a portion will move outward as the field changes to negative value and causes, by the action already described, the number that moves inward in the following cycle to be still greater than N_1. Continuing the process in this way, it will be seen that there will be a cycle at which the number of electrons at the surface of the sphere M will be such a value, say n_0 per unit area, that moving under the field intensity and distribution, it will yield at the inner electrode an ionic density of n electrons per unit area. This density n is high enough to cause the layer immediately around the conductor to be conducting and hence the formation of corona or a progressive rupture. From this conception of the nature of the rupture, it will be noted that rupture does not occur immediately after the application of the rupturing voltage but only after the lapse of a few cycles. This conception seems to be in good agreement with observations on the time lag and transient sparking voltages of the different gaps.

The Law of the Sphere-Gap. In the above discussions, the spheres have been assumed to be concentric. If attention is confined to a small area around the line of centers on the surface of the smaller sphere, the same considerations will also be true for two spheres external to each other.

To find the relation between n and n_0, let us for simplicity again consider two concentric spheres. Denote by N_0 and N, respectively, the number that starts out from the sphere M and that arrives at the inner sphere. Let α be the number of electrons produced by one electron when it travels through a distance of one centimeter under an electric force of G kv. per cm. If there are N electrons passing through a surface,[22] then at a small distance $d\,y$, the number will be increased by

$$d\,N = \alpha\,N\,d\,y \tag{2}$$

If the field is uniform, *i. e.*, if the gradient is the same throughout, α is independent of y and the above can be at once integrated. Otherwise the variation of α with y must be taken into account. In any case (2) may be written as

$$\log N - \log N_0 = \int_a^{y_0} \alpha\,d\,y \tag{3}$$

Introducing the ionic densities n and n_0, equation (3) becomes

$$\log \frac{n\,a^2}{n_0\,y_0^2} = K = \int_a^{y_0} \alpha\,d\,y \tag{4}$$

where K has been written for the first member for brevity.

To integrate (4), it is necessary to express α in terms of y. This can be done if the relation between α and G is known, because, as will be shown in the Appendix, for small distances away from the surface of the sphere, the gradient G varies inversely as the distance from the center of the sphere. Thus, if G_0 is the gradient at the point on the line of centers whose distance from the center of the sphere is y_0, and G_a is the gradient at the surface of the sphere with radius a, then $G_a = G_0\, y_0^2/a^2$; and, in general, if y is the distance of a point on the line of centers from the center of the sphere, the gradient at y is $G = G_0\, y_0^2/y^2 = G_a\, a^2/y^2$, if $y - a$ is small.

Regarding the relation between α and G, Bergen Davis has developed a formula by considering the energy required for ionization as stated in (2) above. In terms of the ionization potential v and the mean free path L of the electrons, this relation takes the form:

$$\alpha = \frac{1}{L} e^{-\frac{v}{GL}} + \frac{v}{G L^2} E\, i \left(- \frac{v}{G L} \right) \qquad (5)$$

where $E\,i$ is the exponential integral. Using the value $v = 10.2$ volts as found by Bishop[23] and taking L as $4\sqrt{2}$ times the mean free path of the molecules in air[24], *i. e.*, $4\sqrt{2} \times 9.83 \times 10^{-6} = 5.55 \times 10^{-5}$ cm. for the free electrons in air, values of α can be calculated for different G's. A calculation of this sort has been made using the tables of Jahnke and Emde[25] for the values of the exponential integral. For values of G covered by the investigation, it is found that an empirical quadratic relation represents the theoretical relation (5) very satisfactorily. This relation is:

$$\alpha = C\,(G - G_0)^2 = 0.134\,(G - 25)^2 \qquad (6)$$

where G is in kv. per cm. The agreement between (6) and (5) is well shown by the accompanying curve, Fig. 9. As relation (5) can not be used for integration in finite terms, relation (6) will be used. Also as $G = G_0\, y_0^2/y^2$, (6) can be written as

$$\alpha = C\, G_0^2 \left[\frac{y_0^2}{y^2} - 1 \right]^2 \qquad (7)$$

Substituting this into (4) and performing the indicated integration, it is found that

$$\log \frac{n\, a^2}{n_0\, y_0^2} = K = 83.7\, a \left[\frac{8}{3} \sqrt{\frac{G_a}{G_0}} + \frac{1}{3} \left(\frac{G_a}{G_0} \right)^2 - \frac{2\, G_a}{G_0} - 1 \right] \qquad (8)$$

In this form, the equation still contains a quantity n_0, of which nothing is known. If it is assumed for the present that the total number of electrons crossing any spherical surface completely enclosing one of the electrodes remains always the same, then the density of electrons on any such spherical surface will vary inversely as the square of the radius. In the equation above given, it is then permissible to put the quantity K equal to a constant. Granting such an assumption, the theory then leads to the result that the sparking gradient is a function of the radius of the smaller sphere only.

In his theory of the corona, Davis had to do with a similar quantity which he assumed to be constant and equal to 6 for concentric cylinders and to 4.3 for parallel wires. If K is taken as 4 for the sphere-gap, it will be found that equation (8) agrees fairly well with the data given by the Institute standards and those of the present investigation when only the case of symmetrical application of voltage is considered, *i. e.*, when both spheres are insulated and are at equal and opposite potentials. In fact, changing the square-root function to a quadratic function by the following empirical relation, which will be found to be accurate to within half of a per cent for values of X lying between 1 and 2, namely,

$$\sqrt{X} \cong - 0.071\, X^2 + 0.630\, X + 0.441 \qquad (9)$$

the relation (8) can be put in the form:

$$G_a = \left(1.105 + \frac{0.288\, \sqrt{K}}{\sqrt{a}} \right) G_0 \qquad (10)$$

With $K = 4$ and G_0 as 25, (10) at once becomes

$$G_a = 27.6 \left(1 + \frac{0.52}{\sqrt{a}} \right) \qquad (11)$$

whose similarity to the relation of Peek, *viz.*,

$$G_a = 27.2\,(1 + 0.54/\sqrt{a})$$

or to that of Russell, *viz.*,

$$G_a = 27.4\,(1 + 0.515/\sqrt{a})$$

is very remarkable and striking.

Concluding Remarks

It should be noted that in the above work, the value of K has been assumed to be constant. It is the simplest assumption. On closer examination, it will be seen that n_0 cannot be as simply related to y_0 as an inverse square relation. For instance, as shown by Davis in his theory, when the spacing is very short, the electrons moving outward will be taken up and neutralized by the other sphere and the process of cumulative multiplication at the surface of the sphere M will not take place as readily. In fact, for short spacings, $n_0\, y_0^2$ decreases as the spacing (hence K increases) because of the disappearance of a number of electrons at the surface of the other electrode. It is therefore possible to explain the rapid increase of the sparking gradient as the spacing is decreased to very short values. Thus the simple relation of Peek and Russell, which may be derived from the theory of Davis, appears to be merely an approximation giving good results only for special cases, namely, when both spheres are insulated and are at equal and opposite potentials, in which case it is permissible to assume K to be a constant independent of the arrangement. As for the cases in which one of the spheres is grounded, the value of K is probably influenced both by the gradient at the surface of the

larger sphere and the spacing between them, so that it is no longer a constant independent of the arrangement. On this account, it is thus also possible to explain why *the constancy of the sparking gradient is not of general validity*. A point of interest to note is that the smaller value of G_0, Peek's notation, for spheres, *viz.*, the value 27.6 as against 31 for concentric cylinders or 29.8 for parallel wires, is a natural consequence of the theory and does not require any explanation such as that advanced by Peek.

The writer is under great obligation to Prof. A. Wilmer Duff and Prof. Harold B. Smith for suggestions made and for facilities and encouragement in the preparation of the paper.

Appendix I

Coefficients of Gradient for Spheres

Given the radii a and b of two spheres and the distance of separation between their surfaces, X, it is required to find the field distribution when both spheres are charged and when one of them is charged and the other connected to ground. In particular, the values of the maximum gradients at the surfaces of the spheres are to be sought.

Let A_1 be the center of the sphere with radius a and B be that of the sphere with radius b. Suppose first that A is at potential V while B is grounded. Put a charge, $Q_1 = V_1 a$, at A_1. This will give to sphere A a uniform potential V_1. But due to it, the potential over sphere B is no longer zero. To reduce the potential over B to zero, put a second charge Q_1' at B_1, the point inverse to A_1 with respect to the sphere B, *i. e.*, $A_1 B \,.\, B_1 B = b^2$ and $Q_1/A_1 M + Q_1'/B_1 M = O$ where M is any point on sphere B. Due to Q_1' the potential over sphere A is now no longer uniformly equal to V_1. To restore it to the value V_1, another charge Q_2 may be put at the point inverse to B_1 with respect to the sphere A, namely, A_2, which satisfies the relation $A_1 A_2 \,.\, A_2 B_1 = a^2$. The magnitude of Q_2 must be such that $Q_2/A_2 N + Q_1'/B_1 N = O$ for any point N on the sphere A. Continuing the process, it is evident that the nth charge Q_n inside of sphere A is related to the nth charge Q_n' inside of B as follows:

$$Q_n/Q_n' = - M A_n/M B_n = - b/B B_n, \tag{12}$$

where M is any point on sphere B, and A_n and B_n are two inverse points with respect to sphere B. Likewise, for any point N on sphere A, the relation must hold:

$$Q_{n+1}/Q_n' = - N A_{n+1}/N B_n = - A_1 A_{n+1}/a \,. \tag{13}$$

Putting $B B_k = u_k'$ and $A_1 A_k = u_k$, the relation of two successive charges is $Q_{n+1}/Q_n = u_n' u_{n+1}/a b$ (14)

To find u_n' and u_{n+1} in terms of the radii a and b and the spacing X, first locate the two inverse points of the spheres, *i. e.*, the two points P and P' defined by:

$$A_1 P \,.\, A_1 P' = a^2 \text{ and } B P' \,.\, B P = b^2 \tag{15}$$

Denoting $A_1 P/a = t$ and $B P'/b = t'$, it will be found that t and t' are given by:

$$2\, a\, d\, t = d^2 + a^2 - b^2 - \sqrt{(d^2 + a^2 - b^2)^2 - 4\, a^2 d^2}$$
$$\text{with } d = a + b + X \tag{16}$$
$$2\, b\, d\, t' = d^2 + b^2 - a^2 - \sqrt{(d^2 + b^2 - a^2)^2 - 4\, b^2 d^2}$$

The general relation between u_n, u_n', and u_{n+1} is, by definition of inverse points, as follows:

$$(d - u_n)\, u_n' = b^2 \text{ and } (d - u_n')\, u_{n+1} = a^2, \tag{17}$$

which gives, on the elimination of u_n',

$$u_n\, u_{n+1} - (d^2 - b^2)\, u_{n+1}/d - a^2/d + a^2 = 0 \tag{18}$$

(18) can be put into the standard form of a difference equation by a change of the variable as follows:

$$u_n = v_{n+1}/v_n + (d^2 - b^2)/d \tag{19}$$

giving

$$v_{n+2} + C\, v_{n+1} + D\, v_n = O, \tag{20}$$

where

$$C = (d^2 - b^2 - a^2)/d \text{ and } D = a^2 b^2/d \tag{21}$$

The solution of (20) is obtained by putting $v_n = z^n$, where z satisfies the quadratic

$$z^2 + C\, z + D = O \tag{22}$$

Using the two roots of (22), z_1 and z_2, the general solution of (20) is then $v_n = A\, z_1^n + B\, z_2^n$ (23)

where A and B are two arbitrary constants to be determined so as to satisfy the boundary conditions of the problem. Introducing for convenience the value of t from (16) into the solution, it is found that

$$v_n = A\, a^n\, (a/d - t)^n + B\, a^n\, (a/d - 1/t)^n \,. \tag{24}$$

To determine the ratio of A to B, the initial condition that when $n = 1$, $u_1 = A_1 A_1 = O$ is used. This yields, from (19),

$$v_2/v_1 = - (d^2 - b^2)/d = a\, (a/d - t - 1/t) \tag{25}$$

together with simplification by using (16). Equating the ratio v_2/v_1 found from (24) to that given by (25), it is found that after reduction and simplification

$$B = - A\, t'^2 = - A\, s^4/t^2 \tag{26}$$

where $s^2 = t\, t'$.

With this value for B, it is found that

$$u_n = \frac{a\, t\, (s^{4n-4} - 1)}{(t^2\, s^{4n-4} - 1)}$$

and

$$u_n' = \frac{b\, s^2\, (t^2\, s^{4n-4} - 1)}{t\, (s^{4n} - 1)} \,. \tag{27}$$

From (14), the ratio of the various charges is then:

$$\frac{Q_{n+1}}{Q_n} = \frac{u_n'\, u_{n+1}}{a\, b} = \frac{s^2\, (1 - t^2\, s^{4n-4})}{(1 - t^2\, s^{4n})} \tag{28}$$

Since $Q_1 = V_1\, a$,

$$Q_n = V_1\, a\, \frac{(1 - t^2)\, s^{2n-2}}{(1 - t^2\, s^{4n-4})}$$

and

$$Q_n' = - Q_n\, u_n'/b = - \frac{V_1\, a\, s^{2n}\, (1 - t^2)}{t\, (1 - s^{4n})} \tag{29}$$

On the lines of centers, we have then:

$$G_{11} = \frac{Q_1}{a^2} + \frac{Q_2}{(a - u_2)^2} + \ldots + \frac{Q_{n+1}}{(a - u_{n+1})^2} + \ldots$$

$$- \frac{Q_1'}{(d - u_1' - a)^2} - \ldots - \frac{Q_n'}{(d - u_n' - a)^2} - \ldots$$

for the gradient (or field intensity) at the surface of the small sphere due to the voltage V_1 on it. This can be reduced by using the values of Q and u already found, and is:

$$G_{11} = \frac{V_1 (1 + t)^2}{a (1 - t)} \left[\frac{1 - t}{(1 + t)^2} + \frac{s^2 (1 - t s^4)}{(1 + t s^4)^2} + \ldots \right] \tag{30}$$

or

$$G_{11} = \frac{V_1}{X} F_{11}$$

with

$$F_{11} = \frac{X (1 + t)^2}{a (1 - t)} \sum_{n=0}^{\infty} \frac{s^{2n} (1 - t s^{4n})}{(1 + t s^{4n})^2} \tag{31}$$

In a similar way, the gradient at the surface of the larger sphere due to the voltage applied to the small sphere is

$$G_{12} = \frac{V_1 a (1 - t^2) (t + s^2)}{b^2 (t - s^2)^2} \sum_{n=1}^{\infty} \frac{s^{2n} (1 - t s^{4n-2})}{(1 + t s^{4n-2})^2} \tag{32}$$

If now the large sphere is charged to the potential V_2 while the small one is kept at the potential zero, the gradient at the surface of the smaller sphere will be an expression similar to (32) with t changed to t' and b to a and a to b. It will be more convenient to express this analogous expression still in terms of t and then it will be found that this gradient is:

$$G_{21} = - V_2 F_{21}/X \text{ with}$$

$$F_{21} = \frac{X (1 + t)^2}{a (1 - t)} \sum_{0}^{\infty} \frac{s^{2n+4} (t - s^{4n+4})}{(t + s^{4n+4})^2} \tag{33}$$

The cases when sphere A is charged to the potential V_1 and the sphere B to potential V_2 will have for the gradients:

$$G_1 = G_{11} + G_{21} = V_1 F_{11}/X - V_2 F_{21}/X$$

and

$$G_2 = G_{22} + G_{12} = V_2 F_{22}/X - V_1 F_{12}/X \tag{34}$$

the coefficients F_{22} and F_{12} being of the same form as those for F_{11} and F_{21} with all the a's and b's interchanged. Since it is immaterial which sphere is taken as the first sphere, it is evident that the values of F_{22} and F_{12} may be found to depend reciprocally on those of F_{11} and F_{21}. Thus it is always true that:

$$F_{11} (X/b, a/b) = F_{22} (X/a, b/a)$$

and

$$F_{12} (X/a, b/a) = F_{21} (X/b, a/b). \tag{35}$$

The tables that have been previously given for these coefficients were therefore calculated for F_{11} and F_{21} only but with values of b/a ranging from zero to infinity instead of merely from one to infinity.

When this reciprocal relation is applied to the case of a plane and a sphere, it will be found that the values become indeterminate. But going back to the original relation and allowing b to become infinite, it is found that the factor outside the summation sign in the expressions for F_{22} and F_{12} becomes simply $4 X/\sqrt{X + 2 a X}$ and the corresponding calculations can then be made. These values have been given in Table III.

The gradient at a short distance, h, away from the surface of the sphere with radius a on the line of centers is

$$G_{11} (a + h) = \frac{Q_1}{(a + h)^2} + \frac{Q_2}{(a + h - u_2)^2} + \ldots +$$

$$- \frac{Q_1'}{(d - a - h - u_1')^2} - \frac{Q_2'}{(d - a - h - u_2')^2} - \ldots$$

$$= \frac{Q_1}{a^2} \left(1 - \frac{2 h}{a}\right) + \frac{Q_2}{(a - u_2)^2} \left(1 - \frac{2 h}{(a - u_2)}\right) + \ldots$$

$$- \frac{Q_1'}{(d - a - u_1')^2} \left(1 + \frac{2 h}{d - a - u_1'}\right) - \ldots -$$

so that in the limit as $h \to 0$

$$\frac{d G}{d a} = - 2 \sum_{0}^{\infty} \frac{a + u_{n+1}}{a^2 (a - u_{n+1})^2} Q_{n+1} = - \frac{2 G}{a} \tag{36}$$

This then shows that for short distances away from the surface of the sphere, the variation of the gradient is inversely as the square of the distance from the center of the sphere, a relation that has been given in explicit form in the theoretical discussions.

Appendix II

Coefficients of Gradients for Cross-Cylinders

Pass the plane of the figure, Fig. 10, through the axis of one of the cylinders and perpendicular to the other. Imagine line charges of q units per unit length to be placed at the positions A and B inside of the cylinders so that the cylindrical surfaces are approximately at the required potentials $V/2$ and $- V/2$ respectively. Let the distances be as shown in Fig. 10. At the point H, the gradient is greatest, its value being $G = 2 q [1/Z + 1/(Z + X)]$. The voltage at H is $V/2 = 2 q \log (Z + X)/Z$, so that on putting $X = n Z$ and eliminating q, the gradient is $G = V F/X$, where the coefficient F is given by

$$F = \frac{n (2 + n)}{2 (1 + n) \log (1 + n)} \tag{37}$$

To compute this, it is necessary to find n first. Consider the forces acting at a point P very near to H on the same plane. The resultant R is normal to the surface

at P so that the tangential components of the two constituent forces R_1 and R_2, due to the two line charges at A and B, respectively, must be equal and opposite *i. e.*, $R_1 \sin \alpha_1 = R_2 \sin \alpha_2$. As R_1 and R_2 are inversely proportional to the distances r_1 and r_2, so $r_1/r_2 = (\sin \alpha_1)/(\sin \alpha_2)$. From the triangle $A\,C\,P$, $A\,P/A\,C = \sin \alpha_2/\sin \alpha_1$, *i. e.*,

$$r_1/(R - Z) = (\sin \alpha_2)/(\sin \alpha_1) = r_2/r_1 \qquad (38)$$

As P approaches H, r_2 approaches $Z + X$ and r_1

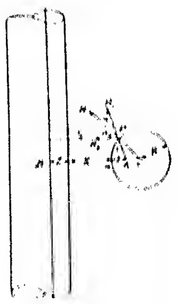

Fig. 10

becomes Z, so that (38) becomes in the limit $Z/(R - Z)$

$$= (Z + X)/Z \qquad (39)$$

With $X = n\,Z$, this can be reduced to a quadratic in n, the solution of which gives:

$$n = \frac{X}{2\,R} - \frac{1}{2} + \frac{1}{2}\sqrt{(X/R - 1)^2 + 8\,X/R} \qquad (40)$$

Thus, for given values of X/R, n can be computed from (40) and substituted into (37) to give the values as given in Table IV.

Discussion

W. B. Kouwenhoven: In Mr. Sah's paper I find no reference to the effect of humidity. At the Johns Hopkins University we have been conducting an elaborate research upon the effect of humidity on the corona-forming voltage; this research is being carried out under our direction at the Bureau of Standards at Washington.

A few weeks ago I received a letter from E. S. Lee of the General Electric Company, saying that he had found that humidity affected his air condenser, and during the same week we obtained our first definite information that this was actually the case. The presence of humidity in the air has an effect on the corona-forming voltage. On perfectly clean surfaces the presence of moisture in the atmosphere raises the corona-forming voltage slightly, the maximum increase we have found is of the order of 1.2 per cent. In order to detect this effect it was necessary to refine our method of measuring and check everything very carefully. At the Bureau of Standards in the research to which I referred a moment ago, they are measuring the wave shape of the voltage directly in the high-voltage side of the circuit and have taken every precaution to insure accuracy. I feel that their results are accurate to at least one part of a 1000, if not better.

We have found also that humidity causes a lowering of the voltage when a corona forms on dirty or dusty surfaces. This lowering of the corona-forming voltage may amount to 5 per cent. In future work with the spark-gap it may be necessary to use correction tables for correcting for the amount of humidity in the air at the time of the test.

A. P. T. Sah: The influence of humidity on sparking voltages has been raised. Our experiments show that it is very small. It is true that humidity has a very pronounced effect on the sparking voltages when corona precedes a spark-over, for instance in the case of the needle gap. But for spherical and cylindrical electrodes, spaced at less than twice the radius of the smaller electrode, corona does not precede a spark-over. Thus in such cases the effect of humidity is negligible as our experiments show.

A Theory of Imperfect Solid Dielectrics

BY MICHEL G. MALTI[1]
Associate, A. I. E. E.

Synopsis.—*This paper covers Chapters VII, VIII, and IX of a thesis presented by the author to the Faculty of the Graduate School of Cornell University, for the degree of Doctor of Philosophy.*

In this thesis a summary is made of the experimental facts regarding the anomalous behavior of solid insulating materials under varying conditions of potential, time, temperature, frequency, humidity, ionizing radiations, and various other factors.

A bibliography containing about 400 articles dealing with experimental and theoretical research is appended to the thesis. These articles are chronologically arranged and numbered.

Five tables are given, including references to experimental research done on (a) dielectric resistivity, (b) dielectric charge and discharge, (c) dielectric constant, (d) dielectric strength, (e) dielectric energy loss.

Hypotheses are here established which account, in a general way, for the observed behavior of solid dielectrics. Definitions of the resistivity, permittivity, electric charge, and electric strength of solid dielectrics under both continuous and alternating potentials are submitted. Terms are introduced and defined: e. g., the "(i—t)-characteristic," the "electrization curve," and the "hystero-viscosity loop."

The various energy losses occurring in dielectrics are traced to their sources and subdivided into hysteresis, viscosity, and resistance losses. Methods are devised for separating the total dissipated energy into its three component parts.

Finally, the classical theory is shown to apply to imperfect solid dielectrics if the submitted definitions and terms be adopted.

* * * * *

Part I. General Considerations and Hypotheses

A. Introduction

THE fact that all theories so far propounded to explain the behavior of solid dielectrics have not stood experimental verification is an indication of the complexity of the phenomena which loom simultaneously whenever insulating materials are electrically tested.

Realizing the futility of a theory built on atomic, molecular, or inter-molecular considerations, the author proposes to abandon such a mode of procedure until our knowledge of the atomic and molecular structure of matter is more mature. This, however, does not prevent us from generalizing the laws governing the behavior of dielectrics nor does it presuppose a complete although temporary abandonment of the whole field of theoretical work. Indeed, if little is known about the physical nature of dielectrics, still less is known about that of magnetics. Yet the engineer, in his lust for the practical application of magnetic materials and their utilization to the highest degree of efficiency, has utterly forsaken any interpretation of the actual internal (molecular and atomic) mechanism of magnetism and has applied himself to the generalization of the gross facts in the form of "working laws."

While this is not the highway trod by the physicist and certainly not scientifically the surest and safest to pursue, yet the justification for the engineer's digression is to be found in the very rapid progress made through the application of such "working laws."

The author's convictions (a) that the electrical behavior of dielectrics is not only atomic but also molecular and inter-molecular; (b) that a complete knowledge of the atomic structure is a prerequisite to a clear understanding of the molecular and inter-molecular configuration; and finally (c) that our meager knowledge of the atomic structure furnishes but a slight encouragement to a prospective mastery of molecular structure, all lead him to pursue, gladly although reluctantly, the trodden path already followed by the engineer in the case of magnetism.

Such a course does not, however, prevent our formulating a picture of the internal workings of dielectrics. Indeed, a few general hypotheses will be next outlined, not with the view of building a mathematical theory of molecular behavior, based on them, but rather with the object of presenting a very sketchy interpretation of the internal phenomena which occur in a dielectric. The value of these hypotheses consists in their adaptability for explaining certain dielectric phenomena.

B. Hypotheses Governing Dielectric Behavior

1. We shall first postulate the existence of three types of electrons in solid dielectrics: free electrons, elastically bound electrons, and viscously bound electrons.

a. The free electrons are responsible for the process of electrical conduction. They actually traverse the body of a dielectric and form what is generally termed the "leaky current." The value of that current is a function of the number of free electrons present as well as the velocity with which they traverse the circuit. The existence of such electrons accounts for the phenomenon of dielectric conductivity.

b. The elastically bound electrons are not free to traverse the dielectric but are displaced under the action of an electric field, from their normal position. Their displacement is instantaneous. Moreover, with this type of electrons, action and reaction are reversible (see Part II-E). The well known phenomenon of dielectric polarization is due, in part, to the existence of this class of electrons.

c. The viscously bound electrons form a class which possesses characteristics that are intermediate between

1. Instructor in Electrical Engineering, Cornell University, Ithaca, N. Y.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

those of classes a and b. These electrons are neither free nor elastically bound. They creep rather sluggishly under the action of an electric field and, in the first stages of the field application, act as if they were free conduction electrons. But as time proceeds, their displacement from the position of equilibrium, in some cases, ceases to increase and they assume a new fixed position, thereby contributing to the polarization of the dielectric and resembling the elastically bound electrons in this respect. The existence of this type of electrons finds confirmation in the phenomenon of residual charge and in the well known shape of the "hystero-viscosity loop" (see Part II E).

2. The foregoing three classes of electrons shall be arranged in three descending orders according to the elasticity of their bonds. The elastically bound electrons shall be considered as belonging to the highest or *first order*, the viscously bound electrons to the *second*, and the free electrons to the *third* order.

3. Although the electrons existing in a dielectric are thus arbitrarily subdivided according to the elasticity of their bonds, it must not be supposed that the elasticity of all electrons belonging to one class is the same. We shall therefore assume, as a separate hypothesis, the existence of various degrees of elasticity within every class of electrons. The two lines of demarcation between the three classes will consist of (1) the reversibility of action and reaction of the perfectly elastic electrons and (2) the absolute freedom of motion of the free electrons.

4. It will be next assumed that the three types of electrons, although distinct in their characteristic behavior, are physically identical. Therefore, an electron belonging to one order may easily assume the characteristic behavior of one belonging to a lower, or a higher order. Such an electron shall then be classified with that order. The external factors which determine the characteristic behavior of the various electrons are the magnitude of the potential applied, the temperature of the sample, the frequency of the e. m. f. source, ionizing radiations, the physical condition of the dielectric, time of potential application, humidity of the sample, and the chemical composition of the dielectric. Thus, with an increase of applied potential, some of the heretofore viscously bound electrons might become free electrons and may, in their turn, be replaced by some of the elastically bound electrons. Confirmation of this hypothesis is to be found, for example, in the increase of the dielectric conductivity γ with an increase in the potential gradient G.

5. This change of an electron or a group of electrons from a higher to a lower order or vice versa shall be assumed to be a discontinuous function of the factor causing the change. For example, within a certain range of potential the total number of electrons, in a given specimen, belonging to any one class, remains the same. A change in their number does not occur until the upper or lower limit of that range of potential shall have been exceeded. This hypothesis explains the results of the conductivity measurements made in (54-21),* where a distinct and abrupt change in the conductivity of calcite, quartz, rocksalt, and mica is noted at certain definite potential gradients, which vary from 51 to 10,000 volts per mm. depending upon the dielectric. Moreover, it is there shown that the same potential limits reveal themselves in the phenomenon of charge where a brisk change in the straight line relation of the $(Q - E)$ curve occurs. The existence of more than one potential limit is easily explained by the third hypothesis.

6. The fourth hypothesis presupposes the necessity of subdividing the various values that a factor (*e. g.*, temperature, potential, etc.) may assume, into several *ranges*, each having for its limits the critical values at which the dielectric behavior assumes an abrupt change. For example, the various values that the potential gradient may assume from zero to G_s may be subdivided into various ranges $A, B, C \ldots . N$ such that $G_A, G_B, G_C \ldots . G_N$ are respectively the upper, and $O, G_A, G_B, G_C, \ldots . G_{N-1}$ the lower limits of ranges $A, B, C, \ldots . N$.

7. We shall further postulate that the transfers of electrons from one order to another (see the fourth hypothesis) are not necessarily superposable. To illustrate this hypothesis let G_A be the upper limit of the potential gradient for range A, and let N_1, N_2, and N_3, be the number of electrons in a certain specimen belonging to the first, second, and third order, respectively. Now, if the potential gradient be raised to G such that $G > G_A$ and then lowered again to G' such that $G' < G_A$, the number of electrons belonging to each order will then be N_1', N_2', and N_3', such that $N_1' \leqq N_1$, $N_2' \leqq N_2$, and $N_3' \geqq N_3$. The nature of the dielectric, its previous history, the magnitude of G, and the time allowed for the internal readjustments to ensue, are among the factors which determine the values N_1', N_2', and N_3'. This hypothesis explains the phenomena of potential hysteresis and temperature hysteresis referred to in (1/80, 13/94, 13-02, 38-08, 39-10, 4-16, 32-16, and 109-21).

8. Finally, it will be assumed that, for ranges exceeding the initial range A, action and reaction are not superposable. This at once limits Curie's law of superposition to just that range and further explains the phenomena revealed by the researches quoted in paragraph 7.

It is hoped that with the foregoing hypotheses a plausible explanation could be made of the various phenomena known as dielectric anomalies. As an illustration of the application of these hypotheses, the phenomenon of residual charge will be explained.

When an e. m. f. is impressed, for a time (t), on a slab of solid dielectric, placed between two metal plates,

*All numbers (*eg.*, 54-21 or 1/80) occurring in this paper, refer to articles in the bibliography.

a current i flows through the connecting wires. This current may be divided into two components; the one i_r, leaks through the body of the dielectric, while the other, i_c, results in the accumulation of charge on the plates. The conduction current i_r is due to the existence of free electrons in the dielectric. The negative charge, which accumulates on one of the plates due to the charging current i_c, exerts a repulsive effect on the elastic and viscous electrons of the dielectric, thereby displacing them from their natural position of equilibrium. The actual molecular condition of the dielectric thus electrically stressed, is far from being known. The net result, however, may be visualized by imagining the negative charges on the plate as repelling the elastic and viscous electrons of the adjacent molecules of the dielectric and attracting their protons. This same phenomenon is communicated by the successive molecules to adjacent ones, thereby forming the state shown in Fig. 1 where the circles represent polarized adjacent molecules. The polarization is not altogether instantaneous because it takes the viscous electrons some time to attain their final positions of equilibrium. The negative and positive charges which appear on the surfaces adjacent to the positive and negative plates

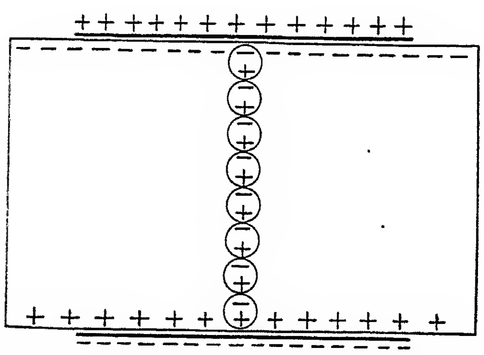

FIG. 1—POLARIZATION IN A SOLID DIELECTRIC

respectively act as counter e. m. fs. opposing the action of the impressed potential. The e. m. f. due to the polarization on each side shall be denoted by the letter E_p. Therefore, the total polarization e. m. f. is $2\,E_p$.

Now, as soon as the impressed e. m. f. is removed, the elastic electrons rebound instantaneously to their positions of equilibrium, thereby making available, for recombination upon short circuit, an equal number of electrons. The viscous electrons, however, being more or less sluggish, do not return instantaneously to their initial positions. The dielectric therefore persists in a state of polarization. Owing to this continued existence of polarization in the body of the dielectric, only a portion of the electrons accumulated on the negative plate of the condenser are available for recombination at the first discharge; the remainder are held by the polarized positive protons of the dielectric. If the condenser is allowed to rest after this first discharge, the internal polarization in the dielectric becomes less intense due to the return of some of the viscous electrons to their neutral position. Thus more electrons, on the negative plate, become available for recombination during the succeeding discharge. This process may be repeated ad infinitum or until all the viscous electrons have resumed their original neutral positions. The dielectric is then in an electrically neutral state and its polarization is nil.

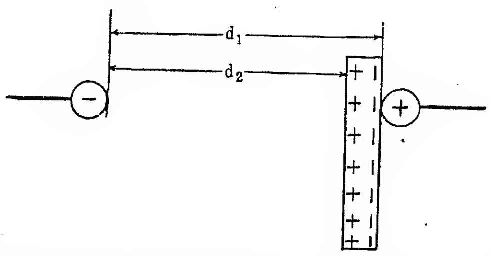

FIG. 2—DECREASE IN THE SPARKING DISTANCE OF A GAS DUE TO PLACING A SOLID DIELECTRIC NEAR THE ANODE

Interesting experiments supporting this view are described in (24-00, 12-02 and 23-18) where two knobs placed in air are subjected to a potential slightly lower than the sparking potential. When a glass rod is placed immediately touching the positive knob and lying in the space between the knobs, a spark passes, but no spark passes at all if the rod is placed anywhere else. The explanation of this phenomenon is that the polarization of the glass rod results in an effective decrease of the sparking distance, from d_1 to d_2 as shown in Fig. 2. That this phenomenon does not take place when the rod is placed next to the negative electrode can be easily explained because it is well known that a spark passes more easily when the point is negative and the plate positive than when the point and plate charges are otherwise.

Part II. Definitions of Terms

A. THE RESISTIVITY ρ OF SOLID DIELECTRICS

1. *Resistivity at Continuous Potential.*

The resistance R of a solid dielectric with a continuous applied potential will be defined as:

$$R = \lim_{t \to t_r} (E - 2\,E_p)/I_r \qquad (1)$$

The notations used in equation (1) may be visualized by referring to Fig. 4.

From equation (1) the resistivity ρ will be:

$$\rho = R\,a/d = [(E - 2\,E_p)/I_r]\,(a/d) \qquad (2)$$

For continuous potentials, and within the same potential range ρ will be constant. However, ρ will assume lower values as higher ranges of potential are reached until at the breakdown potential ρ becomes practically zero. The resistivity defined by equation (2) is easily measured because all the quantities on the right hand side are determinable. E_p is the only factor which seems difficult to measure. Its value, however, may be experimentally determined as was done in (53-15) and (2-25) by first impressing E for a time t_r, then suddenly decreasing E to such a value that i_r

becomes zero. This new value of E at which $i_r = 0$ is the value of $2E$, while (53-15) shows that if this is done, R (at least in the case of quartz and iceland spar) is not only independent of E, within certain limits, but it is also independent of the time t.

2. *Resistivity at Alternating Potentials.*

The value of ρ can thus be experimentally determined when continuous potentials are used. With alternating potentials, the conduction current cannot be experimentally separated from the charging current. The method generally adopted of measuring the power dissipated in a condenser and taking ρ of such a value that $W = I^2 R$, is physically erroneous, because of the fact that the energy dissipated is largely a hysteresis loss, and the $I^2 R$ loss forms but a very small percentage of the total dissipated energy (see 2, 82, 94-12, and 17-15).

Two questions arise in regard to the resistivity when alternating potentials are used:

a. What conception must be formed of ρ with alternating potentials?

b. If ρ is a function of the potential range, what value of ρ must be adopted when alternating potentials assume instantaneous values which fall within more than one potential range?

The answer to the first question is that the concept of ρ with alternating potentials should not differ from that of ρ with continuous potentials.

The answer to the second question would lead to a definition of an effective resistance which, although having no physical basis when the potential gradient exceeds the initial range, leads to an approximate determination of the true $I^2 R$ loss when alternating potentials are used. Thus let $t_1, t_2, \ldots t_n$ be the times at which the sinusoidal voltage wave (Fig. 3) assumes instantaneous values $e_1, e_2 \ldots e_n$ such that $e_1 = E_A, e_2 = E_B, \ldots e_n = E_N$, where $E_A, E_B \ldots E_N$ are the upper potential limits of the potential ranges $A, B \ldots N$.

Then

$$\left.\begin{aligned} W_{r1} &= \int_0^{t_1} (i_{rA})^2 R_A \, d\,t = R_A \int_0^{t_1} (i_{rA})^2 \, d\,t \\ W_{r2} &= \int_{t_1}^{t_2} (i_{rB})^2 R_B \, d\,t = R_B \int_{t_1}^{t_2} (i_{rB})^2 \, d\,t \\ &\ldots\ldots\ldots\ldots \\ W_{rn} &= \int_{t_{(n-1)}}^{t_n} (i_{rN})^2 R_N \, d\,t = R_N \int_{t_{(n-1)}}^{t_n} (i_{rN})^2 \, d\,t \end{aligned}\right| \quad (3)$$

where $i_{rA}, i_{rB} \ldots i_{rN}$ are the conduction currents, $R_A, R_B, \ldots R_N$ are the resistances and $W_1, W_2 \ldots W_n$ are the energy losses that would be obtained at continuous potentials lying within the ranges $A, B \ldots N$.

If hypothesis 8 is correct, then for the initial range A, i_{rA} will be a sinusoidal function of time. Moreover, its effective value will be equal to the final steady value of the conduction current obtained with a continuous potential equal in magnitude to the effective value of an alternating potential whose amplitude is E_A.

The value of the first integrand in equation (3) will then be

$$W_{r1} = R_A \int_0^{t_1} [(I_{rA} \sqrt{2}) \sin \omega\, t]^2 \, d\,t$$

$$= (I_{rA}^2 R_A) \left[t_1 - \frac{\sin 2\,\omega\, t_1}{2\,\omega} \right] \quad \textbf{(4a)}$$

The other integrands in equation (3) cannot be so easily evaluated because, according to the eighth hypothesis, we cannot assert that the conduction currents $I_{rB} \ldots I_{rN}$ are sinusoidal. However, if we should follow the procedure adopted in obtaining equation (4a), the error will be only in the deviation of the current from the sinusoidal value. This error, for potential gradients lying well below the rupturing

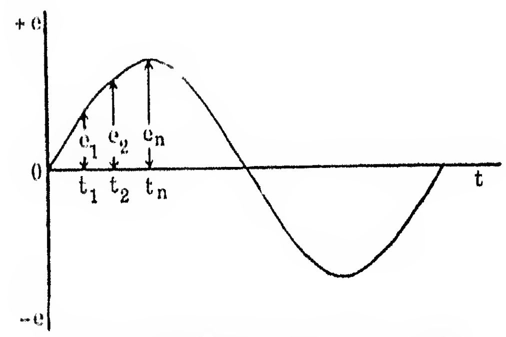

FIG. 3—A SINE WAVE OF VOLTAGE

gradient G_s, cannot be very large. We shall therefore evaluate the remaining integrands as was done in the case of the first and obtain:

$$W_{r2} = (I_{rB}^2 R_B) \left[(t_2 - t_1) - \frac{\sin 2\,\omega\, t_2 - \sin 2\,\omega\, t_1}{2\,\omega} \right] \quad \textbf{(4b)}$$

$$\ldots\ldots\ldots\ldots$$

$$W_{rn} = (I_{rN}^2 R_N) \left[(t_n - t_{n-1}) - \frac{\sin 2\,\omega\, t_n - \sin 2\,\omega\, t_{n-1}}{2\,\omega} \right] \quad \textbf{(4n)}$$

Therefore the total energy dissipated per ¼ of a cycle is:

$$W_r = (W_{r1} + W_{r2} + \ldots + W_{rn}) \quad (5)$$

But with actual conducting materials the energy loss due to the passage of a current of effective value I_{rN} for a period of time $T/4$ is:

$$W_{rn} = I_{rN}^2 R_N \, T/4$$

from which

$$R_N = 4\, W_{rn} / I_{rN}^2 \, T \quad (6)$$

The equivalent resistance of a dielectric at sinusoidal potentials, having instantaneous values which extend

over more than one potential range, may be analogously defined as

$$R_{eq} = 4\,(W_{r1} + W_{r2} + \ldots W_{rn})/I_{rN}^2\,T \qquad (7)$$

where W_{r1}, W_{r2} . . . W_{rn} are defined by equations (4)

At voltages whose amplitudes do not exceed the initial potential range, equation (4a) for ¼ of a cycle becomes:

$$W_r = I_{rA}^2\,R_A\,T/4 \qquad (8)$$

Therefore, the resistance of a slab of dielectric at such alternating potentials is equal to that obtained by using

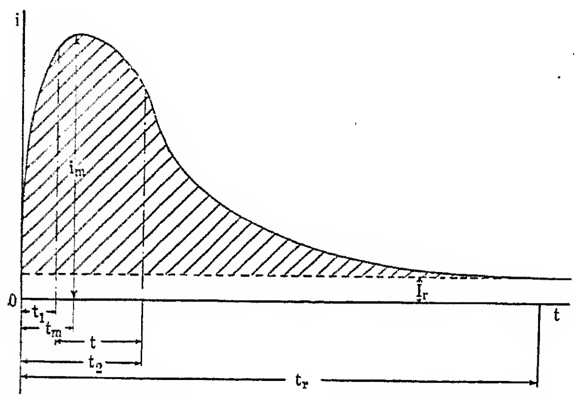

FIG. 4—THE $(i - t)$-CHARACTERISTIC OF A SOLID DIELECTRIC

a continuous potential of a magnitude equal to the effective value of the alternating potential.

It must be remembered that I_{rA} in equation (8) is *not* the effective value of the alternating current, flowing through the condenser, as measured with an a-c. ammeter. It actually corresponds to I_r in equation (1); *i. e.*, it is the true conduction current read at a time t_r on a d-c. instrument, when a continuous potential of a magnitude equal to the effective value of the alternating potential is applied to the condenser.

B. ELECTRIC CHARGE AND DISCHARGE OF SOLID DIELECTRICS

1. *The Charge with Continuous Potentials.*

a. Definition: If, for a definite temperature, humidity, and continuous potential, current readings be taken at various intervals of time, for a circuit with R, L, and C, then, upon plotting those readings, Fig. 4 will be obtained.

The charge acquired by the dielectric in the interval of time $t = (t_2 - t_1)$ will be defined thus:

$$Q = \int_{t_1}^{t_2} (i - I_r)\,d\,t = \int_{t_1}^{t_2} i_c\,d\,t \qquad (9)$$

In equation (9), i is the current measured at any instant and I_r is the leaky current represented by the constant value which it assumes after a time t_r; see equation (1).

b. Remarks on Fig. 4.

1. The value of the charge Q, expressed by equation (9), can be graphically represented by that part of the shaded area in Fig. 4, included between t_1 and t_2. It will be noted that Q is a function not only of the magnitude, $t = t_2 - t_1$, of the time interval, but also of the actual values of the limits t_1 and t_2. For the extreme case where $t_1 = t_r$ and $t_2 > t_r$, the charge is zero because $i - I_r = 0$.

2. The time t_m, corresponding to the maximum value i_m, is solely a function of the constants R, L, and C of the circuit. It can be reduced to a minimum by making $L \rightarrow 0$.

3. The actual value i_m is a function of the dielectric material, the applied voltage gradient, temperature, and various other factors.

4. The character of that section of the curve which extends from t_m to t_r is an indication of the relative number of the three types of the electrons present in the dielectric as well as the degree of viscosity of the electrons belonging to the second order. Indeed, the curve is a function of the rate of growth of the polarization e. m. f. which forms on the boundary surface between the plates and the dielectric. This is best illustrated by Fig. 5, where curves are drawn for various materials possessing the same dielectric resistivity but having different $(i - t)$ - characteristics.

Curve a represents the $(i - t)$ - characteristic of an ideal condenser. The ascending and descending portions of the curve are identical. The descending part of the curve is a reproduction of the inverted ascending portion. Moreover, owing to the perfect elasticity of the ether, i_m is just a point on the curve. Again the final current becomes zero because a perfect condenser is devoid of any conductivity.

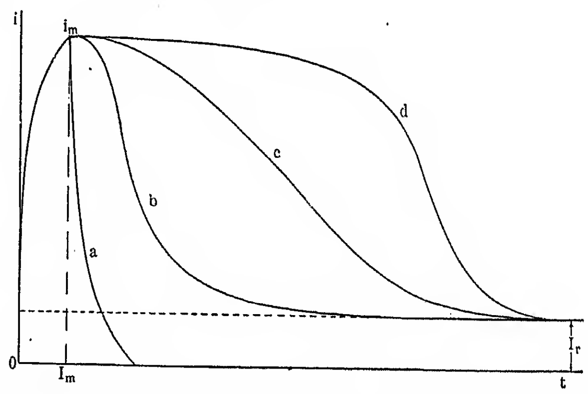

FIG. 5—VARIOUS SHAPES OF THE $(i - t)$-CHARACTERISTICS OF SOLID DIELECTRICS

Curve b stands for a condenser whose dielectric is rich in highly elastic electrons; the portion of the curve beyond t_m is very steep, showing that each of the viscous electrons possesses, to a more or less extent, the same degree of viscosity. That the value of i_m extends for a certain length along the curve, is an indication of the existence of viscous electrons, because it shows that the polarization took some time before approaching its steady final value.

Curve c is drawn for a condenser whose electrons have varying degrees of viscosity as indicated by the gentle

slope of the curve and the time it takes for the polarization to be complete.

Curve d shows that although the electrons are very highly viscous, as indicated by the time required for the first point of inflection to occur, there exists very little difference in their degrees of viscosity. The very steep descent of the curve, as soon as the polarization attains its final value, is an indication of this latter fact.

5. While, in general, a dielectric which possesses the characteristic *Curve b* (Fig. 4) within a certain potential or temperature range, may be expected to exhibit a similar characteristic at other ranges, it must not be inferred that this always holds true. Indeed the behavior of a dielectric is a very complicated function of its internal structure. Therefore, it is very likely that the same dielectric will exhibit the various characteristics represented by *Curves b, c,* and *d,* at different potential ranges. This will be in strict conformity with the hypotheses laid down in Part I.

2. *The Charge with Alternating Potentials.*

a. Some Laws and Corollaries: The $(i-t)$-characteristic represented by Fig. 4 is true for steady continuous potentials. With alternating potentials the shape of the current-time curve is further complicated by the fact that e is a function of time.

Before formulating a definition of charge with alternating potentials we shall cite the laws of charge and discharge established in 2/89, taking the liberty to introduce such changes in them as have been necessitated by more recent researches.

Law 1. Within the initial potential range and for the same conditions of temperature, humidity, etc.,

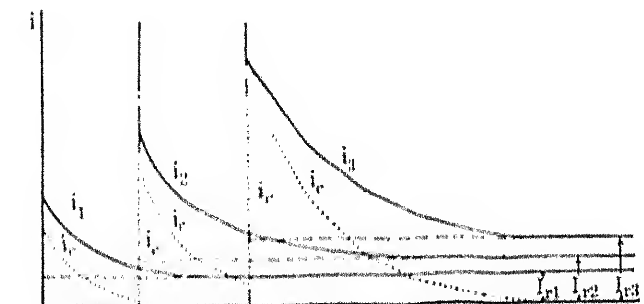

FIG. 6 THE RESULTANT CHARGING CURRENT DUE TO SUCCESSIVELY INCREASING POTENTIALS IMPRESSED UPON A DIELECTRIC

the value of $i_c = (i - I_r)$ for a dielectric at one and the same instant of time (t), after impressing the potential, is proportional to the applied potential E. Thus, if i_c and i_c' are the charging currents measured at an instant t after impressing voltages E and E', respectively, and if E and E' are both less than the upper limit E_A of the initial potential range A, then

$$E/E' = i_c/i_c' \tag{10}$$

Law 2. The charging current i_c, due to successively increasing potentials impressed at successive instants on a condenser, is equal to the sum of the charging currents that would be produced by each potential acting alone, provided none of these potentials exceeds the upper limit E_A of the initial potential range. Thus, let $E_1, E_2, E_3 \ldots . E_n$ be successively impressed on a condenser at times $t_1 < t_2 < t_3 \ldots . < t_n$ and let $E_1 < E_2 < E_3 < \ldots . < E_n < E_A$, then

$$i_{c1} + i_{c2} + i_{c3} \ldots . + i_{cn} = i_c \tag{11}$$

In order to visualize this law, imagine a circuit of such a small inductance that the time t_m, Fig. 4, may

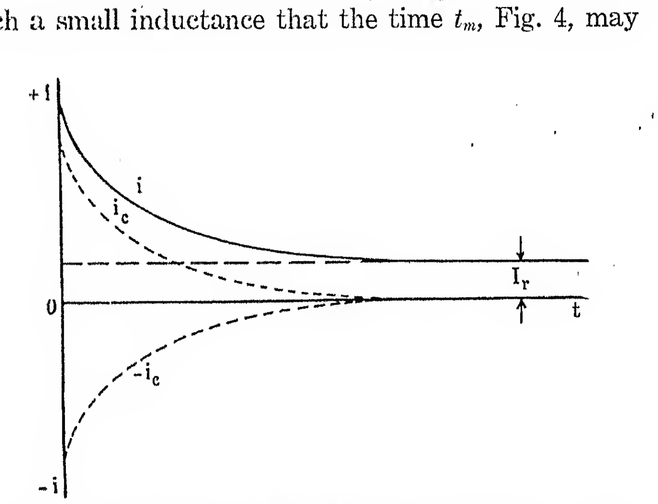

FIG. 7—THE CHARGE AND DISCHARGE CURRENTS OF A SOLID DIELECTRIC

be neglected. The voltages $E_1, E_2 \ldots . E_n$ applied at times $t_1, t_2 \ldots . t_n$ will give rise to the currents $i_1, i_2 \ldots . i_n$; Fig. 6. Then the charging currents $i_{c1}, i_{c2} \ldots . i_{cn}$ will be:

$$\left.\begin{aligned} i_{c1} &= i_1 - I_{r1} \\ i_{c2} &= i_2 - I_{r2} \\ &\ldots\ldots \\ i_{cn} &= i_n - I_{rn} \end{aligned}\right\} \tag{12}$$

and the instantaneous value of the total charging current $i_c = i_{c1} + i_{c2} + \ldots . + i_{cn}$ will be represented by the dotted curve.

Corollary 1. As is pointed out by Curie (2/89), one consequence of Law 2 is that the charging current curve is identical with that for the discharge current curve, but of opposite sign. The discharging of a condenser at short circuit is indeed equivalent to introducing into the circuit a voltage $(-E)$, equal in magnitude but opposite in direction, to that of the impressed voltage. If acting alone, this newly introduced voltage would cause a charging current identical in shape with, but opposite in sign to, the original charging current as is shown in Fig. 7.

Unfortunately this law does not apply to potentials higher than the upper limit of the initial potential range. (See references in hypothesis 7, Part I.) This accounts for the limitation introduced in formulating the law and for the statement made in the eighth hypothesis.

Corollary 2. Up to a certain time t the total charge acquired by a condenser, due to successively increasing

potentials, is equal to the sum of the charges that would be acquired if each of the potentials were acting alone. Thus if $i_{c1}, i_{c2} \ldots i_{cn}$ be the charging currents due to potentials $E_1 < E_2 < \ldots < E_n \ldots < E_A$, impressed at times $t_1 < t_2 < \ldots < t_n$, then the total charge Q acquired by the condenser from t_1 to $t > t_n$ is $Q = Q_1 + Q_2 \ldots + Q_n$ or

$$Q = \int_{t_1}^{t} i_{c1}\, d\, t + \int_{t_2}^{t} i_{c2}\, d\, t + \ldots + \int_{t_n}^{t} i_{cn}\, d\, t \qquad (13)$$

Law 3. The value of the charging current i_c due to a continuous potential E applied to a condenser for more than an infinitesimally short interval (*i. e.* an interval sufficiently long to cause a displacement of the elastic electrons but not of the viscous electrons), is proportional to the interval of time through which the potential acts.

This is a very specious law; it will always remain as a hypothesis because it does not lend itself to experimental verification. Its plausibility will be evident, however, if we admit the hypotheses postulated in Part I. Indeed, if viscous electrons require some time to attain their final displacement, one would naturally expect the time element to enter as a necessary factor in determining the value of i_c.

b. The Equations for the Charging Current and Charge Acquired with Alternating Potentials. Let the potentials $E_1, < E_2, < \ldots < E_n$ be comprised between the limits 0 and E_m, and let $t_1 < t_2 < t_3 \ldots > t = T/4$ be the times at which these potentials are applied. Let E_m be the amplitude and T the period of the sinusoidal applied potential whose equation is

$$e = E_m \sin \omega\, t \qquad (14)$$

then

$$\left.\begin{array}{l} E_1 = E_m \sin \omega\, t_1 \\ \cdots\cdots\cdots \\ E_n = E_m \sin \omega\, t_n \end{array}\right\} \qquad (15)$$

According to the first law expressed by equation (10), the value of the charging currents i_u and i_v measured at the same instant t after impressing E_u and E_v respectively, is

$$i_{cu}/i_{cv} = E_u/E_v = [E_m \sin \omega\, t_u / E_m \sin \omega\, t_v]$$
$$= \sin \omega\, t_u / \sin \omega\, t_v \qquad (16)$$

and for the particular case where $t_v = T/4$ equation (16) becomes

$$i_{cu}/i_{cm} = E_u/E_m = \sin \omega\, t_u/1$$

whence

$$i_{cu} = (\sin \omega\, t_u)\, i_{cm} \qquad (17)$$

In what follows, two notations for time, t and τ, will be adopted in order to differentiate between time measured along the abscissa of the voltage curve (Fig. 8A), and that measured along the abscissa of the $(i - t)$ characteristic (Fig. 8B). Therefore t will be used for voltage variation and τ for charging-current variation with time.

Let

$$i_{cm} = f\left(\tau - \frac{T}{4}\right) \qquad (18)$$

be the function expressing the value of the charging current due to a continuous potential (of magnitude E_m equal to the maximum value of the alternating potential) which is impressed on the condenser at time $t = \frac{T}{4}$. Then the function expressing the value of the charging current for any other continuous potential of magnitude $E = E_m \sin \omega\, t$ impressed on the condenser at a time t and acting through an angle $d\,(\omega\, t)$ will be, by equation (17) and law 3,

$$d\, i_c = f\,(\tau - t)\,(\sin \omega\, t)\, d\,(\omega\, t) \qquad (19)$$

and the total current at any time $\tau \overline{\gtrless} t$ due to all the

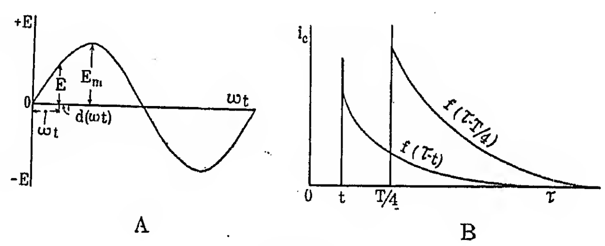

FIG. 8
A—A SINE WAVE OF POTENTIAL
B—THE CHARGING CURRENTS DUE TO TWO INSTANTANEOUS VALUES OF AN ALTERNATING POTENTIAL

instantaneous voltages from 0 to τ each of which acts for an interval $d\,(\omega\, t)$, will be:

$$i_c = \int_0^{\tau} f\,(\tau - t)\,(\sin \omega\, t)\, d\,(\omega\, t) \qquad (20)$$

and the charge Q acquired during ¼ of a cycle is

$$Q = \int_0^{T/4} i_c\, d\, \tau = \int_0^{T/4} \left[\int_0^{T/4} f\,(\tau - t)\,(\sin \omega\, t)\, d\,(\omega\, t) \right] d\, \tau \qquad (21)$$

The same reasoning can be extended to potentials with instantaneous values exceeding the initial potential range. Referring to Fig. 4, let $t_1, t_2, \ldots t_n$ be the times at which the sinusoidal voltage assumes instantaneous values $e_1, e_2, \ldots e_n$, so that $e_1 = E_A$, $e_2 = E_B, \ldots e_n = E_N$, where $E_A, E_B, \ldots E_N$ are the upper potential limits of the potential ranges $A, B, \ldots N$, respectively. Let $f_A\,(\tau - t_1)$, $f_B\,(\tau - t_2) \ldots f_N\,(\tau - t_n)$ be the functions expressing the variations of $i_{c1}, i_{c2}, \ldots i_{cn}$ with τ at continuous voltages $E_A, E_B, \ldots E_N$. Then by analogy with equation (21), the value of i_c at any time τ, according to the corrections indicated, equation (20a) will become:

$$
\left.
\begin{array}{ll}
i_{cA} = \displaystyle\int_0^{\tau} f_A(\tau - t)(\sin \omega t)\, d(\omega t) & 0 \leq \tau \leq t_1 \\[2ex]
i_{cB} = \left.\begin{array}{l}\displaystyle\int_0^{t_1} f_A(\tau - t)(\sin \omega t)\, d(\omega t) + \\ \displaystyle\int_{t_1}^{\tau} f_B(\tau - t)(\sin \omega t)\, d(\omega t)\, .\end{array}\right| & t_1 \leq \tau \leq t_2 \\[2ex]
\cdots\cdots\cdots\cdots\cdots\cdots & \\[2ex]
i_{cN} = \left.\begin{array}{l}\displaystyle\int_0^{t_1} f_A(\tau - t)(\sin \omega t)\, d(\omega t) + \\ \displaystyle\int_{t_1}^{t_2} f_B(\tau - t)(\sin \omega t)\, d(\omega t) + \\ \cdots\cdots\cdots \\ + \displaystyle\int_{t_{N-1}}^{\tau} f_N(\tau - t)(\sin \omega t)\, d(\omega t)\end{array}\right| & t_{N-1} \leq \tau \leq t_n
\end{array}
\right\}
\tag{20a}
$$

The charge acquired by the condenser will be:

$$Q = \int_0^{T/4} i_{cN}\, d\tau \tag{21a}$$

where i_{cN} is expressed by equation **(20a)**.

c. Discussion of Equations (21) and (21a). In equation **(21)** the function $f(\tau - t)$ is that portion of the curve shown in Fig. 4 and extending from t_m to t_r. It should be determined at a continuous voltage equal to the amplitude E_m of the alternating potential. This function will vary with the material of the dielectric, the temperature and humidity of the specimen, and the physical condition of the dielectric.

Equation **(21)** comprises the essence of the cause for the decrease of charge with the frequency of the applied potential. Indeed, the mere inspection of equation **(21)** shows that the value of Q is a function of the upper limit $\frac{T}{4}$. The higher the frequency, the smaller is T and consequently the smaller the value of the integrand. In equation **(21a)**, the values of i_{cA}, i_{cB} . . . i_{cN} substituted from equation **(20a)** contain $f_A(\tau - t)$, $f_B(\tau - t)$ . . . $f_N(\tau - t)$. These functions should be determined at continuous potentials of magnitudes equal to E_A, E_B, . . . E_N.

d. Discussion of Equations (20) and (20a). Equations **(20)** and **(20a)** give the instantaneous values of the charging current i_c for sinusoidal alternating potentials. The shape of this curve will certainly be distorted when instantaneous values of the applied potentials exceed the initial potential range. Whether distortion exists when the amplitude of the applied potential does not exceed the upper limit of the initial potential range, is a question which can be answered only when $f(\tau - t)$ is known. In general, with dielectrics that are rich in elastic electrons or whose viscous electrons have a high degree of elasticity, distortion may be negligible. However, with very viscous dielectrics, a certain degree of distortion in the sine form of the charging current wave may well be expected.

At all events, the current computed from equations **(20)** and **(20a)**, whether sinusoidal or not, will have an effective value which can be computed. It must be remembered that the value of current determined by a current measuring instrument when alternating potentials are impressed on a condenser is the effective value not only of the charging current but of the leaky current, as well as of the current necessary to supply the viscosity and hysteresis losses discussed in part E of this paper. The value of equations **(20)** and **(20a)** consists, therefore, in affording a means of computing the true value of the charging current, thereby separating the current supplied to a condenser into its various components.

C. THE "DIELECTRIC PERMITTIVITY" K OF SOLID DIELECTRICS

Imagine two condensers No. I and No. II, of the same physical dimensions. Let the space between the plates of condenser No. I and condenser No. II be filled with a solid dielectric and vacuum respectively. Let the charges acquired by condensers No. I and No. II, when each is submitted to the same potential, be Q_I and Q_{II}. Then the dielectric permittivity will be:

$$K = Q_I / Q_{II} \tag{22}$$

For continuous potentials:

$$K_1 = \frac{\displaystyle\int_0^{t_r} i_c\, dt}{\displaystyle\int_0^{t_r} i_c'\, dt} = \frac{\text{equation (9)}}{\displaystyle\int_0^{t_r} i_c'\, dt} = \frac{\text{equation (9)}}{E\, K_v\, a/d} \tag{23}$$

For alternating potentials where no instantaneous value exceeds the upper limit of the initial potential range:

$$K_2 = \frac{\text{equation (21)}}{\displaystyle\int_0^{T/4} i_c' (\cos \omega t)\, dt} = \frac{\text{eq. (21)}}{\text{eq. (45)}} \tag{24}$$

and for alternating potentials where instantaneous values do exceed the upper limit of the initial potential range:

$$K_3 = \frac{\text{equation (21a)}}{\displaystyle\int_0^{T/4} i_c' (\text{Cos } \omega t)\, dt} = \frac{\text{eq. (21a)}}{\text{eq. (45)}} \tag{25}$$

The denominators in equations (23), (24), and (25)

can be very easily computed; see Part III. The numerators are defined by equation (**9**) with the limits changed from 0 to t_r, and by equations (**21**) and (**21a**) respectively.

The definitions given above take account of all the factors which influence K; see discussions of equations (**21**) and (**21a**). Moreover, the values of K, determined from these equations will be different for the same material if f and G be changed. The "dielectric constant" is thus a very inappropriate term. A better appellation, "dielectric coefficient", has been suggested. This new name is here replaced by the more descriptive and shorter one, **permittivity,** adopted by some text books. The writer regrets that he has never met with this term in reading the literature.

D. Electric Strength of Solid Dielectrics

1. *Dielectric Strength with Continuous Potentials.*

a. **Definition.** The electric strength (G_s) of a solid dielectric at constant conditions of the factors enumerated in Part I hypothesis 4, and for continuous potentials is:

$$G_s = (E_s - 2\,E_p)/d \qquad (26)$$

b. **Discussion of Equation (26):** The notations used in equation (**26**) will be defined as follows:

G_s = the voltage gradient at which rupture occurs. As indicated by equation (**26**), G_s is *not* obtained by dividing the applied potential by the dielectric thickness (d).

E_s = any voltage lying within the potential range S. This potential range comprises all values of voltage which, when applied to a specimen, will cause rupture.

$2\,E_p$ = the polarization potential which exists on the boundary surfaces between the plates and the dielectric of a condenser and makes its presence felt not only in the case of dielectric strength but also in all other phenomena connected with solid dielectrics.

For one and the same rupturing potential, E_p is a function of:

(1) The time of potential action.

(2) The method of applying the voltage.

(1) *E_p vs. time of Potential action:* If E_p is a polarization e. m. f., then it might be argued that since, in the case of viscous dielectrics, E_p increases with time, see Fig. 4, remark 4, then for G_s to remain constant, E_s must increase as the time of voltage application increases. Experiment shows that this is not the case. On the contrary, E_s decreases the longer the time of voltage application. This apparent contradiction to the definition proposed in equation (**26**) can be easily refuted if use is made of the fourth hypothesis established in Part I. At such high potentials, very radical changes occur in the characteristic behavior of the individual electrons belonging to the various orders. Thus many of the viscous electrons become conduction electrons and a large number of the elastic electrons becomes highly viscous. Therefore, as time proceeds, E_p decreases instead of increasing because of the continual depletion in the number of electrons which can and do take part in the polarization process. G_s thus increases as the time of voltage application increases.

(2). *E_p vs. Method of Applying the Voltage:* Experiment shows (53-19 and 87-25) that E_s is lower when the rupturing potential is attained by a slow rather than by a rapid increase of potential. This phenomenon is in strict conformity with the fourth hypothesis. Its explanation is the same as that given by the foregoing paragraph.

Besides accounting for the above observations, the introduction of E_p into the definition of G_s, explains the phenomenon of the decrease in the value of the rupturing gradient with an increase in the thickness of a dielectric. The polarization e. m. f. is in fact independent of the thickness. Moreover, there exists no reason for supposing that the rupturing gradient, (G_s), *within* the dielectric, would vary with (d). If

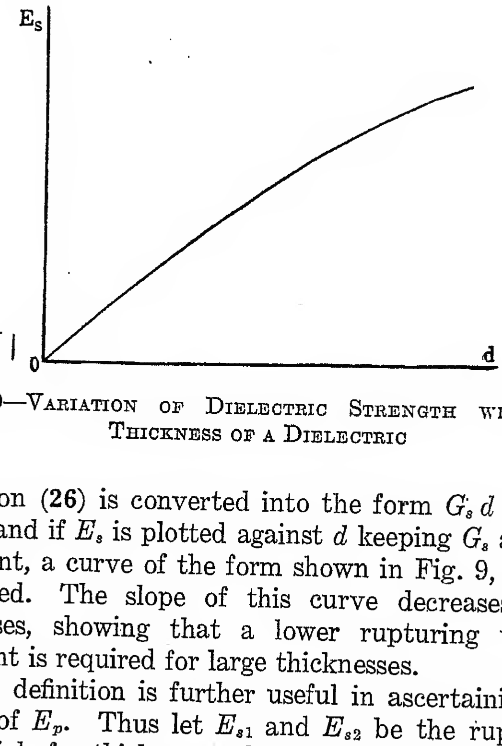

Fig. 9—Variation of Dielectric Strength with the Thickness of a Dielectric

equation (**26**) is converted into the form $G_s\,d + 2\,E_p = E_s$ and if E_s is plotted against d keeping G_s and E_p constant, a curve of the form shown in Fig. 9, will be obtained. The slope of this curve decreases as d increases, showing that a lower rupturing voltage gradient is required for large thicknesses.

This definition is further useful in ascertaining the value of E_p. Thus let E_{s1} and E_{s2} be the rupturing potentials for thicknesses d_1 and d_2, then by equation (**26**):

$$G_s = (E_{s1} - 2\,E_p)/d_1 = (E_{s2} - 2\,E_p)/d_2$$

from which

$$2\,E_p = (E_{s2}\,d_1 - E_{s1}\,d_2)/(d_1 - d_2) \qquad (27)$$

In applying equation (**27**) care should be exercised that the ruptures in the two samples of dielectric occur under identical conditions as to time and method of applying the potential. Moreover, the samples must be identical in every respect except for thickness. Equation (**27**) does not hold for built-up insulation made of such materials as paraffined paper or cambric,

because polarization potentials exist between the various layers of insulation, thus rendering the samples electrically different.

Besides furnishing a satisfactory explanation of the phenomena already cited, equation (**26**) accounts for the facts quoted in (9-04 and 89-25); *viz.*, that the majority of punctures occur along the edge rather than between the plates and that a lower potential will rupture a dielectric when the spark passes at the edge than when it occurs between the plates. Indeed these phenomena are due to nothing other than the presence of the polarization potential at the contact surfaces. Its effect is to reduce the voltage gradient in that portion of the dielectric which lies within the plates, thereby rendering rupture much easier at the edge where the voltage gradient is higher.

2. Dielectric Strength with Alternating Potentials.

a. **Definition:** The dielectric strength with alternating potentials may be defined similarly to equation (**26**) if it be remembered that E_s is a function of time

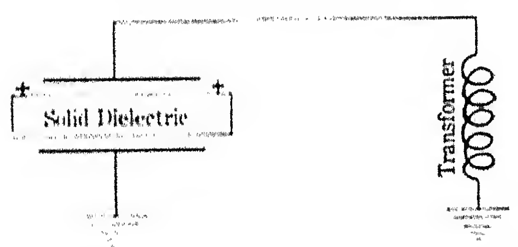

Fig. 10 Unidirectional Polarization of a Dielectric Under Strong Alternating Fields

and E_p is a very erratic quantity which varies not only with the amplitude but also with the frequency of the applied potential. The natural tendency is to substitute sine functions for E_s and E_p and to define dielectric strength at alternating potentials as:

$$G_s \sin \omega t = [E_s \sin (\omega t + \theta) - 2 E_p \sin (\omega t + \phi)]/d \qquad (28)$$

where θ and ϕ are the respective angles between the E_s and the G_s vectors; and between the E_p and the G_s vectors.

Experiment shows, however, (70-20) that, at high alternating potentials, E_p is unidirectional. Moreover, if the connections are as shown in Fig. 10, then a positive charge will appear on the dielectric as indicated.

If this be the case when the plates touch the dielectric, then equation (**28**) becomes:

$$G_s \sin \omega t = (E_s \sin \omega t + E_p)/d \qquad (29)$$

As breakdown occurs more readily when the voltage gradient within the dielectric is highest, it is very natural to assume that rupture would take place when $\omega t = 90$ deg. We then have

$$G_s = (E_s + E_p)/d \qquad (30)$$

Equation (**30**) accounts for the fact that the breakdown occurs at a lower value with alternating than with continuous potentials. It contradicts, however, the known facts alluded to in the discussion of equation (**26**). Moreover, should the findings of (70-20) be utterly discarded, as not applicable to the case when the condenser plates do touch the dielectric, and equation (**28**) be adopted, we shall have three unknowns (θ, ϕ, and E_p) to determine for each dielectric. This leads to utterly fruitless results. Indeed, the writer has done this very thing. But, upon using experimental data to determine these constants, he obtained conflicting values. The length of the mathematical development of equation (28) and the fruitlessness of its results have led the writer to exclude it from this paper.

The absence of valuable data on the nature of dielectric breakdown with alternating potentials renders the formulation of a theory, or even a definition thereof, a matter of wild conjecture. In fact, various experimenters have endeavored to explain the phenomenon, that breakdown occurs at comparatively lower values with alternating than with continuous potentials, by maintaining that the heat generated in the sample due to dielectric hysteresis, with alternating potential, raises the temperature of the sample. Therefore, since G_s decreases as temperature increases, the voltage required to break down a sample is lower when alternating than when direct potentials are used. The writer begs to disagree with the propounders of the so called pyro-electric theory of breakdown (76-21, 104-22, 124-22, and 56-24) on the following grounds:

1. The energy dissipated in a dielectric in the period from the time of voltage application to the time of breakdown is indeed hardly sufficient to raise the temperature of that dielectric to such a degree as to account for the comparatively large decrease in the value of E_s when alternating potentials are used (106-23).

Undoubtedly, for very prolonged potential application, the phenomenon of heat does exert an effect on the rupturing voltage by raising the temperature of the sample. However, a theory built wholly on this effect is of necessity erroneous.

2. Actual temperature measurements (87-25) show that no temperature rise exceeding 10 deg. cent. does occur in glass before rupture.

A close analogy to breakdown with alternating potentials is furnished by the familiar process of breaking a piece of metal by repeated, alternate bending in two mutually opposite directions. The alternate compression and tension seem to be too much for the metal to stand. If an elastic piece of metal breaks down when bent with a certain force F acting *in one direction,* that same piece of metal will also break when a force $F' < F$ acts on the metal alternately in opposite directions. The phenomenon is ascribed to fatigue. An analogous reasoning may be applied to the rupturing potential which acts on dielectrics.

That fatigue does play a prominent part in the phenomenon of breakdown, is shown by (47-23 and 69-25).

In the absence of crucial research on the phenomenon of breakdown, we have to depend on tabulated data of the rupturing potentials. Such data, however, will be valuable only when accompanied with a detailed account of the various conditions under which the breakdown tests are made. Such conditions include: (a) mode of potential application, (b) frequency and wave form of the source, (c) temperature, (d) humidity, (e) shape of electrodes, (f) physical condition and thickness of the dielectric.

E. The Energy Dissipated in Solid Dielectrics

1. *Causes of Energy Dissipation*:

The energy dissipated in solid dielectrics may be due to one or all of the following three clauses:

a. The resistance of a dielectric to the flow of current,

b. Dielectric hysteresis,

c. Dielectric viscosity.

No successful attempt has been made, so far, to separate the total energy loss into its three component parts. Moreover, the three sources of energy loss are not clearly defined. It will be our object, therefore, (1) to investigate the sources of these losses in the light of the established hypotheses; (2) to introduce definitions of the three types of energy loss; and (3) to devise means for the separation of the total energy dissipated into its three component parts.

2. *Sources of Energy Loss with Alternating Potentials.*

In view of the hypotheses established in Part I we shall consider separately the behavior of the three types of electrons in a dielectric subjected to alternating potentials.

a. **Perfectly Elastic Electrons.** When an alternating potential is applied to a dielectric, all the electrons are displaced from their neutral position of equilibrium. Those that are perfectly elastic will be displaced by a distance which may or may not be proportional, at every instant, to the instantaneous value of the impressed voltage. However, for this type of electrons, the same relation between the distance by which the electron is displaced and the instantaneous value of the applied potential exists no matter whether this distance be measured at increasing or decreasing values of potential. If δ is plotted as ordinate and $E_m \sin \omega t$ as abscissa, we get the curves shown in Fig. 11B.

Whether the curve is of the form (A) or (B) will depend entirely upon the characteristics of the individual electron. The interesting fact to remember is that the curve closes on itself and therefore no energy is lost.

b. **Perfectly Viscous Electrons.** The displacement of the viscous electrons gives a very different curve from the ones shown in Fig. 11B. Here the electron displays no elasticity; consequently, it continues to creep in the same direction irrespective of the instantaneous value of the impressed potential, provided that value maintains the same sign. As soon as the polarity of the applied voltage changes, the direction of creepage reverses. The distance covered by the creeping electron is at any instant directly proportional both to the instantaneous value of the applied potential and to the time through which that instantaneous value acts. We thus have for the displacement due to

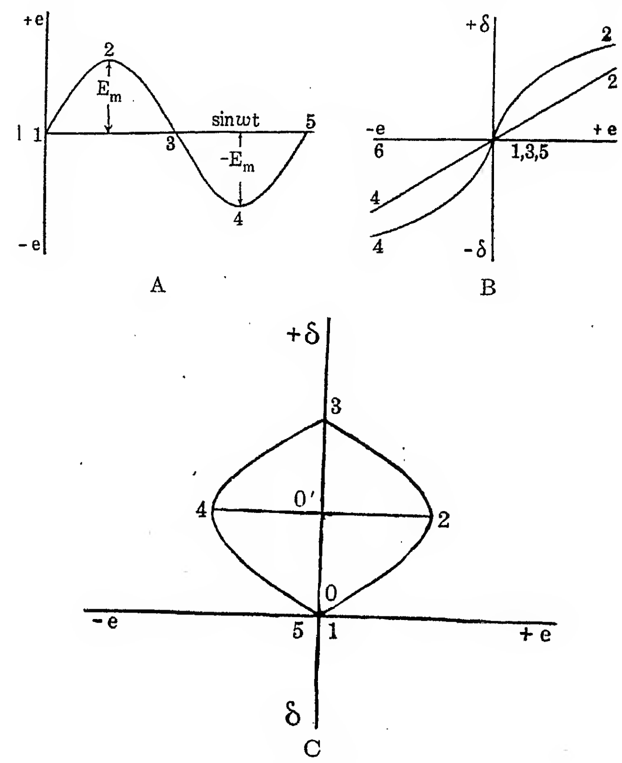

Fig. 11

A—A Sine Wave of Voltage

B—Variation in the Displacement of a Perfectly Elastic Electron with Voltage

C—Variation in the Displacement of a Perfectly Viscous Electron with Voltage

any potential $= E_m \sin \omega t$ and acting for an instant Δt:

$$\Delta \delta = h E_m \sin \omega t \, \Delta t$$

and for the total displacement attained during a time from 0 to t:

$$\delta_t = h E_m \int_0^t \sin \omega t \, dt = \frac{- h E_m}{\omega} \cos \omega t \qquad \textbf{(31)}$$

This curve is plotted in Fig. 11C. It can be best visualized by shifting the origin O to the point O'. The existence of ω in the denominator of equation (**31**) shows that δ_t is a function of the period of the impressed potential.

c. **Slightly Elastic or Partially Viscous Electrons.** In the case of the partially viscous electrons, the elasticity of their bonds furnishes them with enough resilience to rebound whenever the impressed potential

suffers a decrease. The distance by which they rebound is a function of their elasticity, the value of the impressed voltage, and the decrease suffered by that potential. The curve given in Fig. 12 is representative of one type of such a hysteresis loop. For other types of loops, the reader is referred to the very interesting work (51-21) wherein several loops are plotted with charge as abscissa against applied potential as ordinates.

d. **The Hystero-Viscosity Loop.** The hystero-viscosity loop (Fig. 12) may be determined for any dielectric as follows:

A continuous potential-gradient G_1 is impressed on the dielectric for a time t_1 and the charge Q_1 (see Fig. 4), acquired by the dielectric during the interval t_1 is measured. The charge density D_1 will then be:

$$D_1 = Q_1 / a \tag{32}$$

The gradient is next raised to G_2, the charge Q_2 acquired in the time 0 to t_2 is measured and D_2 computed. This process is repeated until the maximum

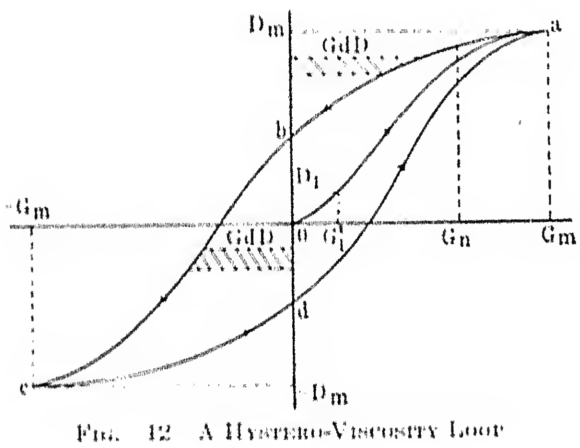

FIG. 12 A HYSTERO-VISCOSITY LOOP

gradient G_m, for which the loop is required, has been attained. We thus obtain the curve $0\,a$ (Fig. 12) which we shall call the "electrization curve" in analogy to the "magnetization curve."

Just as in the magnetization curve the permeability at any field intensity is $\mu = B / H$, so here the absolute permittivity K' of a dielectric at any voltage gradient G is:

$$K' = D / G \tag{33}$$

The voltage gradient is next lowered to a value $G_n < G_m$. If G_n is low enough, *i. e.*, if $E_n < 2\,E_m$ a current will flow in the reverse direction for a time t_n at which time its value becomes zero. This reverse current is due to the fact that, the polarization potential being in excess of the new impressed potential, some of the elastic electrons rebound to their original position, thereby allowing a part of the charge on the plates to recombine. Moreover, the recombined charge in the dielectric is exactly equal to the released charge. If we measure this recombined charge and subtract its value from Q_m we obtain the charge Q_n which remains in the condenser at the gradient G_n. D_n will then be Q_n/a. By a similar process we may compute D_{n-1} at G_{n-1} . . . and D_0 at $G = 0$.

As the time element is of importance in determining this loop, ample time should be allowed for the viscous electrons to readjust themselves to each new state. Therefore, the time consumed in determining the curve $a\,b$ should be at least equal to that spent in ascertaining the curve $0\,a$. Moreover, the short circuit (at $G = 0$) should last long enough to allow all electrons which possess any degree of elasticity at all to rebound to their normal position. This time cannot be fixed for it depends upon the type of material experimented on.

The length of the line $0\,b$ represents the residual charge due to purely viscous electrons. These electrons, being utterly devoid of resilience, need a *coercive force* in the opposite direction to move them to their original neutral position.

The polarity of the applied potential is now reversed at the point b, and the density of charge D, corresponding to any gradient G, measured, as indicated above, until the negative maximum gradient $(-G_m)$ is attained. We thus obtain the curve $b\,c$. The curve $c\,d$ is obtained similarly to the curve $a\,b$ by successively increasing the potential from $(-G_m)$ to zero.

Finally the curve $d\,a$ is plotted from data observed, as described above, by successively increasing the potential from zero to G_m.

e. **The physical nature of the hysteresis and viscosity losses.** The area of the loop will be shown in Part III to represent the maximum unrecoverable energy dissipated in a dielectric due to both viscosity and hysteresis at an infinitely low frequency. The question arises as to what part of the loss should be assigned to hysteresis and what part to viscosity. Before answering this question we shall enter into a discussion of the physical nature of both losses.

The hysteresis loss (W_h) will be ascribed to two causes: (1) the energy dissipated in the adjustment and readjustment of the electrons (both viscous and elastic) to each new variation in potential, and (2) the energy dissipated in the transfer of electrons from a higher to a lower order.

In order to form a picture of the first cause of hysteresis loss, imagine a crowd in a theater where a fire suddenly breaks out. The heretofore orderly populace at once assumes the characteristics of a mob. Each person will knock about in all directions and against all sorts of people before he gains an exit. A great deal of unrecoverable energy is liberated from the mob in the form of excitement, mental stress, noise, and bodily contacts and combats. The condition of affairs is the more frantic the greater the extent of the conflagration. Moreover, in the first stages of the disaster only the quick and energetic members of the mob take part in the excitement. All slow persons behave, for a time, as though nothing extraordinary had occurred until they awaken from their stupor to discover

the peril confronting them. Indeed, if the manager of the theater has enough presence of mind and preparedness to suddenly stamp the fire and place matters under control, those dull, unfortunate (or perhaps fortunate) individuals would hardly suspect that anything had happened. They therefore do not take part in the excitement, and, except for the room they occupy, thereby obstructing the exit of the excited element, they may be considered as an utterly negligible factor in the commotion that takes place.

Such is the state of affairs when the mob of molecules in a solid dielectric is suddenly exposed to a potential gradient. Some unrecoverable energy is liberated in the form of molecular oscillation and molecular friction. Moreover, in the first stages of impressing the potential, practically all the energy dissipated is due to the more or less elastic electrons, the highly viscous ones supplying only a very small portion, in the form of obstruction. As time proceeds, however, they also supply their share of the total lost energy. This loss, however, shall be ascribed to viscosity.

That part of the hysteresis loss which is expended in changing the status of an electron from a higher to a lower order hardly needs comment. The energy of an electron belonging to a lower, is less than that of an electron connected with a higher order. Therefore, when a transfer does occur, the extra energy is naturally liberated in the form of heat.

The hysteresis loss, so defined, is independent of time and is a function only of the nature of the dielectric, its temperature, and the maximum gradient (G_m) attained. The true hysteresis loss per unit volume can be experimentally determined by impressing upon a dielectric potentials of the same amplitude but of different frequencies and noting the range of frequency at which the energy dissipated per cycle becomes constant. The loss per unit volume for frequencies lying within this range is the true hysteresis loss. Unfortunately this loss cannot be represented by a loop of the form shown in Fig. 12; because the element of time effects the shape and size of this loop. Therefore the only similarity that exists between magnetic and dielectric hysteresis is that of the physical nature of the two phenomena. Fortunately, at high fields, magnetic materials reveal no viscosity and the loss per cycle due to magnetic hysteresis may be actually represented for unit volume, by the area of the hysteresis loop. Such is not the case with dielectric materials. The loop in Fig. 12 thus represents the loss per unit volume due both to hysteresis and viscosity at an infinitely low frequency.

The Viscosity Loss (W_h) will also be ascribed to two causes: (1) the energy dissipated in the very slow adjustment and readjustment of the viscous electrons to each new variation of potential, and (2) the energy expended in supplying the work required by the electrons in creeping from their normal position through a distance δ and back again (see Fig. 11c). As both of these factors are increasing functions of time, the extent of the loss due to viscosity can be determined only indirectly as we shall see presently. The hystero-viscosity loop thus offers only an estimate of the magnitude of the combined loss, per cycle per unit volume, due to both hysteresis and viscosity, at infinitely low frequencies.

The above reasoning is strongly supported by (103-22, 9-23, 107-24, 63-10, 12-12, 85-12, and 55-14) which show that the energy loss per cycle, per unit volume is either a decreasing function of the frequency or independent of it. As to the relation of loss to the potential gradient, this will largely depend upon the nature of the dielectric and its behavior under the various potential ranges. Thus no definite relation can be established between the hystero-viscosity loss and the impressed potential.

3. Definitions and Separation of Dielectric Losses.

a. **The Resistance Loss (W_r).** The loss per unit volume, per cycle due to the resistance of a dielectric to the passage of current, at alternating potentials, shall be defined as follows:

1. For potentials whose amplitudes exceed the upper limit E_A of the initial potential range A,

$$W_{r1} = 4 \text{ (equation 5)}/V \quad \text{Joules/cm.}^3 \qquad \textbf{(34a)}$$

2. For potentials whose amplitudes *do not* exceed the upper limit E_A of the initial potential range A,

$$W_r = 4 \text{ (equation 8)}/V \quad \text{Joules/cm.}^3 \qquad \textbf{(34b)}$$

b. **The Total Loss (W_D)** dissipated per unit volume per cycle shall be defined as the total loss, measured by known methods, divided by the volume of the dielectric, divided by the number of cycles made during the time of running the test.

$$W_D = \text{(Measured Loss per cycle)}/V \quad \text{Joules/cm.}^3 \qquad \textbf{(35)}$$

For the same amplitude of applied potential, W_D will decrease as the frequency is increased, until a frequency f' is reached beyond which the loss per cycle is constant and independent of the frequency. This particular value of W_D will be defined as:

$$W_{Df'} = \text{(Measured constant loss per cycle)}/V \text{ Joules/cm.}^3 \qquad \textbf{(36)}$$

c. **The Loss due to Hysteresis (W_h):** The hysteresis loss per unit volume per cycle at any frequency shall be defined as follows:

1. For potentials whose amplitudes exceed the upper limit E_A of the initial potential range A,

$$W_h = \text{(equation (36))} - \text{(equation (34a))} \text{ Joules/cm.}^3 \qquad \textbf{(37a)}$$

2. For potentials whose amplitudes do not exceed the upper limit E_A of the initial potential range A,

$$W_h = \text{(equation (36))} - \text{(equation (34b))} \text{ Joules/cm.}^3 \qquad \textbf{(37b)}$$

d. The Losses due to Viscosity (W_v): Energy dissipated per unit volume per cycle due to viscosity shall be defined as:

$$W_v = (\text{equation } (35)) - (\text{equation } (36)) \text{ Joules/cm.}^3 \quad (38)$$

It must be remembered that the above equations hold true only under constant conditions of voltage gradient, temperature, humidity, etc. The only factors here eliminated are time and frequency.

Part III. Applications of the Classical Theory of Electrostatics to Solid Dielectrics

The classical theory of electrostatics holds true only for vacuum, a non-anomalous, perfect dielectric. It will be our object to show how the formulas and deductions arrived at in this theory may be applied to solid, anomalous dielectrics.

A. *The Concept of Capacitance (Permittance).* Experiment shows that for one and the same dielectric the capacitance (permittance) of a plane condenser (permittor) similar to the one shown in Fig. 1, varies directly as the area exposed to the plates and inversely as the thickness of the dielectric. This gives the equation:

$$C = K\,K_v\,a/d \text{ farads} \quad (39)$$

where K is defined by equation (23) for continuous, and by equation (24) or equation (25) for alternating potentials, and K_v is a constant given by equation (42) below.

Equations (23), (24), and (25) give the relative permittivity of a dielectric instead of the absolute permittivity. The absolute permittivity is equal to the relative permittivity multiplied by the permittivity of vacuum. It so happens that in the electrostatic system of units $K_v = 1$. Therefore, the absolute and relative permittivities in this system of units are identical. In Heaviside's system, however, $K_v \neq 1$; see equation (42). This accounts for introducing K_v as a factor in equation (39). Whenever the term permittivity is used it will be understood to mean relative permittivity. The symbol K' will be used for absolute permittivity; see equation (33).

The permittance of a vacuum permittor is similarly defined as:

$$C_v = K_v\,a/d \text{ farads} \quad (40)$$

Moreover, since in the case of vacuum, Q is proportional to E for all potential ranges, we have:

$$Q_v = C_v\,E = K_v\,E\,a/d \text{ coulombs} \quad (41)$$

The value of K_v in Heaviside's system of units can be shown to be:

$$\left.\begin{aligned} K_v &= 0.08242 \times 10^{-12} \text{ farads/cm. cube} \\ &= 0.2244 \times 10^{-12} \text{ farads/inch cube} \end{aligned}\right\} \quad (42)$$

Therefore, Q_v for a vacuum condenser can be easily ascertained. Its value is identical with Q_{11} in equation (23).

The denominators of equations (24) and (25) can be computed by making use of the fact that the capacitive reactance of a vacuum condenser at a frequency f is:

$$X_c = 1/(2\,\pi\,f\,C) = d/(2\,\pi\,f\,K_v\,a) \text{ ohms} \quad (43)$$

$$i_c' = E_m \cos \omega\,t / X_c = (2\,\pi\,f\,K_v\,a/d)\,E_m \cos \omega\,t \text{ amperes} \quad (44)$$

and

$$\int_0^{T/4} (i_c' \cos \omega\,t)\,d\,t = 2\,K_v\,a\,E_m/d \text{ coulombs} \quad (45)$$

Equation (45) expresses the value of the denominator in equation (24) and equation (25) in terms of the amplitude of the applied potential and the dimensions of the condenser.

B. *The Concept of Elastance.* As it is sometimes convenient for the purpose of computations to use the inverse of certain constants we shall use the term elastance S and define it as:

$$S = 1/C = (1/K)\,(1/K_v)\,(d/a) \quad (46)$$

In equation (46) the term $(1/K)$ shall be known as the "elastivity" of a dielectric and shall be denoted by the letter σ thus:

$$\sigma = 1/K \quad (47)$$

The value of σ will vary inversely with K and will depend upon (a) the amplitude and frequency of the alternating potential used, or (b) the magnitude of the applied continuous potential.

Similarly the elastivity of vacuum is:

$$\begin{aligned} \sigma_v = 1/K_v &= 11.3 \times 10^{12} \text{ darafs/cm. cube} \\ &= 4.45 \times 10^{12} \text{ darafs/inch cube} \end{aligned} \quad (48)$$

Substituting equations (47) and (48) in (46), we have:

$$S = (\sigma_v)\,d/a \quad (46a)$$

With these new definitions of permittance and elastance the well known relation:

$$Q = C\,E \quad (49)$$

becomes true for all potential ranges because the variation between Q and E is accounted for by the variation in the value of the coefficient C.

With continuous potentials, the writer would suggest the use of the electrization curve (Fig. 12) to define the absolute permittivity K' of a dielectric at any potential gradient G and for any charge density D. Then the value of C in equation (49) will be:

$$C = K'\,a/d \quad (50)$$

From equation (49) we have $Q = E/S$ or

$$E = Q\,S \quad (51)$$

But $E = G\,d$, $Q = D\,a$, and $S = (\sigma\,\sigma_v)\,d/a$

Substituting these values in equation (50) and simplifying:

$$G = \sigma\,\sigma_v\,D \quad (52)$$

from which

$$D = G/\sigma\,\sigma_v = G\,K\,K_v \quad (53)$$

Equations (51) and (52) hold true only for constant potential gradients and constant charge densities. For

variable values of these quantities integration should be resorted to. We thus have:

$$E = \int G\,d\,d \tag{54}$$

and

$$Q = \int D\,d\,a \tag{55}$$

C. Energy in Dielectrics. Consider a plane concondenser (Fig. 1) which has a plate area (a) and a thickness (d). If i is the instantaneous value of the current supplied by the source of e. m. f. of instantaneous value e, then the energy delivered by the source during any interval of time $d\,t$ will be

$$d\,W = e\,i\,d\,t = e\,(i_c + I_r)\,d\,t \tag{56}$$

and the total energy supplied during an interval of time t_r is:

$$W = \int_0^{t_r} e\,i_c\,d\,t + \int_0^{t_r} e\,I_r\,d\,t$$

$$= \int_0^{t_r} e\,d\,q + \int_0^{t_r} e\,I_r\,d\,t \;.\;.\;.\text{ watt seconds} \tag{57}$$

The energy per unit volume supplied to the dielectric is:

$$W' = W/a\,d = \int_0^{t_r} (e/d)\,(d\,q/a) + \int_0^{t_r} (e/d)\,(I_r/a)\,d\,t$$

$$= \int_0^{t_r} G\,d\,D + \int_0^{t_r} G\,U\,d\,t \text{ watt sec/cm.}^3 \tag{58}$$

Forgetting for a moment the second integrand in equation (**58**) (because its value does not enter in the energy storage), we shall prove that the area of the hysteresis loop (Fig. 12) represents the energy dissipated per unit volume per cycle, on account of hysteresis and viscosity at an infinitely low frequency.

1. From the point a to the point b, each decrease (G), in the voltage gradient, results in a corresponding decrease $d\,D$ in the density of charge accumulated on the dielectric. Therefore, energy is delivered from the dielectric to the external circuit. The amount of energy per unit volume is, according to equation (**58**),

$$-\,W_{ab}' = -\int_a^b G\,d\,D = -\,(\text{Area } a\,b\,D_m) \tag{59}$$

2. During the part of the cycle extending from b to c energy is supplied from the source of e. m. f. for the purpose of transporting the viscous electrons represented by the line $o\,b$ to their neutral position and for the further object of charging the condenser in the reverse direction. This energy may be represented by equation (**58**) as:

$$+\,W_{bc} = \int_b^c G\,d\,D = (\text{Area} - D_m\,b\,C) \tag{60}$$

3. Similarly, from the point c to the point d, energy is delivered by the dielectric to the circuit of such amount that

$$W_{cd} = -\int_c^d G\,d\,D = -\,(\text{Area} - D_m\,C\,d) \tag{61}$$

4. Finally, the energy supplied to the dielectric during the part of the cycle $d\,a$ is

$$W_{da} = \int_d^a G\,d\,D = (\text{Area } d\,a\,D_m) \tag{62}$$

The net energy retained by the dielectric and dissipated in the form of hysteresis loss per cycle per unit volume is:

$$\begin{aligned} W_h + W_v &= (\text{equation } (\mathbf{60}) + \text{equation } (\mathbf{62})\,) \\ &\quad - (\text{equation } (\mathbf{59}) + \text{equation } (\mathbf{61})\,) \\ &= \text{Area of the loop } a\,b\,c\,d\,a \end{aligned} \tag{63}$$

Notations

Symbol	Quantity	Units
a	Area	Cm².
c	Chemical composition of a dielectric	
C	Capacitance (Permittance)	Farads
c	(Subscript) charge	
d	Thickness	Cm.
d	(Subscript) discharge	
D_c, D_d	Charge and discharge density	Coulombs/cm.²
E	Voltage (Continuous or effective)	Volts
e	Voltage, instantaneous	Volts
f	Frequency	Cycles/sec.
G	Voltage gradient	Volts/cm.
H	Humidity	= Per cent
I	Current, continuous or effective	Amperes
i	Current, instantaneous	Amperes
K	Dielectric constant (Permittance)	Numeral
M	Material of electrodes	
N	Refractive index; any number	
p	Physical condition of a dielectric	
P	Mechanical pressure on a dielectric	kg./cm.³
p	(Subscript) Polarization thus E_p = polarization e. m. f.	
Q_c	Charge	Coulombs
Q_d	Discharge	Coulombs
R	Resistance	Ohms
R_γ	Ionizing radiations	
s	Shape of electrodes	
S	Elastance = i/C	Darafs.
s	(Subscript) strength thus G_s = dielectric strength	
t,	Time	Sec.
T	Temperature	Deg. Abs.
U	Current density	Amps./cm.²
V	Volume	Cu. cm.
W	Energy	Watt-sec.
W'	Energy density	watt. sec/cu. cm.
ρ	Resistivity	mho/cm.³
γ	Conductivity	ohm/cm.³
σ	Elasticity	Darafs.
θ ϕ	Angles	Deg.
ω	$2\pi f$ (Angular velocity)	radians/sec.
$A, B, \ldots S$	(Subscripts) Limits of ranges	
$A, B \ldots S$	(Not subscripts) Ranges.	

Appendix

TABLE SHOWING EXPERIMENTAL EVIDENCE RELATIVE TO THE VARIATION OF *R, Q, K, G*, AND *W*, WITH THE VARIOUS FACTORS INDICATED AS COLUMN-HEADINGS

(For interpretation of column headings see notations)

Property of dielectric	Mode of variation	Number of researches showing the mode of variation with:												
		G	*t*	*f*	*T*	*P*	*H*	℞	*s*	*M*	*a*	*d*	*c*	*p*
Resistivity ρ	Direct	0	10	1	0	0	0	0	0	0	0	2	0	0
	Inverse	19	0	1	28	2	10	12	0	0	0	0	0	0
	Indefinite	0	1	1	3	0	0	0	0	3	0	0	2	15
	No	0	0	0	0	0	0	0	0	0	0	0	0	0
Charge Q	Direct	21	21	0	9	3	2	3	0	0	0	0	0	0
	Inverse	0	0	0	1	0	0	0	0	0	0	0	0	0
	Indefinite	0	0	0	0	0	0	0	1	0	0	1	0	2
	No	0	0	0	0	0	0	0	0	0	0	1	0	0
Permittivity K	Direct	3	7	0	20	4	1	5	0	0	0	0	0	0
	Inverse	1	0	23	3	5	0	0	0	0	0	0	0	0
	Indefinite	0	0	0	1	0	0	0	0	1	0	0	3	12

Discussion

S. J. Rosch: In considering the total loss in a dielectric, Mr. Malti claims to have been able to separate that particular loss due to hysteresis and he gives an expression $W_h = W_d - I^2 R$. In justification of this expression he states that as the frequency of the test voltage is increased, the loss per cycle decreases until some value of frequency is reached after which the loss per cycle remains a constant.

In order to accept this equation, we must assume that the loss due to hysteresis is constant at the lower frequencies. That is, something we have not as yet been able to substantiate and until its accuracy has been deduced as the result of experimental work in connection with different dielectrics, I would counsel caution in the acceptance of this expression.

Nevertheless, as a working hypothesis, the point is well taken and it would certainly be a worth-while fact for some of the research engineers to establish as a step toward the better understanding of the behavior of an imperfect solid dielectric.

E. S. Lee: The mechanism of dielectric breakdown is still unknown to us. Mr. Malti suggests the occurrence of certain internal phenomena in the dielectric to account for external phenomena as observed. While these internal conceptions may possibly be helpful, he does not make it clear how they may be made useful for prediction of phenomena not as yet observed. If this might be done, his work would have greater value.

Mr. Malti indicates the absence of crucial research on the phenomenon of breakdown. This is the dielectric property of greatest interest. There surely ought to be recognition of the large amount of work of high caliber which has been carried on and published relative thereto, which, if it has not been crucial research, has nevertheless given us considerable insight into the phenomena involved and the magnitude of their extent.

F. M. Clark: In discussing Mr. Malti's paper I am thinking more of the oil-treated cellulose material than I am of the type such as mica and glass.

Mr. Malti is to be congratulated in attacking the electronic phase of dielectric failure. I think, however, that he has perhaps fallen out of the frying pan into the fire when he endows his electrons with a degree of mentality. He has three or four different types of electrons. Free electrons, we can dispense with by the statement that they are there. If we want to increase them we subject the insulation to ionizing radiation, but when we come to electrons of various degrees of viscosity ranging all the way from elastic to viscous electrons, I am rather doubtful as to the source of those electrons themselves.

In view of the fact that he admits as everyone does that the electrons are practically identical with regard to charge and mass, it is hard to see how two electrons under the same conditions can one of them choose to be elastic and the other one choose to be rather viscous.

I want to suggest an idea on which we are working in the laboratory of the General Electric Company; that is, the consideration of the dielectric problem from the standpoint of molecular moment. If we have a molecule in which the center of mass gravity corresponds to the center of electrical gravity, we say it has no moment. That molecule ought to be inert chemically and a very good dielectric. If, on the other hand, we have the center of mass gravity not corresponding with the center of electrical gravity, then we have a molecule which is endowed with electric moment. With this fundamental idea, one can explain most dielectric behavior very similarly to the way Mr. Malti has done in adopting different viscosities for electrons.

I can illustrate one point very simply in following out that idea. I hope we shall soon have our data ready to present before the Institute. Mr. Malti discusses polarization. If you adopt the polar molecule you will get the same sort of a diagram as Mr. Malti has obtained. But immediately you raise the question that in some molecules, preferably with paraffin material, the electric moment is almost negligible. In that case if there is no electric moment we are compelled to admit then that we do not get orientation in the electric field.

Therefore, we have approached pretty close to what we might consider as a perfect dielectric. But even then we should have to explain the perfect dielectric as being not only of no electrical moment, but of having infinite affinity for its electrons, because as we raise the voltage we should get electron displacement and eventually should get electrons knocked off with resulting ionization.

It must be remembered, too, that in the ordinary type of solid insulation and I mentioned oil-treated cellulose the material is colloidal in character. If it is not a true colloid, it is colloid-like and subject to colloidal laws. Colloids in the electrical field, of course, will assume a charge, and for all intents and purposes we have then a polar molecule, even though inherently it is of no moment.

From that definition then, we would conclude that the perfect dielectric would be a molecule of no electrical moment and with infinite affinity for its electrons.

I shall not try to apply that idea to all of Mr. Malti's work, but I want to say that with such an idea, d-c. breakdown is subject to entirely different fundamental laws from a-c. breakdown. Only in a case of what we have defined as a perfect dielectric would the d-c. and a-c. breakdowns be subject to the same characteristics or laws.

Passing over to d-c. breakdown, Mr. Malti mentions the fact that d-c. breakdown is subject to time, is a function of insulation thickness and is therefore subjected to the mode of voltage application, and logically following these conclusions, is subject to a fatigue effect.

We have done considerable work in fatigue effect under a-c. potential, and we have been able to trace it out pretty well.

However, we have never been able, under carefully controlled conditions, to trace out a fatigue effect under d-c. potential. If the experiment is carefully controlled, the d-c. breakdown appears almost independent of the thickness. The rate of voltage application is not markedly effective. The time-voltage curve is almost flat. These ideas fit in very nicely with the suggestion of molecular moment which I am offering.

Mr. Malti is led to the conclusion that the pyroelectric theory is to be rejected. That conclusion I think, should be carefully considered before it is generally accepted. For example, Mr. Malti's two reasons which he gives for this conclusion are of interest. We recognize that there are two types of breakdown perhaps the instantaneous type and the so-called long-time type. To my idea the weakness of the pyroelectric theory has not been that it is wrong. It is apparently true, as far as I can see, that insulation failure is a heat phenomenon if you exclude the instantaneous type of breakdown. However, the pyroelectric theory begs the question almost entirely on the fundamental cause of that heat and it is hard to see why Mr. Malti can adopt his own ideas of viscous electrons and still retain the pyroelectric theory. If the heat theory is to be rejected on his ideas, what would he say is the direct cause of insulation failure? The motion of electrons is bound to create heat, and heat itself, from the second paragraph of his first reason, does exert an effect.

Mr. Malti also rejects the idea of pyroelectric theory because of measurements on glass. This is one place where I want to emphasize what Mr. Lee has said. It is the present tendency to give up the study of oiled solids and pass over to the study of what are thought to be perfect dielectrics such as glass and salt crystals. In doing that you must remember that as we pass from cellulose materials to salt crystals, we are passing from the organic to the inorganic realm. Whatever the molecular attraction may be in the organic realm, there seems to be considerable doubt that it is electrostatic. In the inorganic series, it is pretty certain that the attraction between atoms in the molecule is electrostatic.

In going from the organic to the inorganic, from cellulose materials to glass, we are passing to a material which has all the appearances of being an electrolytic conductor. With salts such as silver sulphide, it has been shown conclusively that the conductivity is partly electrolytic and partly metallic in character.

The dielectric characteristics of an inorganic insulator are probably affected by laws which do not apply to an organic molecule. I do not see how we can make any marked progress in obtaining a theory of insulation failure (by insulation meaning oiled organic material), by going over into a crystaline structure where in most cases we are dealing with inorganic materials showing either electrolytic or metallic conduction, or both.

Herman Halperin (by telegram): It would obviously be of very great assistance to the art if Mr. Malti would conduct a series of experiments to verify some of his theories and statements especially in regard to Fig. 9 showing the variation of dielectric strength with the thickness of dielectric and to his disagreement with the pyroelectric theory. In connection with the pyroelectric theory, it has been found in a series of tests at various voltages on several hundred samples of impregnated paper insulated cables of various voltages and sizes that about 75 per cent of the failures in accelerated life tests occur at points along the cable sheath which were considerably warmer previous to the failure than the adjacent sheath. This percentage increases with the thicker insulations. Further data on this point are given in the paper on the quality rating of high-tension cables by Mr. Roper and myself.[1]

M. G. Malti: In answer to Mr. Halperin's telegram and to the various speakers as to my attitude on the pyroelectric theory of breakdown, I should like to refer to the following statement on the tenth page of my paper:

"Undoubtedly, for very prolonged potential application, the phenomenon of heat does exert an effect on the rupturing voltage by raising the temperature of the sample. However, a theory built *wholly* on this effect is of necessity erroneous."

Again, referring to the appendix (Column T) it will be noted that I am aware of at least seven references which confirm the view that the dielectric strength decreases with an increase in temperature. The question is really much deeper than would appear. It is this: *For very short time of potential application* is heat the *result* or the *cause* of breakdown? My answer is that for short time intervals heat is both a result and one of the weakest contributing factors of breakdown.

The reason I assert that heat is a *result*, in the case of instantaneous breakdowns, is that the phenomenon of breakdown is nothing more than the tearing up of the electrons from their orbits. The energy dissipated due to the consequent electronic oscillations, vibrations and friction appears in the sample as heat.

Answering Mr. Lee, I fully recognize the large amount of work of high caliber which has been carried on and published relative to dielectric breakdown. However, I beg to repeat that none of it appears to be crucial. If he finds opportunity to do some research I would suggest the following: take a group of samples of the same insulation all of the same thickness and all made by the same process of manufacture and as uniform in quality as can be had. Let these samples be tested under the following conditions:

1. Continuous potential (time of potential application S_1 seconds, breakdown potential applied in one step).

   a. Flat plates of the same material (plates not touching the insulation),

   b. Flat plates of the same material (plates touching the insulation),

   c. Flat plates of the same material (plate forming intimate contact with insulation),

   d. Increase and decrease size of plates and repeat tests a, b, c,

   e. Use spheres of varying diameters and repeat tests a, b, c,

   f. Use needle points and repeat tests a, b, c,

   g. Use a, b, c, d, e, and f in various combinations,

   h. Change material of plates and repeat tests a to g,

   i. Use plates of two different materials under various combinations and repeat tests a to g,

   j. Repeat tests a to i with various sources of continuous potential (*e. g.*, kenetron tube, d-c. generators, induction machines, etc.).

2. *Alternating potentials (time of potential application S_1, seconds*, full potential applied in one step): Repeat all tests listed for continuous potentials with alternating potentials of pure *sine waves* or of waves whose form is definitely known. Use ranges of frequency varying from 1 cycle per sec. to as high as laboratory facilities permit.

3. Repeat tests 1 and 2 for a breakdown of S_2, S_3 . . . . S_n seconds.

4. Repeat tests 1, 2, and 3 with potential gradually increased to breakdown. This series of tests should be made under the same conditions of temperature, humidity, etc.

5. Change the thickness of the dielectric and repeat tests 1 to 4.

6. Change the temperature of the sample and repeat tests 1 to 4 for various thicknesses.

7. This suggested research should give some *crucial* results as regards only that one material. Therefore, repeat it for other materials.

8. Give a very detailed description of the physical and chemical properties of the samples used.

I know of no published work that has strictly followed this procedure. If this research can be made with the required

1. A. I. E. E. TRANSACTIONS, 1926, Vol. 45, p. 528.

material and *high-class labor*, the results will shed a bright light on the mechanism of breakdown.

I do not know that phenomena Mr. Lee refers to when he says "prediction of phenomena not yet observed." Each of the phenomena mentioned in my paper is an entity. They are all well known and have been observed for ages.

Mr. Rosch takes exception to my definition of hysteresis loss appearing in Eqs. (**37a** and **37b**) on the ground that, these expressions would be correct if, and only if, the hysteresis loss remained constant at various frequencies. He further suggests that some research engineers should establish this fact.

Unfortunately both hysteresis and viscosity are so intimately connected together that they cannot be experimentally separated. In order to affect their separation we have to discover a dielectric that possesses one but not the other property. Paraffin ozokerite closely approaches this ideal. It would be indeed well worth while if an experimental research engineer would establish or refute my equations. I wish to thank Mr. Rosch for this suggestion.

Mr. Clark seems to infer, from the simile I give between the electrons and a crowd in a theater, that I endow the electrons with a degree of mentality. This simile is drawn only to help one's imagination as to what goes on when a potential is impressed on a dielectric. He cannot see how, if all the electrons are of the same nature, some of them can be viscous, others elastic and still others free. I beg to refer him to part I section B of my paper and to state that the terminology used there might help him. I refer there to these electrons as *free elastically bound* and *viscously bound*.

According to the modern electron theory of matter electrons are assumed to revolve in orbits of various diameters and various eccentricities about the proton. The picture is similar to our solar system with the proton corresponding to the sum and the electrons corresponding to the various planets.

Now from the fundamental laws of electrostatics, $F = \dfrac{q_1 q_2}{r^2}$

where q_1 and q_2 correspond to the charges on the proton and the electron and r to the distance and F is the force of attraction between the electron and proton[2].

It can be easily seen from this equation that the greater the distance between an electron and a proton, the less the force of attraction. Therefore, we may introduce, on this basis, the following definitions of the three types of electrons: 1. Free electrons are those which lie in the outermost orbit or orbits,

2. Viscously bound electrons are those lying in orbits nearer to the proton than those of the free electrons, and

3. Elastically bound electrons are those which occupy the innermost orbits.

Mr. Clark refers to the old Maxwellian conception of molecular moments. However, in the light of modern developments the old Maxwellian views are known and have been proven to be very crude and incorrect.

In regard to fatigue with d-c. potential Mr. Clark would probably be interested in the experiments of Professor Langsdorf and others. They have found fatigue. I shall be glad to supply a complete bibliography on the subject of fatigue which will not only be of interest to him but will probably suggest different modes of procedure from those he has been following in an effort to determine insulation fatigue.

As to the cause of insulation failure, I beg to refer Mr. Clark to my answer of Mr. Halperin's and Mr. Lee's discussions.

2. This definition is known not to be true for atomic structure but it is approximately true to illustrate my point.

High-Voltage Measurements on Cables and Insulators

BY C. L. KASSON[1]
Member, A. I. E. E.

Synopsis. *This paper presents some of the results of a series of high-voltage tests on cables and insulators, extending over a period of eight years, to determine the electrical characteristics of the insulation. Leakage current, insulation resistance, and watt input tests were made with direct and alternating current. Paper-insulated and rubber-insulated cables and a 27,000-volt porcelain insulator were tested.*

From these tests several conclusions were drawn, the principal ones being as follows:

1. Insulation resistance of paper and rubber-insulated power cables increases to a maximum with increasing applied d-c. voltage, the characteristic depending upon the temperature.

2. It is necessary to use shields as well as guards in making tests to determine the electrical characteristics of cable insulation under d-c. voltage stresses above the ionization point.

3. The watt input to the insulation of a paper cable under d-c. stress, at a given temperature, depends upon the character of the voltage wave; the greater the ripple, the greater the watt input.

4. It is necessary to use shields as well as guards in making tests on short cable samples to determine the a-c. electrical characteristics, such as dielectric loss of cable insulation under voltage stresses above the ionization point.

5. The ionization point is very variable depending upon the physical circuit, together with the atmospheric conditions, and represents, in reality, local air breakdown.

6. The better (i. e., the more uniform) the dielectric, the greater is the tendency for the material to break down in its entirety rather than at a single point. Practically, of course, no dielectric is perfectly homogeneous, so that failure will be restricted to the weakest spot or spots.

Tests on Paper-Insulated Cables

The first series of tests described in the paper is that on paper-insulated, lead-covered cables. These were tested with direct current from a kenotron set and a high-voltage battery and with 60-cycle alternating current.

The results of the tests were plotted to show the variation of leakage current, insulation resistance, and watt input with applied voltage at given temperatures. These curves show the insulation-resistance-voltage

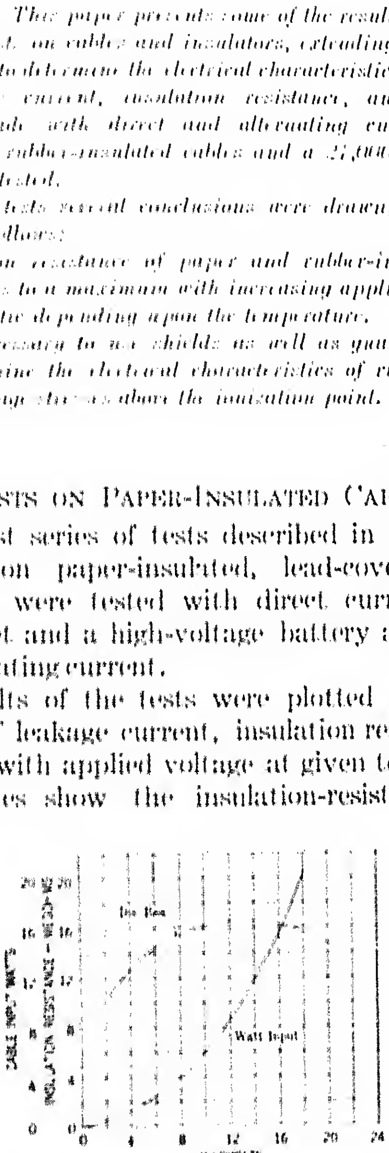

Fig. 1 Variation of D-c. Characteristics (Insulation Resistance and Watt Input with Voltage) of Old 13,800-Volt Paper-Insulated Cable Line

Tests made on Line 5-97, consisting of rosin-oil impregnated, three-conductor, 4/0 copper cable, 18,283 ft. long. Conductor insulation, 7/32 in., outer belt, 7/32 in.

stress and watt input voltage stress characteristics of the cables. The former indicates the resistance reaction of the insulation to d-c. voltage stress and the latter, the power input or dielectric loss. These latter characteristic curves are important because over a given period of time they are a measure of the energy input to the insulation, with resultant heating.

Insulation Resistance Varies with Voltage Applied. The first conclusion, namely, that insulation resistance increases to a maximum with increasing applied d-c.

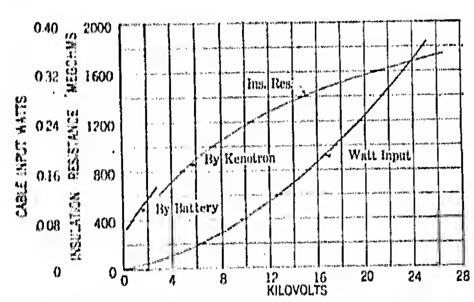

Fig. 2—Variation of D-c. Characteristics of New 15,000-Volt Paper-Insulated Cable Line

Tests made on Line 38-118, consisting of petrolatum impregnated, three-conductor, 300,000 cir. mils cable, 22,079 feet long. Conductor insulation 7/32 in., belt, 3/32 in.

Voltage applied from kenotron and low voltage battery.

voltage, is supported by the tests the results of which are shown in Figs. 1 to 6 and 10 to 14, inclusive.

An inspection of these curves indicates that both old and new cables show this characteristic in varying degree, depending upon the temperature. At the lower temperatures the insulation-resistance rise is very pronounced, but at the higher temperatures the rise is slight.

The first series of tests was made on an old (line 597) and a new (line 38-118) 15,000-volt cable. These cables were respectively 18,283 ft. and 22,079 ft. long. The results are shown in Figs. 1 and 2.

The old cable (Fig. 1) shows a maximum insulation resistance at the given temperature, under a stress of only 13 kv. d-c. The new type cable (Fig. 2) shows a

1. Edison Electric Illuminating Co., Boston, Mass.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

characteristic still rising at 26 kv. From the character of these curves and values of insulation resistance it might be possible to draw partial conclusions as to the general condition of the insulation of these paper cables. On this basis the condition of line 5-97 appears to be poor and that of line 38-118 good.

Effect of Temperature on Variation of Insulation Resistance with Applied D-c. Voltage. The effect of

Tests on 15,000-volt, three conductor, 350,000-cir. mil cable lengths. Conductor insulation 7/32 in., belt 3/32 in. Cable A, 644 feet long; petrolatum-impregnated; cable B, 645 feet long, impregnated with petrolatum and rosin-oil.
Voltage applied from kenotron.

temperature is shown in Fig. 3 for two new paper cables (*A* and *B*) of different types. Further temperature effects upon the insulation-resistance-voltage-stress characteristics are shown in Figs. 4 and 5, for new

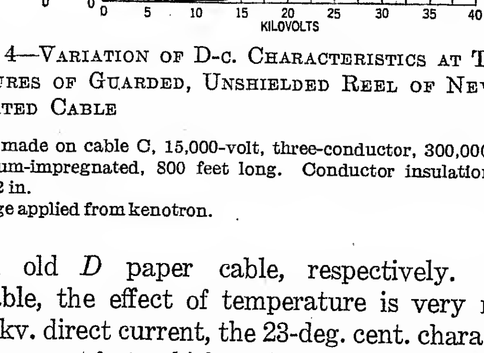

Fig. 4—Variation of D-c. Characteristics at Two Temperatures of Guarded, Unshielded Reel of New Paper-Insulated Cable

Tests made on cable C, 15,000-volt, three-conductor, 300,000 cir. mils, petrolatum-impregnated, 800 feet long. Conductor insulation 7/32 in., belt 3/32 in.
Voltage applied from kenotron.

C and old *D* paper cable, respectively. On the old cable, the effect of temperature is very marked. At 40-kv. direct current, the 23-deg. cent. characteristic is falling very fast, which probably indicates impending failure. The 60-deg. cent. curve would show a corresponding drop if plotted to suitable scale.

Necessity for Using Shields. In making tests to determine the electrical characteristics of reel lengths of cables it became evident that complete shielding is very important. Figs. 3, 4, 5, and 6 illustrate cable characteristics measured without shields. In these figures most of the insulation-resistance curves against

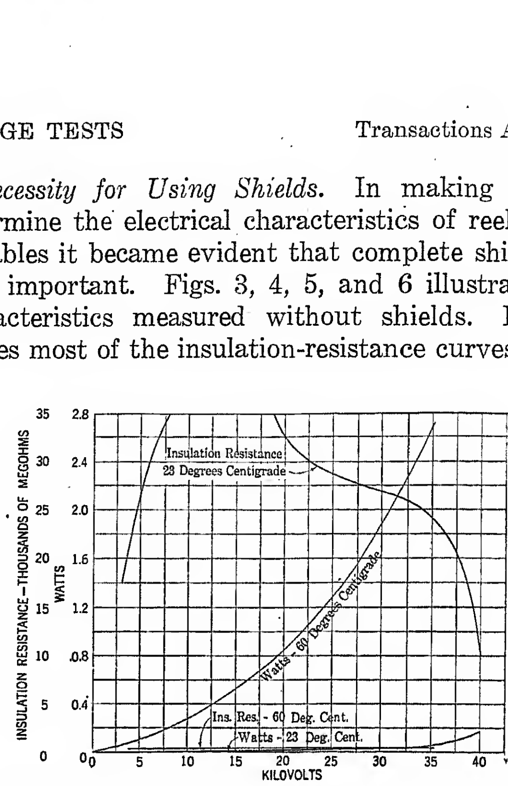

Fig. 5—Variation of D-c. Characteristics at Two Temperatures of Unshielded Reel of Old Paper-Insulated Cable

Tests made on cable D, 15,000-volt, three-conductor, 2/0, rosin-oil impregnated, 101 feet long. Conductor insulation 9/32 in., belt 9/32 in.
Voltage applied from kenotron.

voltage stress rise to maximum and then decline. This decline is apparently due to ionization of the air, either within or outside the cables. The effect of the ionization of the air at the ends of the cable becomes proportionally less as the leakage current through the insulation increases; in fact, in case of very high leakage through the insulation, it may be a negligible percentage of the total measured current.

Where the leakage current is low, however, the end

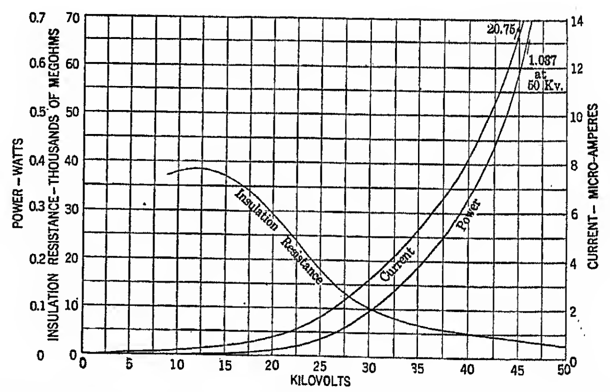

Fig. 6—Variation of D-c. Characteristics (Leakage Current, Insulation Resistance, and Watt Input with Voltage) of Unshielded Reel of New Paper-Insulated Cable

Tests on cable C (see Fig. 4). Voltage applied from high-voltage battery. Temperature 26-29 deg. cent.

effects may equal or completely swamp the cable insulation effect at stresses above the ionization point. In these cases, whether the cable is long or short, it is necessary to use shields and guards to obtain the true

leakage current values through the insulation, from which values the cable characteristics are derived.

Further tests were made, therefore, on cable *C* using shields and the results are given in Figs. 10, 11, 13, and 14. These results support the second conclusions, that it is necessary to use shields as well as guards in making tests to determine the electrical characteristics of cable insulation under d-c. voltage stresses above the ionization point.

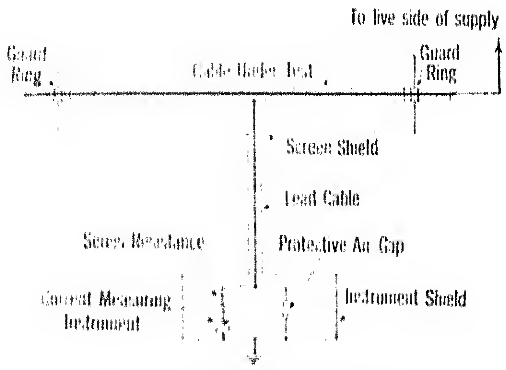

FIG. 7—DIAGRAM OF CONNECTIONS FOR TESTS WITH CABLE AND INSTRUMENTS SHIELDED

The term "shielded guarded" means that a complete system of shielding was used in making these tests in addition to the ordinary guards or guard rings. This system of shields, in the case of the paper cable, is diagrammatically outlined in Fig. 7. The actual cable and instrument shields are shown in Figs. 8 and 9, respectively. From Fig. 7, it will be noted that the cable, measuring instruments, and connections are completely shielded.

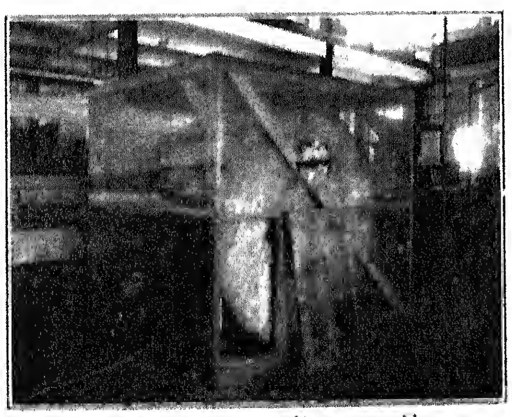

FIG. 8—SHIELD FOR REEL OF CABLE

Figs. 10 and 11 were obtained with shields and guards, and No. 6 without them on an 800-ft. length of 15,000-volt paper cable *C*. It will be noted that the shielded guarded values are only a fraction of the unshielded unguarded values at the higher stresses. For instance, the shielded guarded values of insulation resistance, leakage current, and input watts at 50 kv. are 104,000 megohms, 0.48 microamperes, and 0.024 watts, respectively.

For comparison, the unshielded unguarded values at 50 kv. are 2400 megohms, 20.8 microamperes, and 1.04 watts, respectively. It will be observed that the leakage current and watt input at 50 kv., unshielded, unguarded are 43 times the shielded guarded, or true values.

Subtracting one value from the other indicates that the leakage current and watt input, in the surrounding atmosphere, amount to 20.3 microamperes and 1.02 watts, respectively, at 50 kv. Of course, these values depend upon the physical arrangement of test circuits and the atmospheric conditions.

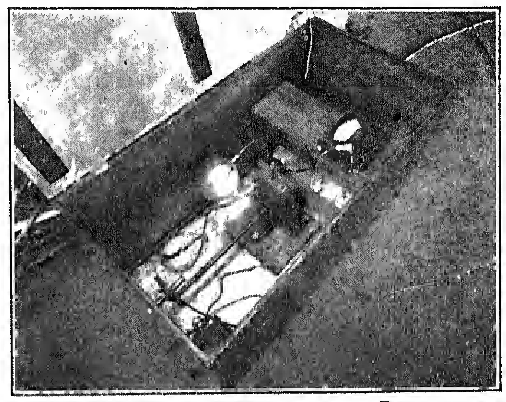

FIG. 9—SHIELD FOR MEASURING INSTRUMENTS

Fig. 12 shows the comparisons between the characteristic curves of insulation resistance against voltage stress with and without shields and guards. From an inspection of Fig. 12, it appears that the curves of insulation resistance under the two conditions diverge at stresses far below the usual so called ionization point. There is a marked divergence at 10 kv. d-c. It will be noted that the shielded guarded curve continually rises and it might be inferred that it must reach a maximum and decline previous to failure due perhaps to the ionization of the air within the insulation.

FIG. 10—VARIATION OF D-C. (BATTERY) CHARACTERISTICS ON SHIELDED REEL OF NEW PAPER-INSULATED CABLE

Tests on cable C (see Fig. 4). Voltage applied from high-voltage battery. Temperature 26-29 deg. cent.

Fig. 16 shows the total end loss in watts, which is the difference between the unshielded unguarded and

shielded guarded results, plotted against voltage stress. This curve evidently represents the power dissipated into the air at the various d-c. stresses.

It is apparently possible to dissipate 0.03 watt at 25 kv., 0.17 watt at 35 kv., 0.31 watt at 40 kv., and 1.02 watts at 50 kv. into the atmosphere under the

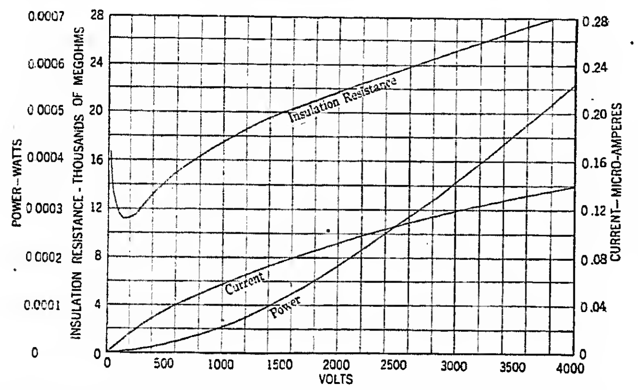

FIG. 11—VARIATION OF D-C. (BATTERY) CHARACTERISTICS OF SHIELDED REEL OF NEW PAPER-INSULATED CABLE

Results of Fig. 10 plotted to larger scale

given test conditions with a battery source of d-c. stress as shown by Fig. 16. It is obvious that the value of watts will increase rapidly with the higher voltages and is subject to the local atmospheric conditions at the ends of the cable.

These results lead the author to believe that nearly all laboratory tests on cables and other insulations under d-c. stresses must be made with shields as well as guards

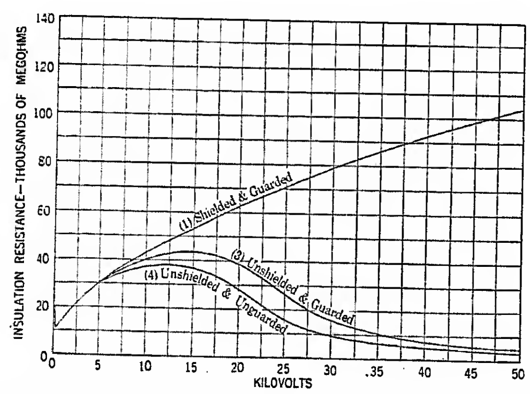

FIG. 12—CURVES SHOWING EFFECT OF SHIELDING AND GUARDING ON MEASURED INSULATION RESISTANCE OF REEL OF NEW PAPER-INSULATED CABLE

Tests on cable C (see Fig. 4). Voltage applied from high voltage battery. Temperature 26-29 deg. cent. (Includes data of Figs. 6 and 10.)

in order to secure true and accurate results. Further, it is believed that such shields are necessary at stresses far below the ordinary ionization point.

The need for the shield is due to the fact that the end effects are composed of surface leakage and leakage through the air. The guard takes care of the surface leakage and the shield takes care of the leakage through the air at the end of the cable.

The use of guards or guard rings is an old practise and some observers have used shields for instruments, but the author believes that the use of shields on the cable or dielectric under test is new and also very vital. These shields and guards are necessary in all cases where the end effects are of sufficient magnitude to interfere with the determination of the true d-c. leakage current through the insulation.

The relative effects of the guard and shield have not been fully determined as yet. In fact, it will be practically impossible to establish it as all guards are in a measure partial shields. From such preliminary work as has already been done, it appears that the shield effect predominates over the guard effect under d-c. stresses and that this predominance is very marked at the higher d-c. stresses. Comparison of the curves in Fig. 12 shows that, for paper-insulated cable C, the effect due to shields is very much greater than that due to the guards, the difference becoming more marked at the higher voltages.

An inspection of Figs. 10, 11, 13, and 14 indicates that

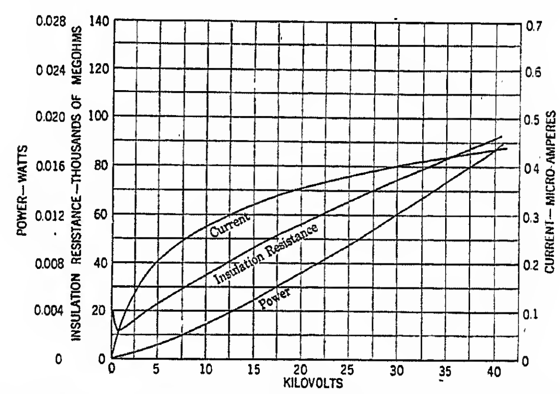

FIG. 13—VARIATION OF D-C. (KENOTRON) CHARACTERISTICS OF GUARDED SHIELDED REEL OF NEW PAPER-INSULATED CABLE

Tests on cable C (see Fig. 4). Voltage applied from kenotron. Temperature 26 deg. cent.

with both battery and kenotron d-c. stress, the insulation resistance curves show a slight drop at the start before the general rising characteristic begins. It is thought that this results from either a residual electrification or a change within the insulation. This reverse action is perhaps important as indicating a complete change of conditions within the dielectric. It is perhaps related to the particle action and the initial state of the dielectric. This aspect of these tests is worthy of further study from the standpoint of dielectric action under stress.

The various curves presented show that the insulation resistance of modern paper cables under shielded conditions is exceedingly high and increases with increasing applied d-c. stress up to certain limits. From the d-c. standpoint a good paper cable dielectric is a much better insulator than has been previously apparent. In fact, a modern cable is a first class condenser of exceedingly low leakage. From the operating standpoint, perhaps it may be worth while to have a

certain amount of leakage in a long cable to act as a safety valve when the line is subjected to a high transient voltage. In other words, perhaps a certain amount of leakage acts as a stabilizer provided that in obtaining this leakage there is no unnecessary sacrifice of dielectric strength.

Comparison of Battery and Kenotron Tests. Shielded guarded Figs. 10 and 11 obtained by use of the Cruft high-voltage battery may be compared with Figs. 13 and 14 by kenotron, for the 800-ft. length of 15,000-volt paper cable *C*. The results are quite similar, but the watt input with the kenotron is a little higher than that with the battery source. This is shown by Fig. 15. It is believed that this is due to the ripple of the kenotron wave.

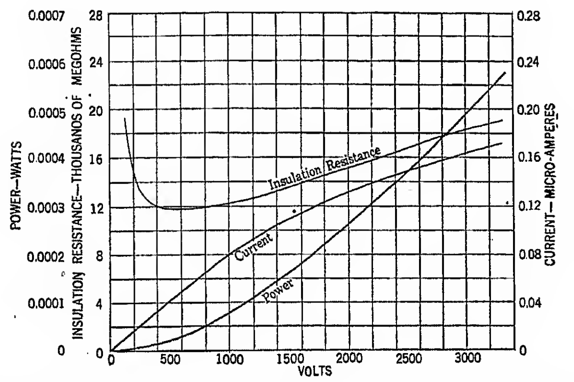

Fig. 14—Variation of D-c. (Kenotron) Characteristics of Guarded, Shielded Reel of New Paper-Insulated Cable

Results of Fig. 13 plotted to larger scale

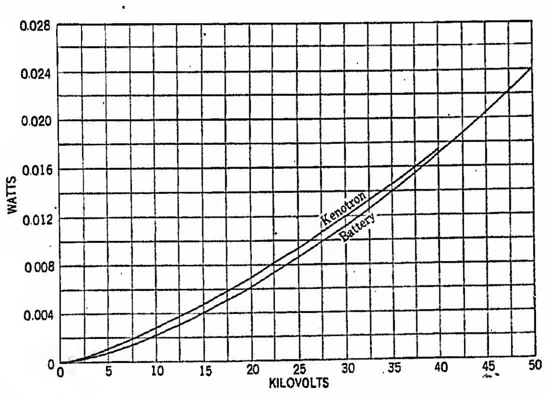

Fig. 15—Comparison of Watt Inputs with Kenotron and Battery on Shielded Reel of New Paper-Insulated Cable

Data of Figs. 10 and 13

From this the third conclusion is drawn, that the watt input to the insulation of a paper cable under d-c. stress, at a given temperature, depends upon the character of the voltage wave; the greater the ripple, the greater the watt input. This would agree with the accepted fact that the watt loss in a dielectric increases with frequency. In other words, the watt loss in a dielectric at given ambient temperature ranges from a minimum on direct current with wave form better than that supplied by battery, to a maximum at high frequency.

A-c. Dielectric Loss Tests, Shielded and Unshielded. The failure of insulation is largely a matter of heat and its relative distribution in the material. Under d-c. stress the watt input and the consequent heating is very slight in comparison with that under so called equivalent a-c. stresses. On cable *C* the a-c. watt input at 24,000 volts, 60 cycles, was 131.8 and the d-c. watt input at 50 kv. was 0.024 watts, at room temperature.

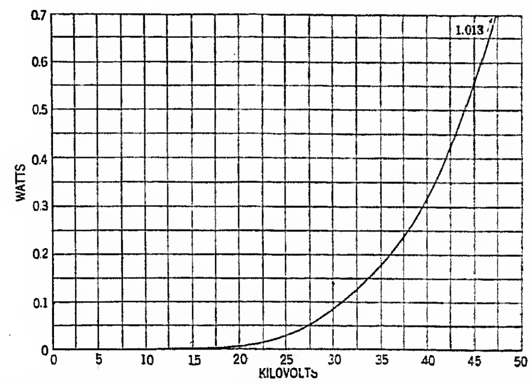

Fig. 16—Variation of Watts End Loss with D-c. Voltage (Battery) on Reel of New Paper-Insulated Cable

Tests on cable C (see Fig. 4). Voltage applied from high-voltage battery. Temperatures 26-29 deg. cent. Data from Figs. 6 and 10

The shielded guarded values on cable *C* at 24,000-volts a-c. were 131.8 watts as against an unshielded unguarded value of 133 watts. This would indicate that shielding is not necessary in making a-c. dielectric loss tests on long cables, 800 or more feet in length, unless the dielectric losses are exceedingly low.

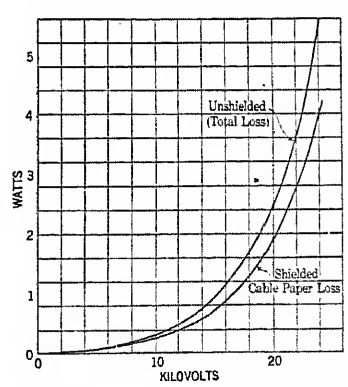

Fig. 17—Variation of Watt Inputs with 60-Cycle Voltage on Short Lengths of New Paper-Insulated Cable, Shielded and Unshielded

Tests made on cable G, 15,000-volt, three conductor, 300,000 cir mils, petrolatum-impregnated, 24 ft. long. Conductor insulation 7/32 in., belt 3/32 in.
Voltage applied from 60-cycle source. Temperature 25 deg. cent.

Fig. 17 shows the curves of a-c., 60-cycle watt input (dielectric loss) against voltages stress for a 24-ft. length of 15,000-volt paper cable *G* with and without shields and guards. On such a short cable the a-c.,

60-cycle end losses are not negligible and shields and guards are necessary to insure proper accuracy of dielectric loss measurements at stresses above the ionization point. The shielded and guarded value at 24,000 volts was 4.05 watts and the unshielded unguarded value 5.43 watts.

The difference of 1.38 watts, which is the end loss, compares favorably with that of 1.2 watts obtained in the previous case of the 800-ft. cable. The term end loss as used is the total end loss or difference between the unshielded unguarded value and the shielded guarded one as previously outlined in the case of the d-c. tests. The relative effect of shield and guard is very difficult to obtain because all guards act as shields. Leakage taking place 1/1000 of an in. above the surface of the paper is leakage through the air. Any guard ring intercepts this as well as the true surface leakage. All tests made so far have shown different values with and without shields even if guard rings were left on during the latter condition.

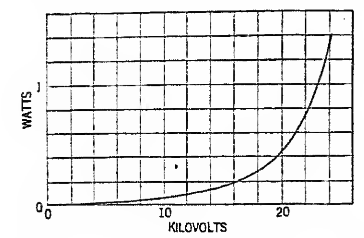

Fig. 18—Variation of Watts End Loss with 60-Cycle Voltage on Short Length of New Paper-Insulated Cable

From data of Fig. 17

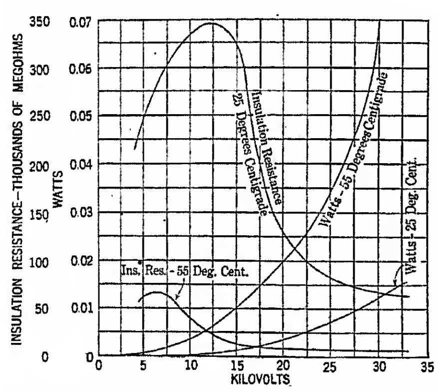

Fig. 19—Variation of D-c. Characteristics (Leakage Current, Insulation Resistance, and Watt Input with Voltage) at Two Temperatures of Unshielded Reel of New Rubber-Insulated Cable

Tests made on cable E, 10,000-volt, single conductor, 4/0, 7/32 in. insulation, 505 feet long
Voltage applied from kenotron

The error of 34 per cent in the unshielded unguarded measurements indicates the necessity for using shields and guards in making measurements of a few watts loss under stresses around 24,000-volts a-c. From this, it may be deduced that unshielded unguarded watt loss measurements on cable samples of 10 ft. or less under a-c., 60-cycle, 24,000-volt stresses might be 100 per cent in error. The author believes that this is one of the reasons why dielectric loss measurements taken at different laboratories and more especially those on short lengths of cables as against long lengths, have sometimes failed to agree in the past.

From the foregoing results the fourth conclusion has been drawn that it is necessary to use shields as well as guards in making tests on short cable samples to determine the a-c. electrical characteristics, such as dielectric loss of cable insulation under voltage stresses above the ionization point.

Fig. 18 shows the variation of total watt end loss with voltage stress. This loss is made up of surface and air electrical leakage as in the previous cases. The relative proportion is very difficult to determine but it is believed as a result of preliminary tests that both factors are important and neither negligible. Further preliminary tests have indicated that the guard effects vary depending on the relative position of the guard ring to the copper conductor and the lead sheath. This is further proof that the guard ring acts as a partial shield.

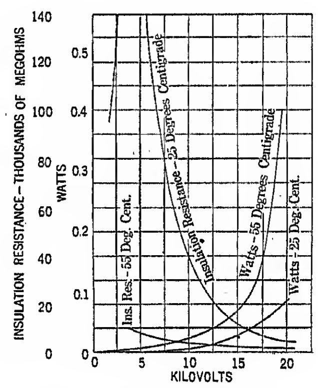

Fig. 20—Variation of D-c. Characteristics at Two Temperatures of Unshielded Reel of Old Rubber-Insulated Cable

Tests made on cable F, 10,000-volt, single-conductor, 4/0, 7/32 in. insulation, 319 feet long.
Voltage applied from kenotron

Ionization Point is Indeterminate. It will be observed that the difference between the shielded guarded and unshielded unguarded measurements steadily increases with increasing stress. The difference probably represents the increasing air loss at the ends of the cable. It will be noted that these curves (Fig. 17) diverge at even the lower stresses, as in the case of the previous d-c. tests shown in Fig. 12.

From this and the previous results, the fifth conclusion is drawn: that the so called ionization point is very variable depending upon the physical circuit together with the atmospheric conditions and represents, in reality, local air breakdown. This is supported by the tests with direct current on paper and rubber cables

as well as by the a-c. tests on paper cable. In all cases the curves with and without shields and guards diverge at the lower values of stress below the commonly accepted ionization point.

From this, it may be deduced that the air conducts at all stresses both direct current and alternating current and that ionization points represent local air break-

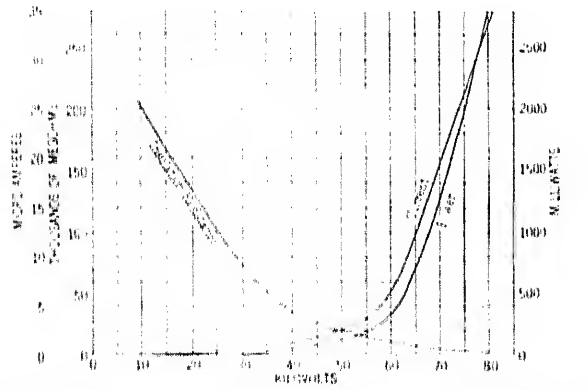

Fig. 21—Variation of D-c. Characteristics of Unshielded Length of New Rubber-Insulated Cable

Tests made on cable H, 10,000 volt, single-conductor, No. 6, 7/32 in. insulation, 89 feet long
Voltage applied from kenotron

down due to the local physical circuit, atmospheric, and stress conditions.

Tests on Rubber-Insulated Cable

Tests similar to those on the paper-insulated cables were made also on rubber-insulated cables.

Insulation Resistance Varies with Voltage Applied. A new and an old rubber cable showed the same general insulation-resistance-voltage-stress characteristic at 25 deg. cent. as did the paper-insulated cables. Figs. 19

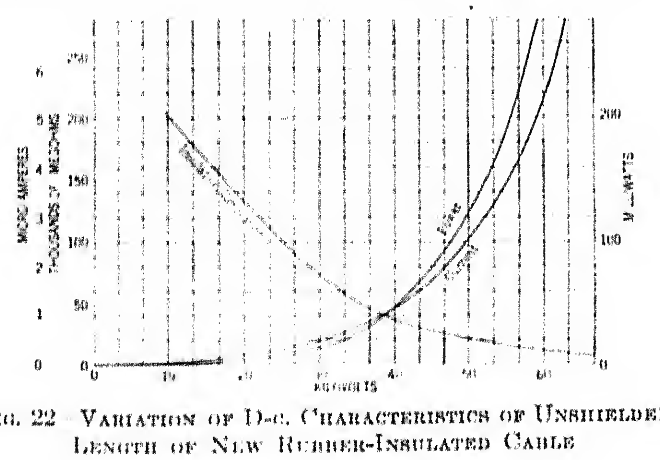

Fig. 22—Variation of D-c. Characteristics of Unshielded Length of New Rubber-Insulated Cable

Data of Fig. 21 plotted to larger voltage scale.

and 20, giving results of tests on cables E and F, respectively, illustrate this. The new rubber cable E, Fig. 19, also shows the characteristic at 55 deg. cent., but the old cable F, Fig. 20, shows only a falling characteristic at this temperature. It is probable that if the test range had been extended, the curve of insulation resistance would have shown a rising charac-teristic at the lower voltages and a rapidly falling one at the higher voltages approaching the breakdown point.

A series of d-c. tests by kenotron was made on an 89-ft. length of new 10,000-volt rubber cable H, both with and without shields. In these tests, the stresses were carried up to the breakdown point. The results are shown by Figs. 21, 22, 23, 24, and 25. The

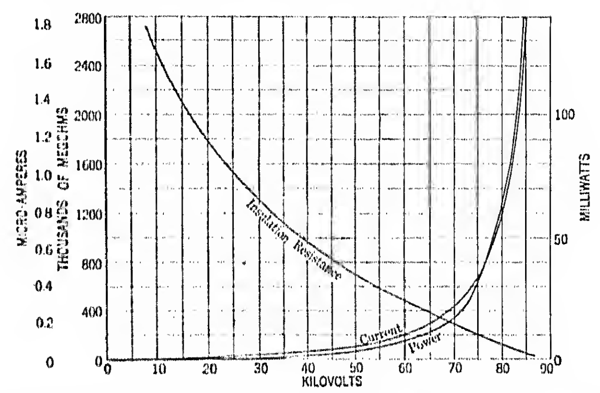

Fig. 23—Variation of D-c. Characteristics of Shielded Length of New Rubber-Insulated Cable

Tests made on cable H (See Fig. 21). Voltage applied from kenotron

same shields and test set-ups were used as in the case of the paper cable.

From the curves, it will be noted that the insulation-resistance-voltage-stress curve, at room temperature, continually falls from the 10-kv. point. It is probable that at stresses below 10 kv., the curve would show a rising characteristic.

It is apparent that the leakage current and input watts rise very rapidly after the critical point of 60 kv. is reached under the unshielded condition. This is

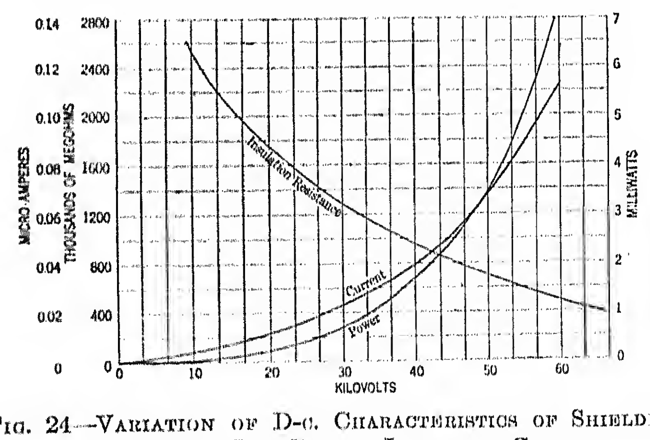

Fig. 24—Variation of D-c. Characteristics of Shielded Length of New Rubber-Insulated Cable

Data of Fig. 23 plotted to larger voltage scale

probably due to the ionization of the external air surrounding the ends of the cable.

On the other hand, the abrupt rise under shielded conditions does not occur until 70 kv. is reached. This must be due to the ionization of the air entrapped in the dielectric itself. It would thus appear that the ioniza-

tion of the external air around the cable ends takes place before the ionization of the air entrapped in the insulation, unless the test results are seriously modified by the action of surface leakages. Perhaps this is a question of air pressure and movement.

Effect of Shields. The effect of shielding and guarding is very marked in these tests as in the case of the paper cable. The true or shielded guarded watt input at 80 kv. d-c. was 0.064 watt and the unshielded unguarded value 2.80 watts, making the end loss 2.74

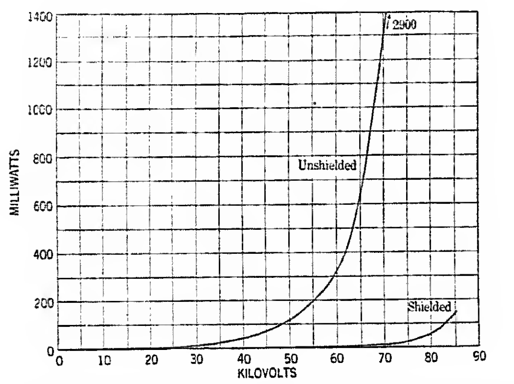

FIG. 25—COMPARISON OF CURVES OF WATT INPUT WITH D-C. VOLTAGE ON NEW RUBBER-INSULATED CABLE, SHIELDED AND UNSHIELDED

Tests on cable H (see Fig. 21). Data of Figs. 21 and 23

watts. It will be observed that the true loss is only 1/44 of the apparent or unshielded unguarded loss at the given stress. The relation is shown graphically by Fig. 25.

The use of shields as well as guards is thus absolutely

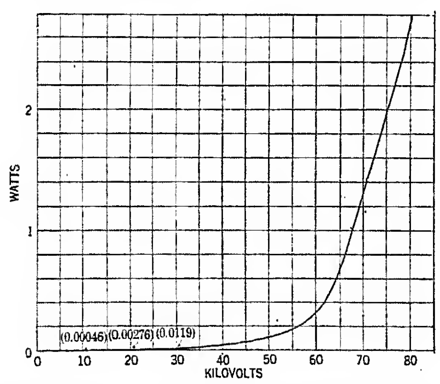

FIG. 26—VARIATION OF WATTS END LOSS WITH D-C. VOLTAGE ON LENGTH OF NEW RUBBER-INSULATED CABLE

Tests on cable H (see Fig. 21). Data from Fig. 25

necessary in making d-c. measurements on short rubber cables at high stresses in order not only to insure the accuracy of results but to determine the true characteristics of the cable insulation.

If the cable in question had been 10 ft. long, the measuring error at 80 kv. d-c. might have been of the order of magnitude of 39,000 per cent, without shields. On the other hand, if the cable had been 18,000 ft. long the error might have been 21 per cent.

From the data it may be deduced that in testing an installed rubber cable of 18,000-ft. length, by kenotron at stress of 40 kv., the error in measuring the watts loss, due to end leakage, might be 13 per cent. The shielded leakage current and watt input at 40 kv. d-c. for the above cable would be approximately 8.1 microamperes and 0.34 watts, respectively.

According to this data, a kenotron test set used on such a cable ought to show approximately 9.16 microamperes and 0.39 watt without shields. Thus, shielding is hardly necessary in making field measurements on long lengths of installed rubber cables at moderate stresses direct current. As a matter of fact, shields could not be used as outlined here because the cable sheaths are directly grounded.

The field measurements with kenotron set usually show 100 microamperes to one milliampere for the above cable when tested at 40 kv. This large difference is

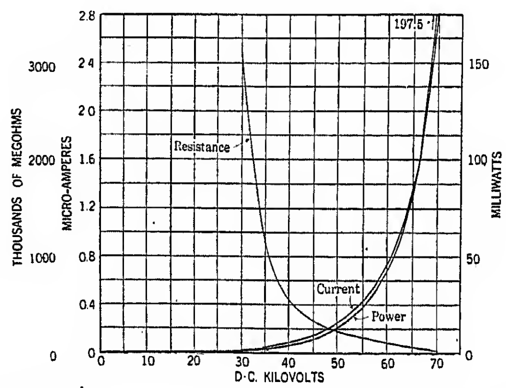

FIG. 27—VARIATION OF D-C. CHARACTERISTICS (LEAKAGE CURRENT, INSULATION RESISTANCE, AND WATT INPUT WITH VOLTAGE) OF UNSHIELDED 27,000-VOLT PIN-TYPE LINE INSULATOR

Voltage applied from kenotron

due to the leakages and rectified charging currents of the set itself. Thus, many kenotron test measurements on installed cables do not indicate the true leakage current through the cable insulation, and give values that are much too high.

The great value of shields lies in their use when measuring dielectrics in the laboratory and in thus obtaining true data to use in studying dielectric phenomena.

Fig. 25 shows the comparison between the shielded and unshielded watt input to the rubber cable. The great difference between the two will be noted. Obviously, the shielded curve, if extended through the breakdown point, would rise nearly perpendicular to the abscissa (stress) becoming an asymptote. After breakdown, the current would be very great under stresses of 85 kv. and upward. Many very interesting speculations outside the scope of this paper can be drawn from this fact.

The end loss is given by Fig. 26. The general discussion on the paper cable end losses applies also to the rubber cable end losses.

Insulation Failure. Fig. 23 shows the true shielded guarded insulation-resistance-voltage-stress curve from 10 to 85 kv. Under the shielded condition, at approximately 84 kv., the curves of leakage and watt

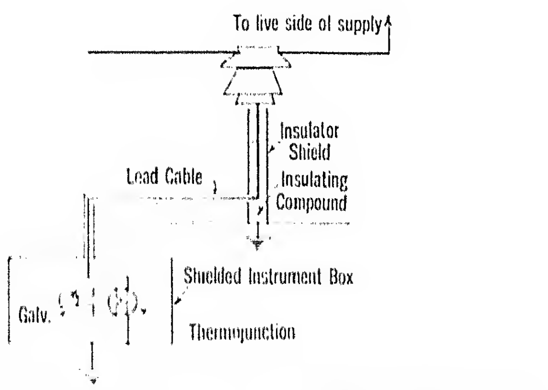

FIG. 28 DIAGRAM OF CONNECTIONS FOR MEASUREMENTS ON SHIELDED LINE INSULATOR

input are rising very rapidly and are nearly perpendicular to the abscissas (voltage stress). This, of course, indicates that the dielectric is about to fail. As a matter of fact, failure did take place at 85 kv. Upon examination, this new rubber cable was found to be literally riddled with incipient faults. After the first failure, a number of these other faults were developed by applying a comparatively low voltage. The rubber insulation had been stressed far above its safe or electrical elastic limit, and a general deterioration had set in.

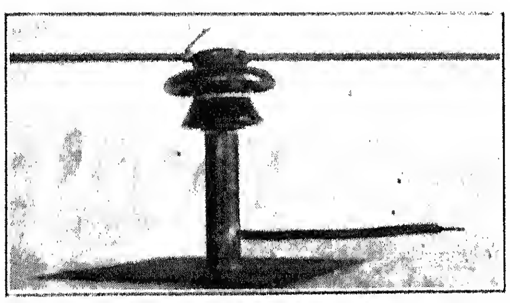

FIG. 29 SHIELD FOR PIN-TYPE LINE INSULATOR

This leads to the sixth conclusion, that the better, *i. e.*, the more uniform the dielectric, the greater the tendency for the material to break down in its entirety rather than at a single point. Practically, of course, no dielectric is perfectly homogeneous, so that failure will take place at the weakest spot or spots. From this it might be deduced reasonably that the better the insulation the more care should be taken not to over-stress it. Such over-stressing, while not producing actual failure, must deteriorate and weaken the whole insulation. It might be further deduced from this that there must be an electrical elastic limit in dielectrics analogous to the physical elastic limit in metals. If the stress exceeds this limit a strain and eventual failure is the result.

TESTS ON A LINE INSULATOR

Besides the tests on paper and rubber cables a similar series has been made on a 27,000-volt porcelain line insulator, both with and without shields. Fig. 28 shows the diagrammatic arrangement, Fig. 29 is a reproduction of a photograph of the insulator shield, and Fig. 9 of the instrument shield.

Results of D-c. Tests. Figs. 27 and 30 show the d-c.

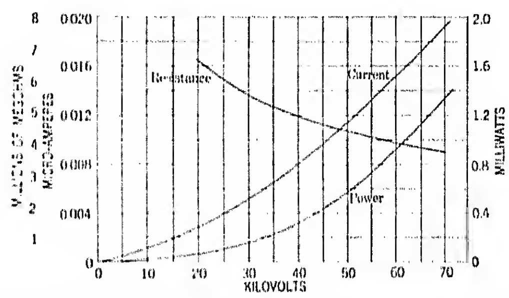

FIG. 30—VARIATION OF D-C. CHARACTERISTICS OF SHIELDED 27,000-VOLT, PIN-TYPE LINE INSULATOR

Same insulator as in Fig. 27. Voltage applied from kenotron

unshielded and shielded test results. It will be noted that the shielded insulation-resistance-voltage-stress curve has a slowly falling characteristic from 20 kv. upward. It is believed that this curve would have been nearly flat if the shield had been brought closer to the porcelain.

At 70 kv. d-c. the shielded values are 0.019 micro-ampere, 1.32 milliwatts, and 3.5 millions of megohms. The corresponding unshielded values are 2.8 micro-

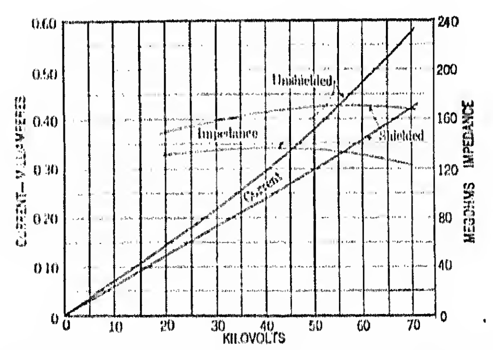

FIG. 31—VARIATION OF CURRENT AND IMPEDANCE WITH 60-CYCLE VOLTAGE ON 27,000-VOLT, PIN-TYPE LINE INSULATOR, SHIELDED AND UNSHIELDED

Same insulator as in Fig. 27. Voltage applied from 60-cycle source

amperes, 197.5 milliwatts, and 25,000 megohms. The relations shielded to unshielded are: leakage current and watt input 1/150 and resistance 150/1.

From these curves, it will be noted that the shielded value of insulation resistance falls rather slowly and that the watt input is not increasing very rapidly at 70 kv.,

which is a low stress for the insulator. The porcelain apparently presents a more nearly constant resistance to electrical stress than impregnated paper and rubber insulation.

The unshielded curves show the effect of the electrical leakage through the air around the outside of the insulator. At 60 kv. the leakage and watt input curves rise very abruptly as in the case of the rubber cable. This is probably due to the ionization of the external surrounding air. The shielded curves (Fig. 30) of leakage current and watt input do not even show a rapidly rising characteristic at 70 kv. d-c. This leads to interesting speculation on the general question of ionization and dissipation of d-c. electric energy from a body of given configuration under given atmospheric conditions, at various stresses.

Results of A-c. Tests. Fig. 31 shows the results for the same insulator under a-c., 60-cycle stresses. These results indicate that shields are necessary to obtain true readings under a-c., 60-cycle stresses. At 70-kv. a. c. the shielded values of current and impedance are 0.42 milliamperes and 166 megohms. The corresponding values unshielded are 0.57 milliamperes, and 122 megohms, respectively. Shielding thus established the true value of 0.42 as against the apparent value of 0.57, a difference or error of 36 per cent.

It will be noted that the impedance voltage-stress curves are nearly flat, perhaps indicating that the insulator is well within its safe electrical stress limits. If, in future tests, these curves can be carried through the lower and higher ranges, undoubtedly new and valuable data can be obtained.

No a-c. watt measurements were made on this insulator but it is believed that these are very important and will throw further light on the situation. It is hoped to do more work along this line in the future.

Remarks and Suggestions

In all these tests and researches, the attempt has been made to determine the insulation-resistance-voltage-stress curve and the watt-input voltage-stress curve. It is believed that if such curves can be obtained for various insulations under electrical stresses, both direct current and alternating current of various frequencies from zero to breakdown at several temperatures, then the way will be opened for the practical study and determination of dielectric action under electrical stress.

The work covered by this paper involved for the most part d-c. stresses and it is not known how far the results reflect the action of the insulating material under a-c. stresses. From the d-c. standpoint, it might well be argued that the insulation-resistance-voltage-stress curves are a measure of insulation condition. As long as the resistance increases with increasing voltage stress the insulation might be said to be on the safe side. The maximum value would then be the electrical elastic limit and the falling portion of the curve would represent the tendency of the insulation to deteriorate or electrically age. A sharp drop in the insulation resistance curve would indicate impending breakdown.

If this d-c. picture represents also the a-c. situation then a new means is provided for studying insulation under electrical stress. A large amount of a-c. research, however, must be conducted and matched against the direct current before these conclusions are justified.

The problem is further complicated because the d-c. insulation-resistance-voltage-stress curves vary widely with temperature, and the application of the higher a-c. stresses produces a temperature change in the insulation.

The author believes that continuation of this line of investigation will open the way for a real practical study of dielectric phenomena.

Data on Test Methods, Instruments, Etc.

All tests and research work were carried on by the Standardizing and Testing Department of The Edison Electric Illuminating Company of Boston except those recorded in Figs. 3, 4, 5, 19, and 20, which were made by

graduate students of the Massachusetts Institute of Technology at the suggestion of the Standardizing and Testing Department.

The tests and research work were performed at the substations and laboratory of the above company, at the Massachusetts Institute of Technology, and at the Cruft Laboratory of Harvard University.

The tests recorded in Fig. 3 were part of a student thesis prepared by T. M. Burkholder and D. E. Replogle. Figs. 4, 5, 19, and 20 show some of the results obtained from tests made in connection with a student thesis written by E. E. Piepho and J. E. Handy.

The kenotron tests were made with a single-tube 50,000-volt and a two-tube, 100,000-volt kenotron test set of the Standardizing and Testing Department of The Edison Electric Illuminating Company of Boston. The high-voltage battery tests were made with the 100,000-volt battery of the Cruft Laboratory at Harvard University.

The test connections, time of electrification, and measuring equipment used in the various tests are given in the foregoing table. As the current flow on the d-c. tests varied with time of electrification, it was necessary to select arbitrarily a reasonable time of charge. In each case a value was taken at which the current had become fairly constant.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Professor G. W. Pierce and Professor E. L. Chaffee, of Harvard University, for the use of the 100,000-volt storage battery, and to Dr. V. Bush of the Massachusetts Institute of Technology for his cooperation and assistance in the matter of thesis tests.

The author thanks Messrs. T. M. Burkholder, D. E. Replogle, E. E. Piepho, and J. E. Handy for their theses, and appreciates the work of the members of the staff of the Standardizing and Testing Department of The Edison Electric Illuminating Company of Boston, particularly Messrs. H. C. Hamilton, R. W. Chadbourn, C. H. Smith, and W. B. Elmer.

Discussion

W. B. Kouwenhoven: I am very glad that Mr. Kasson has pointed out again the necessity of using shields and guards in making high-voltage measurements on cables. I pointed out at the Mid-Winter Convention of 1926 that unless shields and guards are employed the results may be widely in error.

It is not only important to shield specimens properly from all electrostatic fields but in case of the a-c. measurements of loss, it is also necessary that the voltage of a shield be the same as the voltage of the conductor it protects. It is therefore essential to place in series between the shield and ground an impedance that is the same as the impedance of the measuring instrument used. Unless this is done the difference in potential between the shield and its shielded conductor will cause an error in results. This point, I am afraid, is often overlooked.

Mr. Kasson's curves in Fig. 3, showing the effect of temperature on d-c. insulation resistance, do not conform with the law that we have found for some of our cable samples. This law states that the logarithm of the conductivity is equal to a constant divided by the temperature, plus another constant. When the logarithm of the conductivity is plotted against the temperature the curve is a straight line, although, some of our specimens give this straight line relation, there are others that are exceptions to the rule.

There is one other point which I would like to mention in regard to Mr. Kasson's work and that is his method of procedure. The time of charge must be considerable to obtain accurately the conductivity of specimens. It may take several hours before the final leakage current is reached, owing to the presence of the absorbed charge, and unless the test is continued over a long period of time you cannot be sure that the current measured is actually the final leakage current, corresponding to the conductivity of the sample.

One method that we have used at Johns Hopkins in this work, and which will shorten the time somewhat, is to take a charging run for about 45 min. and then immediately throw the cable in discharge and measure the absorbed charge coming out for the same period of time. The difference between these two curves represents the final leakage current.

Another difficulty that arises when measuring the conductivity or leakage current at several different voltages is the superposition of the curves. If, for example, you apply 5000 volts for a certain length of time and take a reading of the conductivity, and then raise the voltage to 10,000 volts the second curve is superimposed on top of the first and you cannot be sure of the results. If possible, it is best to discharge the cable between each run.

I should like to ask Mr. Kasson what method of measuring he used in determining his a-c. losses.

If, as pointed out by Mr. Kasson, it is possible to tell from the shape of the d-c. resistance curve plotted between resistance and voltage whether a cable is getting old and deteriorating, or whether it is in good condition, we have a very important aid with which the operating companies can determine the condition of their cables. We have been endeavoring to determine some such relation in our research work at Johns Hopkins but to date have not been able to find any definite relation.

Herman Halperin: (by telegram) In Mr. Kasson's paper, Fig. 1, shows, for cable with 7/16 in. insulation to sheath, the maximum insulation resistance occurs at 13 kv., which using the d-c. to a-c. ratio of 2.4 corresponds to about 5-kv. a-c. This indicates electrical action in the cable at a potential of only about half the operating voltage of this old cable. A-c. ionization tests made on several samples of old 12-kv. three conductor cables, removed from the system of the Commonwealth Edison Company have shown practically flat power-factor voltage characteristics up to 10- or 15-kv. three-phase. As the insulation on these cables was considerably less than on Mr. Kasson's cable, the stresses at which ionization took place in our cables would be approximately three times as much as the stress at which a change occurred in his d-c. tests. Perhaps by means of these tests he has discovered a new characteristic of the insulation in connection with the effect of shielding. In Fig. 8 he shows a metal box around the entire reel of cable. If the shielding is to take care of ionization near the end of the cable, I am wondering whether a metal box over each end of the length of cable would not be sufficient. Referring to the paragraph regarding the nonuniformity of cables, our testing has shown that cables with poor quality of insulation are liable to be more irregular in their quality than the cables of high quality which checks Mr. Kasson's statement. For instance poor cables would develop several hot shots in accelerated life tests and fail in rather short times. In some accelerated life tests at 2.5 rated voltage we took several 50-ft. samples from various sections of one make of a given size of high-tension cable which was giving

trouble in service and shown to be irregular in factory tests. One sample failed, after a total of 26 hr., while another sample developed hot spots without failure after 405 hr. and a third sample withstood the test for 596 hours without any failure or hot spots.

S. J. Rosch: Several theories have been brought forward in explanation of dielectric phenomena, and I believe that the probabilities are that each theory may be correct as relating to the behavior of the particular dielectric under consideration. Our error in the past has been chiefly, in trying to make one theory or one set of laws govern the behavior of all dielectrics. That is why we have failed up to the present in solving the dielectric problem and in my estimation if we commence to study each dielectric individually, we shall come nearer to obtaining a truer picture of the laws governing its behavior.

Even in a general dielectric such as a paper cable, Dr. Kouwenhoven brought out the point that he has only been able to substantiate some of the results obtained by Mr. Kasson on some samples of cable, but not on others. Undoubtedly the observations made by Dr. Kouwenhoven that were not in accordance with those by Mr. Kasson, were made on samples of cable which although equally good as far as quality was concerned, nevertheless as dielectrics possessed characteristics obeying entirely different laws. We must establish the accuracy of this fact before we can hope to go further in solving the laws of dielectrics.

Mr. Halperin in his discussion, has stated that if we took the results of d-c. measurements as established by Mr. Kasson and converted them to the equivalent a-c. voltage, by using as a divisor the factor 2.4, the values thus obtained would be much lower than those obtained by Mr. Halperin. Here again we must question why we should use 2.4 when the work of Hayden, Eddy, and Delon has definitely proven that the ratios of d-c. to a-c. vary all the way from unity to 2.6 depending again upon the type of dielectric used. It may be that in the case of the cables tested by Mr. Kasson the ratio for that particular dielectric should have been about 1.4 in which case the results would have been comparable with those obtained by Mr. Halperin.

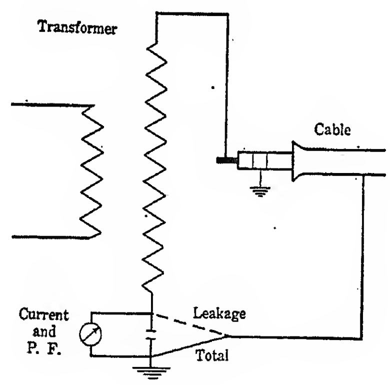

Fig. 1

I believe that before rejecting any of the theories propounded in the past, we ought first to establish definitely whether or not they are applicable in the case of some particular class of dielectrics.

E. S. Lee: Mr. Kasson has shown with great certainty the need for proper shielding to prevent the end loss of cable samples from being included with the measured loss. Wherever the end loss is high compared with the measured loss, then more perfect shielding becomes necessary. This is particularly the case with measurements on cables made with high direct voltages.

The variation of insulation resistance with voltage has been obtained at various times as shown in Figs. 3 to 6, though it has never been possible to justify with certainty the rapid decrease of the resistance with increase in voltage after passing the maximum point. It is quite gratifying to have Mr. Kasson point out that this variation is not true but has been obtained because of a faulty measurement.

It is pertinent that the end loss is also present in a-c. measurements of dielectric power loss, and it behooves us to investigate these particular measurements as they are being variously made, to be assured that the end losses are not included with the measured loss to vitiate the results.

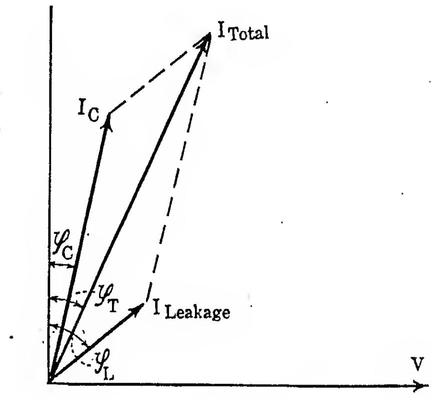

Fig. 2

P. T. Graff: With reference to the shielding of cables in making tests on cables for dielectric loss, we found that on short samples the power factors showed up rather high, and a method of test was devised which gave results on short samples, without resorting to shielding, that compared very well with the values for long lengths of cables.

The method used is shown in Fig. 1 herewith. Current and power-factor values for leakage and leakage plus cable losses are read. By the vector subtraction shown in Fig. 2 herewith the cable current and its phase angle with respect to the applied voltage are obtained. That figure shows relatively what is typical of actual cases. The effect of a small leakage current can be considerable in taking the apparent cable power factor.

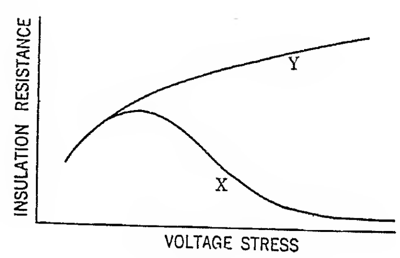

Fig. 3

Because hot spots are found where cables eventually break down on voltage tests, it cannot be construed that Mr. Malti is mistaken in not accepting the pyroelectric theory. That is based on weak microscopic filaments whereas hot spots may be due to imperfect "imperfect dielectric." No cable is uniform in its entirety and it is rather hard to apply a theory to such a dielectric. The electrophysicists are better able to handle such theories, and as engineers we should concentrate on making perfect "imperfect dielectrics."

C. L. Kasson: In regard to Mr. Halperin's comment on the difference between his results and those we obtained in Boston,

I might say that perhaps the cable we used was different from the cable he used, and this point has been brought out by several other speakers. Fig. 1, to which Mr. Halperin referred, gives the results for very old rosin-oil cable that has failed repeatedly in service.

I believe that shields must be tried by a good many others before we can be sure of the results. I tried to bring out here simply the work of one group of engineers which must be checked by others before it can be accepted.

In regard to Professor Kouwenhoven's remarks, absorption curves were made in all cases and carried out until they became practically flat. The values of leakage current used were those taken from the flat portion of the curve. It usually required about 15 min. for the curve to become reasonably flat.

Professor Kouwenhoven asked in respect to the instrument used to measure the a-c. losses. A dynamometer with series resistance was used for this purpose.

In closing, I should like to show typical insulation-resistance voltage-stress curves. We plot insulation resistance and d-c. voltage stress on a short length of cable unshielded and obtain a curve something like X in Fig. 3 herewith. On the same cable, with shields, we obtain a curve like Y. Y is a very different curve from X, and it is apparently due to the fact that curve X is influenced by the ionization of the external air, and perhaps in some of the results in the past we have been talking about ionization of external air at the ends of the cable, rather than ionization of air within the cable.

In all nature we are interested in stress on one hand and in resistance on the other hand. To every stress there is resistance; to every resistance there is stress. Therefore, a resistance stress curve of a dielectric, *i. e.*, the resistance reaction of the dielectric against the stresses placed upon it, should be an important thing, and in order to obtain what we believe is a true curve, we must resort to shielding or at least some equivalent method.

Non-Harmonic Alternating Currents

BY FREDERICK BEDELL[1]

Fellow, A. I. E. E.

Synopsis.—*Certain principles are presented for solving non-harmonic a-c. problems. Graphical methods are already well known for solving practically any problem, when currents and electromotive forces are sinusoidal, by vector diagrams in a plane. In certain special cases such diagrams give correct results when currents and electromotive forces are non-sinusoidal, but in general diagrams in more than two dimensions are necessary. A wide range of material, some of which has been published before in scattered places, is brought into relation; no single general solution seems attainable. A bibliography with 61 references is appended.*

Scope and Limitations of Usual Sine-Wave Assumption. It is common, in discussing the theory of alternating currents, to assume that currents and electromotive forces are simple harmonic functions of the time; that is, they are plotted as sine waves. It has been found that, for most purposes[2], such a wave is superior to a wave that is irregular or complex, which, to distinguish it from a simple harmonic wave, may be referred to as non-sine, or non-harmonic. The technique of alternator design has been highly developed with a view to attaining a sine wave of electromotive force as closely as possible, the subject being fully discussed in many texts and special articles, bibliography, 33. Methods have been developed for measuring and penalizing departure from a sine wave and much study has been given to the specification of allowable limits to such departure, bibliography, 9, 43, 44, 46, 47, 58, 61.

On the sine-wave assumption there has been developed a very complete analytical theory of alternating currents and, in parallel with it, a graphical method of representation and analysis that gives ready and accurate solution to practically any problem that arises. It has been found that harmonically varying quantities can be represented as vectors in a plane, and that these vectors, by showing the phase and amplitude of the several harmonic quantities, completely define them. Furthermore, any vector may be resolved into components and conversely, two or more vectors may be added or combined, as in the polygon of forces. Thus, a current may be resolved into two components at right angles to each other, one a power component in phase with electromotive force and the other a reactive component in quadrature thereto. Similarly, an electromotive force vector may be resolved into its power component in phase with current and a reactive component in quadrature, bibliography, 11.

Apparent power is the product of the electromotive force E and the current I, but real power is the product of E, I, and a power factor, $\cos\theta$, where θ is the angle of phase difference between E and I. Real power may, accordingly, be looked upon either as the product of the electromotive force and the power component of current or as the product of the current and the power component of electromotive force. The product $EI \sin\theta$ is a pulsating reactive power with average value zero, where $\sin\theta$ is the reactive factor and $I \sin\theta$ is the reactive component of current; $E \sin\theta$ is the reactive component of electromotive force.

There is scarcely a circuit problem that cannot be solved by methods based upon these principles; the whole treatment, however, is based upon the sine-wave assumption.

An exact sine wave, however, is practically never obtained from commercial apparatus. In practise, currents and electromotive forces deviate to a greater or less extent from a simple sine function of the time. It is true that in many cases, though there be this deviation from a sine wave, conclusions based on a sine-wave assumption are sufficiently accurate for practical purposes; indeed, in certain cases, conclusions thus obtained are strictly correct and the results are the same irrespective of whether we are dealing with sine or non-sine waves. In other cases, however, deviation from a sine wave causes error in results obtained on a sine-wave assumption, and this error may be large or small according to the conditions of the problem. A careful study of non-harmonic alternating currents, therefore, is desirable.

Complex Wave Represented by Fourier's Series. Any periodically varying quantity, such as we are here discussing, can be completely represented by a constant term and a series of sine terms, of definite amplitude, phase, and frequency. Cosine terms are unnecessary when the phase of each sine term is included. The series of sine terms used to represent an irregular a-c. wave includes a *fundamental,* or sine wave of fundamental frequency, and various *harmonics* with frequencies that are odd or even multiples of the fundamental frequency; a constant term is added in the general case. The introduction of factors of exponential form, that occur in transients and in cases of damping, will not be considered here, bibliography, 30.

For Usual Alternating Currents, Positive and Negative Areas are Equal and the Constant Term is Zero. The average value of any complex wave, expressed as in the

1. Professor of Applied Electricity, Cornell University, Ithaca, N. Y.

2. Although a sine wave-form is superior for general use, some other wave-form may, in certain respects, be better for a particular purpose; thus, as is well known, a peaked wave of electromotive force gives a flat wave of magnetic flux and by reducing the maximum flux, reduces the core loss in a transformer.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

preceding paragraph, is the constant term, the average value of the fundamental and the various harmonics, taking account of sign, being zero. The average value must be taken over a complete period. In an ordinary alternating current, with no predominating flow in one direction, the average value or constant term is zero; and, since the average of the positive ordinates is equal to the average of the negative, the areas of positive and negative half-waves are equal. Inequality of areas indicates a direct current combined with the alternating and this direct current would be represented by the constant term. This is a case that sometimes occurs.

In a generated electromotive force wave, the equality of positive and negative areas indicates that the total flux cut in a positive sense is equal to the total flux cut in a negative sense, as is the case in any dynamo-electric machine. It is seen, therefore, that in the wave for electromotive force, as well as in the wave for current, the constant term is zero.

When Positive and Negative Half-Waves are Alike, Odd Harmonics only can be Present. Omitting the constant term, any deviation from a simple harmonic function is represented by even and odd harmonics in addition to the fundamental. During the second half-period the fundamental wave and any odd harmonic have, respectively, the same values as during the first half, but with sign of each reversed. When only odd harmonics are present, each half-wave is, therefore, a repetition of the preceding half-wave with sign reversed; negative and positive half-waves, except for sign, are identical.

On the other hand, during the second half period of the fundamental, any even harmonic has the same sign as during the first half; hence, since the fundamental has reversed sign, an even harmonic that adds to the fundamental at any given point of the positive wave subtracts from the fundamental at the corresponding point of the negative wave. When even harmonics are added to the fundamental, the negative and positive waves are, therefore, unlike in form; that is, one is not the repetition of the other. This may be readily seen by sketching curves for a few typical cases.

A Symmetrical Generator Produces only Odd Harmonics. Any harmonics that exist, whether even or odd, must be produced either in the receiving circuit (as will be considered later) or in the generator. In practically all generators, with either revolving armature or revolving field, the generated wave of electromotive force is symmetrical, the negative half-wave being a repetition of the positive; hence, odd harmonics only are present[3]. Even harmonics in the electromotive force wave can be produced by a generator only when *both* field and armature are unsymmetrical, a condition that does not commonly exist, bibliography, 31.

Average Product Theorem. The average product of the instantaneous values of two harmonic quantities of different frequencies is zero. This is true irrespective of their relative phase positions and the ratio of their frequencies; the same is true of the product of any periodic quantities, each of which is represented by a series of harmonic terms.

This may be illustrated experimentally by passing currents of different frequencies through the two coils of a wattmeter and noting that the reading is zero. Formally, it may be shown by integration of the product of two sine functions, having different periods, over the least common multiple of the two periods, or over the longer period when one period is a multiple of the other. In case the two periods were nearly equal and their least common multiple very large, beats would occur, but the average value of the product over a sufficiently long time would still be zero, bibliography, 13, 14 (p. 391).

The average value of a constant, multiplied by a sine function, or by the sum of several sine functions, is likewise zero.

The results of these relations are far reaching; r.m.s. values and average power for non-harmonic waves both depend upon this average product theorem.

Root-mean-square Value of Non-harmonic Wave. A non-harmonic wave, as already explained, consists of a series of harmonic components of fundamental and higher frequencies. It will be shown that the r. m. s. value of the total wave is equal to the square root of the sum of the squares of the separate harmonic components. Thus, if the fundamental is A, and the several harmonics B, C, and D (r. m. s. values), the r. m. s. value of the total wave is $\sqrt{A^2 + B^2 + C^2 + D^2}$. This will be referred to later as the *square law*. It will be seen that the result is *independent of the phase and frequency* of the several components. The effect

3. With a symmetrical armature, irrespective of what the field may be, if a particular armature conductor cuts certain flux, another armature conductor connected in the opposite sense will cut this same flux just half a period later; hence, negative and positive half-waves are alike and odd harmonics only can be present. In a like manner, with a symmetrical field, irrespective of what the armature may be, if a particular armature conductor cuts certain flux, that same conductor will cut equal flux in an opposite sense just half a period later; hence, in this case also, negative and positive half-waves are alike and odd harmonics only can be present. Lack of symmetry of field may be produced by inequality of dimensions, spacing, or material; and, even when the structure is symmetrical, it can be produced by unequal excitation of various poles. Armature windings are commonly symmetrical, but may be otherwise, as in armatures with an odd number of slots.

It is here assumed that the speed at which the generator is driven and its field excitation are constant, as is usually the case. If the field is excited with alternating current and the armature is rotated synchronously, an electromotive force of double frequency is generated. If the field is excited with direct current and a superimposed alternating current, the electromotive force generated will, accordingly, consist of a fundamental and a second harmonic. It is thus possible to generate an even harmonic in a symmetrical armature. A development of this method may be employed for obtaining high frequencies, as in the Goldschmidt alternator.

of each component is added as though it were in quadrature to each other component, bibliography, 13, 14.

This may be demonstrated experimentally by taking voltmeter readings of the separate and total voltages when two or more electromotive forces, not of the same frequency, are connected in series; or, more laboriously, by plotting curves for the instantaneous values of the components and determining r.m.s. values of their sum.

If, collectively, the harmonics B, C, and D are represented by H, where $H^2 = B^2 + C^2 + D^2$, the r. m. s. of the total wave is $\sqrt{F^2 + H^2}$, where F is the fundamental. It is seen that the collective harmonics add as a component in quadrature to the fundamental.

The proof of the foregoing is readily seen. The non-harmonic wave may be represented by a series of sine terms of different frequencies. One of these terms may be a constant, representing a d-c. component, if desired. When this series is squared, to get the r. m. s. value, every term is multiplied by itself (so that any term, as A, becomes A^2) and by every other term. But the cross-products, obtained by multiplying together terms of different frequencies, all vanish, for their average product, by a theorem already stated, is zero. The only terms remaining are the square terms, as A^2, B^2, etc., the r. m. s. value of which is $\sqrt{A^2 + B^2 + C^2 + D^2}$.

One of the terms in the preceding expression may be a constant, representing a d-c. component. It is thus seen that a direct current, when superimposed on an alternating current, adds vectorially in quadrature, in the same manner as an alternating current of a different frequency; the resultant is the square root of the sum of the squares of the component currents.

Principles of Independent Superposition of Harmonic Alternating Currents of Different Frequencies. When a pure sine electromotive force is impressed upon a circuit in which the various resistances, inductances, and capacities are constant, the current that flows is a pure sine wave of the same frequency, with amplitude and phase dependent upon the constants of the circuit.

When the electromotive force wave contains not only the fundamental sine wave, but harmonics as well, the current will contain a fundamental and harmonics of these same frequencies. Furthermore, each harmonic component of the electromotive force will produce in the current a corresponding harmonic component of the same frequency, *exactly as though all other components were absent,* bibliography, 6, Chap. XI.

This holds true of any part of a complex circuit, as well as of the circuit as a whole. Thus, if the harmonic components of the electromotive force, either in the whole circuit or in a part, are E_1, E_3, E_5, the corresponding components of current are I_1, I_3, I_5, each component being determined independently as though it alone existed.

By the square law, the sum of the component electromotive forces is

$$E = \sqrt{E_1^2 + E_3^2 + E_5^2}.$$

The sum of the component currents is

$$I = \sqrt{I_1^2 + I_3^2 + I_5^2}.$$

The phase of each harmonic component, as well as its amplitude, is determined independently. Although these phase relations affect the wave-shape, they do not affect the r. m. s. value of the total current.

When a circuit contains a constant resistance only, the harmonics in the current wave will have the same relative amplitudes and phase positions as the several harmonics in the electromotive force wave; that is, the current and electromotive force are similar in wave-form. With reactance present, however, this will not be true, for the relative amplitudes and phase positions of the several harmonics in the current will vary with their several frequencies.

In the case of inductive reactance, the reactance of the circuit for the several harmonics increases in proportion to frequency, thus increasing the lag and decreasing the amplitude of the corresponding harmonics in the current wave. Inductance tends to choke out the higher harmonics and to make a smoother current curve. Capacity reactance, on the other hand, amplifies harmonics in the current and so increases, rather than smooths out, irregularities in its wave-form. With either inductive or capacity reactance present, the wave-forms of current and electromotive force, except in the case of pure sine waves, are no longer similar. The resultant wave-form of current, however, is built up from its separate harmonic components, for the principle of independent superposition holds, so long as resistance, inductance, and capacity are constant. When one function, as current, is related to another, as electromotive force, by a linear differential equation in which the coefficients are constant, as a matter of course, one function may be derived from the other by a so called "distributive" operation, and the principle of independent superposition holds.

Should resistance, inductance, or capacity be variable, the principle of independent superposition cannot be applied. In this case, as discussed later, a sine-wave electromotive force does not produce a sine-wave current; the separate harmonic components of a complex electromotive force, therefore, do not produce corresponding independent components in the current.

When a Current Comprises Components of Different Frequencies, Each Component has Its Independent Resistance Loss; the Total Resistance Loss, $R I^2$, is the Sum of the Losses due to the Separate Components. As already shown, when a current I comprises components I_a, I_b, I_c, etc., of different frequencies, the r. m. s. value of the total current is the square root of the sum of the squares of the separate components;

$$I = \sqrt{I_a^2 + I_b^2 + I_c^2 + \ldots}$$

Hence,

$$R I^2 = R I_a^2 + R I_b^2 + R I_c^2 + \ldots$$

Each component has its own resistance loss as though it alone existed; the total loss is merely the sum of these separate losses. This is equally true when one component is direct current.

As an illustration, if two unlike currents, either direct and alternating, or alternating currents of different frequencies, of 10 amperes each, are superposed in a circuit having a resistance of one ohm, the total loss is 200 watts, the separate losses being 100 watts each. This is an interesting contrast with the case when two *like* currents, two direct currents, or alternating currents of same phase and frequency, of 10 amperes each, are superposed in the same circuit having resistance of one ohm; the total loss in this case is 400 watts, although the loss would be only 100 watts for either current flowing alone. (For references, see next paragraph.)

Copper Saving in Composite Systems of Power Transmission. It is obvious from the foregoing that a considerable copper economy could be effected were it possible to use the same lines for the simultaneous transmission of power by unlike currents, that is, by direct and alternating currents or by alternating currents having different frequencies.

Inasmuch as copper drop is proportional to copper loss, each current in such a composite system would have its own independent copper drop as well as copper loss; and, where the amount of copper is determined by allowable copper drop or loss, no more copper would be required to carry several currents for composite transmission than would be required to carry one current alone. The independence of copper drop is very striking. Thus, if two generators transmit unlike currents over the same lines to independent loads, one for lighting and the other for power, the regulation of the lighting load is in no way affected by most extreme variations in the power load; for example, an entire power load with line drop of, say, 50 per cent could be thrown off and on without producing even a flicker in the lamps constituting the lighting load. These results are *confirmed* by test.

Although several composite systems have been proposed, the complications involved have thus far prevented their general adoption, bibliography 16, 17, 19, 20, 21, 22.

Equivalent Sine Wave. Although a non-harmonic alternating quantity requires a series of harmonic terms for its complete representation, it can be represented, for many purposes, by a single sine wave having the same r. m. s. value and the same frequency. Such a wave is called an *equivalent* sine wave. It is equivalent, however, in a restricted sense only. Thus, inductance and capacitance can completely neutralize each other in case of true sine waves only, complete neturalization being impossible for non-sine waves or for their equivalent sine waves.

If a non-sine wave is plotted in polar coordinates, the equivalent sine wave is plotted as a circle with the same area. If a non-sine wave and its equivalent sine wave are plotted in rectangular coordinates, the curves formed by the squares of their ordinates enclose equal areas, thus giving equal mean-square and r. m. s. values.

Vector Representation of Equivalent Sine Wave. A non-harmonic alternating quantity can be represented by a vector corresponding to its equivalent sine wave. There seems to be no criterion, however, for satisfactorily defining the absolute phase location of an equivalent sine wave with respect to the irregular wave to which it is equivalent, although the phase displacement of one equivalent sine wave with respect to another, as a current with respect to an electromotive force, can be determined. As discussed later, this phase relation is, in general, definite between pairs of quantities only. Accordingly, except in special cases, only two equivalent sine waves can be represented as vectors in a plane and three such waves as vectors in space, if all their phase relations, as well as magnitudes, are to be correct. More vectors would require more dimensions, or would necessitate a lack of significance in the relative phase positions of some of the vectors. The sum of two equivalent sine waves can be vectorially represented, however, in the same plane as the two waves themselves, and the sum of three equivalent sine waves can be represented with them in space, as discussed later.

Equivalent Phase Difference. The equivalent phase difference between two non-sine waves of the same frequency is the phase difference between the two equivalent sine waves when so located with respect to each other that the mean product of their instantaneous values is the same as the mean product of the instantaneous values of the two non-sine waves of which they are the equivalent. In the case of a current and an electromotive force, this mean product is the average power, the equivalent phase difference being an angle whose cosine is equal to the power factor.

Lag or Lead of Non-Sinusoidal Current. In case of sine waves of current and electromotive force, inspection of the waves plotted with respect to time shows at once whether the current is lagging or leading in relation to the electromotive force. If the current is lagging, the current passes through zero and attains successive values, as $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$ and full maximum value, a certain interval of time, depending upon the constants of the circuit, after the electromotive force attains its corresponding value. This time interval or lag is the same between zero as between maximum values of current and electromotive force and is a measure of the phase difference. Power and power factor are increased when a lagging current is advanced, or when a leading current is retarded, in phase.

In case of non-sine waves, however, these definite relations do not hold. Except in special cases, the time-lag measured between zero points of current and electromotive force is different from the time-lag measured between maximum values, and in neither case

does its value correspond to the equivalent phase difference. Indeed, the current might lag behind the electromotive force in reaching its maximum value and be in advance of it in passing through zero, so that inspection does not show whether the current is lagging or leading, nor whether the angle of equivalent phase difference is negative or positive. This uncertainty, however, does not affect the numerical value of the power factor, for the cosine of an angle is independent of its sign.

Arbitrarily, a current is said to lag when its maximum value occurs later than the maximum value of the electromotive force, bibliography 61; but the time of passing through zero has also been used as a criterion, bibliography, 26. Although not used, a better criterion might depend upon power. Thus, current would be referred to as lagging when an increase in power and power factor is brought about by advancing it in phase, and as leading when increase in power and power factor is brought about by retarding it. This is discussed later under power factor.

Two Equivalent Sine Waves of the Same Frequency, and their Sum or Difference, can be Represented by Vectors in a Plane. Three vectors, 1, 2, and 3, representing non-harmonic quantities of the same frequency, do not in general lie in a plane. Thus, if the equivalent phase difference between 1 and 2 is 40 deg., and between 2 and 3 is 10 deg., the equivalent phase difference between 1 and 3 may be neither 30 deg. nor 50 deg. The representation of three non-harmonic quantities by vectors in a plane is correct, however, when one of the quantities is the sum or difference of the other two; that is, the vectors in this case correctly show the relative phase differences between the three quantities, as well as their magnitudes. Thus, let A and B be the r. m. s. values of two non-harmonic quantities and C the sum. If three vectors are drawn in a plane so that C is the vector sum of A and B, it will be found that the angle between any two vectors will be their equivalent phase difference, as already defined; if one vector represents an electromotive force and the other a current, the cosine of this angle gives the true power factor. Or, if two vectors A and B are drawn with an angle between them equal to their equivalent phase difference, their vector sum will give the r. m. s. value of the sum of the two non-harmonic quantities that they represent, bibliography, 13, 14 p. 391, 15, 39.

Again, if a is the equivalent phase difference between two non-harmonic quantities and if b is the phase difference between them when one of the quantities is reversed, the sum of the angles a and b is 180 deg.; the vector representing one of the quantities is reversed, as though the quantities represented by the vectors were harmonic.

The correctness of vector addition and subtraction of non-harmonic quantities may be rigorously proved, or may be verified either by experiment or graphical construction, bibliography, 13, 14.

The once famous three-voltmeter and three-ammeter methods are illustrations of the general theorem that vectors in a plane may represent two non-harmonic waves and their sum. In the three-voltmeter method, three voltmeter readings are drawn as vectors in a plane; E_1 measured across a load; E_2 measured across a non-inductive resistance in series with the load; and E, their sum, measured across the two. In this case, not only the three voltages but also the current I can be represented[4] as vectors in a plane, for $I = E_2 \div R$, where R is constant, and any representation of I is the same as the representation of E_2 with the scale changed. The equivalent phase difference between E_1 and I in the load is thus determined, giving power factor cos θ, and power. In the three-ammeter method there is a similar relationship, vectors in a plane being drawn to represent the electromotive force E as well as the currents, I_1 in a load, I_2 in a non-inductive parallel circuit, and I, their sum. The three-voltmeter and three-ammeter methods may be considered as proved by the general theorem; or, they may be considered as a proof of the theorem for these special cases, bibliography, 2, 7.

Otherwise stated, we may represent as vectors in a plane the various currents and voltages in a system consisting of one unknown load circuit of any character and a single pure resistance, either in series or in parallel with it. By extension, see preceding footnote, we may include in the system any number of pure resistances connected in any way whatsoever with the one unknown circuit; thus, some of the resistances may be in series and some may be in parallel wth it, provided in each one there is a linear relation, $e = R\, i$, between current and electromotive force. In the one unknown load circuit, however, there need be no simple relation between e and i; the current in it may be distorted, as by hysteresis, and have a very different wave-form from the electromotive force. A single voltage and a single current in the unknown load circuit are included in the vector representation in a plane. If the voltage or current in the unknown circuit is split up into parts or components, such parts or components cannot be represented in the plane.

Three Equivalent Sine Waves of the Same Frequency, and their Sum, can be Represented by Vectors in Space. In a like manner three non-harmonic alternating quantities, together with their sum, can be represented as vectors in space, the length of the vectors being equal to the r. m. s. values of the various quantities and the angle between any two vectors being equal to their equivalent phase difference. More quantities can be so represented only when they are linear functions of those already represented; thus, if three currents are

4. More generally stated: Where certain quantities are represented as vectors in a plane, any other quantities that are linear functions of these may likewise be so represented, bibliography, 15, 23. When $e = R\, i$, e is a linear function of i. When $e = R_1\, i_1 + R_1\, i_2$, e is a linear function of i_1 and i_2.

represented in space, any voltage drops proportional thereto may also be represented. This follows as an extension of the preceding case, bibliography, 16, 18 to 23, 25, 29 pp. 217-9, 34, 42, 45, 53.

More than three vectors representing non-harmonic quantities cannot, in general, be drawn in space; but the resultant of two of these can be used, together with the other two, to construct a three-dimensional figure. In the same way, three vectors cannot, in general, be drawn in a plane; but the resultant of two of these can be drawn with the third in a plane. The three resultants of any number of quantities can thus be represented in space, or two resultants in a plane, bibliography, 34, but this is a cumbersome procedure of doubtful utility.

Variation of Resistance, Inductance, or Capacitance Causes Wave Distortion. In a circuit with constant resistance, inductance, and capacitance, a sine electromotive force causes a sine current to flow without distortion; in case of a complex electromotive force, each harmonic component of electromotive force produces a corresponding harmonic component of current, as already pointed out in the paragraph on independent superposition. With a sine electromotive force, the current has a phase position with respect to the electromotive force depending upon the frequency and the relative values of resistance, inductance, and capacitance. When there is inductance or capacitance alone in the circuit, the current lags behind, or is in advance of, the electromotive force by an angle of 90 deg. and represents no power, for the power factor, cos 90 deg., is zero; with resistance alone, current and electromotive force are in phase and power factor is unity.

Should the values of resistance, inductance, or capacitance vary during a cycle, the current will be distorted, and, with a sine electromotive force, the current wave will contain harmonics in addition to the fundamental. Furthermore, in case of a varying inductance or capacitance, where the variation always involves hysteretic loss, the phase difference between the fundamental current wave and the electromotive force will be *less* than 90 deg., and the power factor will no longer be zero. Similarly, with a varying resistance, the phase difference between fundamental current and electromotive force will not be zero and power factor can never be unity, as discussed in detail in subsequent paragraphs.

Iron Introduces Odd Harmonics and so Distorts the Current Wave on Account of Variable Permeability; It Advances the Fundamental of the Current Wave in Phase and makes Increasing and Decreasing Values of Current unlike on Account of Hysteresis Loss. The instantaneous value of an inductive electromotive force, by Faraday's law, is always proportional to the rate of change of magnetic flux. The inductive electromotive force wave is, accordingly, the differential of the flux wave, and the latter is the integral of the former; therefore, if either one of these waves is a sine wave, the other is necessarily a sine wave differing from it 90 deg. in phase. This is true whether the circuit contains iron or not.

In a circuit containing no iron, permeability and inductance are constant, and current and flux are proportional; a sine flux, which always necessitates a sine electromotive force, also necessitates a sine current. However, when permeability is not constant, as in a circuit embracing iron, the current and flux are no longer proportional, this lack of proportionality being shown by the well-known curve of magnetization or hysteresis loop; a sine flux and sine electromotive force, accordingly, *necessitate a non-sine current.*

With the usual symmetrical hysteresis loop, the negative part of the distorted current wave will be a repetition of the positive and hence, for reasons already given, the current *contains odd harmonics only.* The S-like shape of the hysteresis loop indicates that the third harmonic must be prominent and this is always found to be the case; the fifth and higher harmonics have considerably smaller, although sometimes significant, values. Thus, a third harmonic of 30 per cent might be accompanied by a fifth harmonic of, say, 8 or 10 per cent, higher harmonics than the third being usually much smaller.

On account of the distortion of the current wave, a vector diagram in three dimensions can be advantageously used, the current harmonics produced by distortion being represented collectively at right angles to the fundamental plane, bibliography 25. This construction may be used whenever there is current distortion due to pulsations of any of the constants of the circuit.

Inasmuch as the ascending and descending curves that form a hysteresis loop are not alike, *the distorted current wave is not symmetrical* but has a different form for increasing and decreasing values of current. It is found that the third harmonic has such a phase position as to subtract from the fundamental during most of the time when the current is increasing and to add to the fundamental when the current is decreasing, thus humping the right hand (descending) side of the current wave.

Furthermore, reference to the hysteresis loop shows that maximum current occurs simultaneously with maximum flux, but that *zero current occurs before zero flux.* Although the flux wave always lags 90 deg. behind the electromotive force, the fundamental of the current wave is thus caused to lag *less* than 90 deg. This gives a power factor greater than zero, which accounts for the hysteretic consumption of power. *All* the power due to iron loss is thus supplied by the fundamental, for the harmonics in the current, when the electromotive force is sinusoidal, represent no power, bibliography, 1, 4, 5, 9, 10, 12, 25, 28, 35, 37, 52, 57.

In an imaginary case in which varying permeability gave like ascending and descending curves of magnetization, enclosing no area, there would be no hysteresis

loop and no hysteresis loss. The varying permeability would nevertheless distort the current wave by introducing harmonics, but the fundamental would in this case lag 90 deg. behind the electromotive force, as always when there is no consumption of power.

Frequency Multiplication by Iron Distortion. It was early pointed out (bibliography 4) that the production of harmonics by wave distortion due to iron might be employed as a means for frequency multiplication. This is accomplished by combining circuits in such a way that the fundamentals of two waves oppose or neutralize each other, leaving a residuum of harmonics, of which the third is usually predominant. Triple frequency is thus obtained; or double frequency, by use of cores unsymmetrically magnetized by superposed d-c. excitation. Although the efficiency is not high enough to warrant the use of these methods in power transmission, they have been used in radio communication.

Harmonics in Three-phase Circuits. Obviously, in 3-phase circuits, the harmonics of triple frequency in the three circuits, whether originating in the generator or in transformers due to iron distortion, are in phase with each other. This is true not only for the third harmonic but for its multiples as well. In star-connected circuits, these harmonics appear in the electromotive force wave between line and neutral, tending to cause current to flow out through the three lines in parallel, but no current flows unless there is a grounded neutral or return neutral circuit to form a path for the return current.

In high-voltage circuits supplied through transformers, the harmonics produced by the iron in the transformers may be large enough to seriously strain insulation by increasing the maximum value of the electromotive force wave, particularly when some harmonic becomes amplified by resonance. To avoid this, the *primary or secondary windings* of transformers on three-phase circuits, or, in some cases, tertiary windings, are *commonly connected in delta*, so as to provide a local circuit in which the third harmonic current and its multiples can flow.

These harmonic currents act as magnetizing currents and reduce the corresponding harmonic voltages to a small value, just sufficient to circulate the current through the impedance of the three windings in series. The additional heating due to these local currents in delta-connected transformer windings is small. The delta connection of one set of transformer windings prevents the rise of voltage in any of the windings, even though some of these are not delta-connected.

Harmonic voltages in a generator are usually small compared with those produced by iron distortion in transformers and can be reduced by design. Delta connection of generator windings is therefore unnecessary. *Generators are usually star-connected* in order to provide a neutral for grounding.

The harmonic current in a neutral or ground return or in delta-connected windings of generator or transformers, as already pointed out, consists of the third harmonic and its multiples, for these are in phase in the three parts of a three-phase circuit. Other harmonics, as well as the fundamental, appear as voltages from line to line and cause current to flow only in the load, bibliography, 57, with full bibliography.

Pyramidal Space Diagram. The three star voltages of a three-phase system, which lie in a plane when there is no wave distortion, have the neutral point raised from the plane by the third harmonic voltage and its multiples, so that the three star voltages become the edges of a pyramid. Similarly, a diagram with vectors in space is required for representing line and delta currents, when harmonic currents circulate in the delta without appearing in the line, bibliography, 29, pp. 217-9. Commonly this effect of harmonics is ignored and plane diagrams are used, being sufficiently correct for most purposes.

T-connected Transformers Produce Dissimilar Wave Forms. Although the third harmonic does not ordinarily appear from line to line in a three-phase system, it may so appear when a two-phase generator with a third harmonic in the electromotive force wave of each phase is connected through T-connected transformers to a three-phase line. In this case the three line voltages are distorted dissimilarly, for the third harmonic appears differently in each, bibliography, 41.

A Resistance that Pulsates during a Cycle Introduces Odd Harmonics into the Current Wave; the Current and Electromotive Force Pass Through Zero at the Same Instant, but Power Factor is Less than Unity. In a circuit containing a constant resistance only, the value of the current at any instant is proportional to the value of the electromotive force at that instant, for $e = R\,i$; a curve plotted between e and i is a straight line. The current wave and electromotive force wave are, accordingly, identical in shape and pass through zero at the same instant; furthermore, the power factor of the circuit is unity.

In some cases resistance varies with the instantaneous value of current, as in an incandescent lamp in which resistance is a function of temperature, bibliography, 27, 38. In a solid conductor this variation in resistance is small, usually less than one per cent, but the instantaneous values of current i are no longer strictly proportional to the instantaneous values of electromotive force e; the curve plotted between e and i being a loop, showing a lag or hysteresis in temperature changes. The wave form of current differs, therefore, from the wave form of electromotive force. A sine electromotive force thus produces a non-sine current; in other words, a periodic variation in resistance introduces harmonics into the current wave and these harmonics will be odd when the resistance has the same series of values for negative as for positive currents.

With resistance only in the circuit, the current and

electromotive force pass through zero at the same instant, with a pulsating as with a constant resistance. Power factor, however, is less than unity, in solid conductors usually only a fraction of a per cent less; for, with a sine electromotive force, the harmonics introduced into the current wave by the pulsating resistance represent no power. There will be, accordingly, a small phase difference between the equivalent sine wave of current and the electromotive force corresponding to the power factor.

It can be shown, bibliography, 42, that, as in the case of distortion produced by iron, the distortion in current produced by pulsating resistance is accounted for chiefly by the introduction of a third harmonic, that the current wave is either flattened or peaked, and the fundamental of current is either slightly advanced or retarded in phase, according to whether the temperature coefficient is positive or negative. The current, like any distorted current, can be shown in a vector diagram of three dimensions, the harmonics due to distortion being shown as a single vector at right angles to the fundamental plane, bibliography, 42. But all these effects of distortion, large when produced by iron, are so minute as to be usually negligible when produced by the pulsations in resistance of a solid conductor.

In a gas, however, as in the case of an arc lamp or mercury arc, the current distortion and resulting harmonics are very pronounced, so that power factor is, in some cases, reduced to 0.85 or less, bibliography, 3, 24, 26. In an arc that is discriminating, as between a ball and point, even as well as odd harmonics are introduced in the current. In a transmission line, an arc to ground introduces harmonics which may cause a dangerous rise in voltage through resonance, bibliography, 32.

It may be noted that power factor is less than unity with a direct current, in case resistance is pulsating or there are variations in current without corresponding variations in electromotive force.

Variable Capacitance Causes Wave Distortion, which is Practically Negligible in a Condenser; Corona Causes Pronounced Wave Distortion. In a perfect condenser, charge Q is proportional to potential E; the capacitance C is constant in the expression $Q = C\,E$ and the plot between Q and E is a straight line. When this plot is not a straight line, but is a curve or loop, bibliography, 8, harmonics are introduced and the current wave is distorted, as in case of varying inductance or permeability. In case of usual condensers such effects are practically negligible. In case of corona, however, there is a well-defined hysteresis loop in the curve plotted between Q and E, and a pronounced distortion in the current wave.

An increase in charging current and in charge Q, due to corona, occurs when the voltage is above a certain critical value, *i. e.*, during the peak of the voltage wave. There is a pulsation, therefore, in the ratio of Q to E and so in the capacitance of the line. The pulsation in capacitance may be explained in part as due to a periodic change in the effective diameter of the wire, but this does not account for the whole effect.

This periodic change in capacitance produces a pronounced third harmonic, as already shown for periodic changes in resistance or inductance, and this appears as a triple-frequency current to ground in a three-phase system, when the neutral is grounded at both ends of the line, bibliography, 50, 51, 54, 55, 56.

Power. When alternating currents and electromotive forces are complex, containing components of fundamental and higher frequencies, each component has its own independent power and power factor. The total power is the sum of the power of the separate components; thus, the total average power is

$$E\,I\cos\theta = E_1\,I_1\cos\theta_1 + E_3\,I_3\cos\theta_3 + \ldots$$

The independence of the average power of the separate harmonic components results from the fact, already pointed out, that the average product of harmonic components of different frequencies is zero, so that, when complex currents and electromotive forces are multiplied together, only products of currents and electromotive forces of the same frequency remain. This relation is always true, irrespective of the nature or the amount of distortion in the electromotive force or current wave.

Apparent power is not, in general, the sum of the separate apparent powers. *The instantaneous power* for each component is a quantity of double frequency varying harmonically about its average value, bibliography, 36.

Power Factor. From the foregoing, it follows that power factor, in case of a complex wave, is

$$\cos\theta = (E_1\,I_1\cos\theta_1 + E_3\,I_3\cos\theta_3 + \ldots) \div E\ I,$$

θ being the equivalent phase difference between the complex E and I.

It will be seen that in determining the combined power factor, $\cos\theta$, the power factor of each component is given a weight in proportion to the ratio of the apparent power of the component to the total apparent power. There is, however, no simple general relation between the combined power factor and the power factor of the separate components.

A circuit with reactance increasing and power factor decreasing with frequency, as R and L in series or R and C in parallel, will have a lower power factor with an irregular electromotive force wave than with a sine wave. On the other hand, a circuit with reactance decreasing and power factor increasing with frequency, as R and C in series or R and L in parallel, will have a higher power factor. It is thus seen that harmonics in an electromotive force wave may decrease or increase power factor according to the character of the circuit.

Any change in the relative amplitudes of the separate components of electromotive force and corresponding

components of current changes the total power factor and at the same time changes wave form. Any change in their relative phase positions, however, while changing wave form, has no effect on power factor.

An exception occurs when the power factors cos θ, cos θ_1, cos θ_3, etc., are all equal, so that

$$E\,I = E_1\,I_1 + E_3\,I_3 + \ldots$$

In this case total apparent power is the sum of the apparent powers of the separate components, and, furthermore, the value of the total and separate power factors is not affected by any change in the relative amplitudes of the component electromotive forces and corresponding changes in component currents. This occurs when power factor is unity and in one special case, as discussed later.

Unity Power Factor Occurs only when the Current Wave is Precisely Similar to the Electromotive Force and in Phase with it. Reactance must be Zero and Resistance Constant. As power factor is real power $R\,I^2$, divided by apparent power $E\,I$, it is obvious that, in order to have unity power factor, $E\,I$ must equal $R\,I^2$ and $E = R\,I$. This can be true only in case the reactance of the circuit is zero and there is no capacity or inductance present.[5]

Power factor is the ratio of resistance R to the impedance Z. This ratio is unity only when reactance is zero and the circuit contains resistance only. Furthermore, for unity power factor, the resistance must be constant, for it has already been shown that a pulsating resistance reduces power factor to less than unity.

Constant resistance means that the current wave is similar to the electromotive force wave; the current i at any instant is proportional to the electromotive force e at that instant; $e = R\,i$. In this case the current and electromotive force pass through zero simultaneously and their maximum values coincide. Under no other circumstances can power factor be unity. There is no limit, however, to the irregularity of the current and electromotive force waves with unity power factor, provided the two waves are similar.

As a numerical illustration of unity power factor in case of a complex electromotive force, let the electromotive force $E = 50$, comprising a fundamental $E_1 = 40$ and a third harmonic $E_3 = 30$, be connected to a circuit with $R = 10$. The current is similar to the electromotive force; thus, $I_1 = 4$; $I_3 = 3$; $I = 5$. Power $R\,I^2 = R\,I_1^2 + R\,I_3^2$; or $250 = 160 + 90$. Apparent power $E\,I = 50 \times 5 = 250$. Power factor $= 1$. In like manner, the electromotive force may contain any number of harmonics and these may have any phase positions, as well as any amplitudes, for the phase of one harmonic with respect to others or with respect to the fundamental has no effect on power factor. For a more formal proof, see bibliography 23, 34.

5. In case of a pure sine wave, capacity and inductance may be present and just neutralize each other, so as to give zero reactance and unity power factor, but this is possible with a sine wave only.

Power Factor Less than Unity is due either to Current Displacement or Current Distortion. It will be seen that power factor is less than unity in two cases: (*a*) When an alternating current is shifted in phase with reference to the electromotive force, so that the zero and maximum values of current occur earlier, or later, than the corresponding zero and maximum values of electromotive force, power factor is less than unity, no matter what the wave forms of current and electromotive force may be. This is the common case and usually comes to mind when the power factor of an alternating current is referred to as being less than unity; the angle θ in the expression, power factor equals cos θ, represents a true phase displacement. (*b*) When current and electromotive force are unlike in wave form, power factor is less than unity, no matter what may be the phase position of the current with respect to the electromotive force; power factor may be brought to a maximum value by shifting the current wave with respect to the electromotive force, but this maximum is always less than unity.

The sign of θ, in the expression power factor equals cos θ, is ambiguous and does not indicate whether the current is lagging or leading. In fact, when the reduction in power factor is due to distortion, there may be neither lag nor lead. Thus, power factor 0.85, for example, indicates a phase angle of 32 deg. between the vectors I and E, representing current and electromotive force. If there is no lag or lead, the vector I is apparently caused to swing out of the usual plane of reference, as already referred to in the discussion of distortion due to pulsating resistance, inductance, or capacity.

Either current displacement or current distortion may operate alone to reduce power factor, or the two causes may operate simultaneously. Customarily the two effects are lumped together in a single resulting power factor cos θ, which, in some cases, may be separated into two factors, cos α due to current displacement and cos β due to current distortion. The angle α then represents lag or lead in the usual sense in the plane of reference and the angle β the amount the current vector swings out of that plane due to distortion, power factor being the product cos α cos β. A single factor, however, is more convenient and is quite sufficient for ordinary purposes. The values of the two separate factors are not readily determined and, except in special cases, are not independent of each other. bibliography, 59.

Peculiar Special Case. When the current wave is not similar to the electromotive force, any change in amplitude of any harmonic component changes the complex power factor, except in one peculiar case, namely, when only one harmonic, the nth harmonic, is present and the lag of the current of this harmonic with respect to its electromotive force is exactly equal to the lead of the fundamental current with respect to the fundamental electromotive force. This occurs

when, in addition to a resistance, the circuit has a capacity reactance $1/C\ \omega$ which, for the fundamental, is n times the inductive reactance $L\ \omega$, bibliography, 59.

In this case, and in this case only, the harmonic and fundamental have the same power factor, lagging in one case and leading in the other, and this is the power factor of the complex wave. Whether the complex current is lagging or leading with respect to the complex electromotive force is apparently indeterminate.

Suppose, with a suitable frequency mixer, bibliography, 60, the relative values of fundamental and harmonic can be varied, so that the total r. m. s. value of the complex electromotive force remains constant. The current taken by the circuit, its real and apparent power, and its power factor remain unchanged, as the wave form of the electromotive force is varied from 100 per cent fundamental with leading power factor, to 100 per cent harmonic with lagging power factor. When fundamental and harmonic are both present in any proportions, the current vector apparently swings around in space, maintaining a constant phase angle while changing from lagging to leading. In a somewhat similar way, current in a synchronous motor changes from lagging to leading, with increase of field excitation, without the power factor passing through unity, bibliography, 49.

Conclusions. This paper, which is in itself a summary, may be further summarized by surveying the headings of the various paragraphs. It has been pointed out that there are well-known methods for obtaining the general solution for practically all problems dealing with simple harmonic alternating currents. There seems, however, to be no similar method that can be applied in all cases to the solution of problems when the currents are non-harmonic. Such problems have to be solved more or less separately, without a general solution. The purpose of this paper has been to present certain principles simply and clearly, in order that use may be made of them wherever applicable.

Attempts to use some kind of distortion factor, bibliography, 44, for modifying the usual alternating current solutions, so that equations and graphical diagrams based on the sine assumption may be extended so as to apply to non-sine currents, have not borne fruit, bibliography, 34, 45, nor has a general analytical discussion of non-sine alternating currents given practical working solutions, bibliography, 48. Although certain general principles are established, they do not afford the immediate solution of every particular problem.

An outstanding fact is that graphical diagrams for precisely representing non-harmonic alternating currents and electromotive forces require, except in some special cases, more than two dimensions. The ordinary plane diagrams are at best only approximations.

It is a consolation to know, however, that the errors in plane diagrams are commonly not large enough to assume importance, bibliography, 40, p. 228, except when leading as well as lagging currents are involved, in other words, except in circuits containing capacity reactance, as in condensers and synchronous machinery.

In inductive circuits, harmonics are, to a certain extent, choked out, so that errors are limited and there is no tendency for them to become amplified. The errors may be likened to the errors in using a drawing accurately made on a rumpled paper, which is later ironed out flat. The flat diagram, although not precise, may be accurate enough for most purposes. Thus, transformer diagrams drawn in a plane give excellent working results, despite wave distortion. In a synchronous motor, on the other hand, certain discrepancies due to current distortion may be corrected or eliminated by use of a diagram in three dimensions, bibliography, 49. It is well known that the power factor of a synchronous motor does not become unity when current changes from lagging to leading, as the plane diagram and usual theory based on the sine-wave assumption would indicate. The three-dimensional diagram makes it possible for the current vector, in passing from lagging to leading, to swing around in space so that the power factor passes through a maximum less than unity.

Plane diagrams are subject to the greatest errors in case of circuits containing inductance and capacity, when resonance for a particular harmonic may greatly amplify the errors due to wave distortion.

Discussion

A. Boyajian: Professor Bedell is a pioneer in the theory of alternating currents, and his early book is still a classic on the subject. A few years ago I listened with great fascination to Professor Bedell narrating his early experiences in the fundamental theory of alternating currents. He said in the course of his narrative that when he analyzed the flow of currents in condensers, resistances, and inductances due to sine-wave voltage, his mathematical analysis showed him that the current of the con-

denser should be 90 deg. ahead of the voltage, the current of the inductors 90 deg. behind, and in a resistance in phase with the voltage. Up to that time nobody knew anything about phase relationship and this was very puzzling. It was peculiar how in a condenser you could get current ahead of voltage, like having an effect precede the cause instead of following the cause. They made some tests, plotted oscillograms, verified the mathematical analysis, and everybody was happy.

What he had done at that time for sine-wave voltages he has later done for non-harmonic voltages, and his paper puts together a lot of developments since that time.

One feature, or one problem, discussed in his paper which interested me a great deal was the subject of losses due to mixed frequencies. He emphasizes very strongly the fact that if we have two currents of different frequencies, the losses do not correspond to the square of the arithmetical sum of the currents, but that the losses for each current are independent of the other with the implication that it might be possible to take advanatage of this fact and increase the capacity of conductors for transmission of power.

A few years ago I had occasion to examine the possibility of increasing the transmission capacity of a line by the superposition of different frequencies, and I was sorry to come to the conclusion that such a thing was impossible. For given kilowatts to be transmitted at a given r. m. s. voltage, the $I^2 R$ line losses are the same regardless of whether this is done at a single frequency or mixed frequencies. The truth of this statement may be more easily seen considering the fact that "mixed frequencies" is another name for a distorted voltage. Is there any fundamental copper economy in transmitting power at a distorted voltage instead of sine-wave voltage? In any scheme of superposed frequencies, it will be found that any $I^2 R$ loss economy is due to raising the r. m. s. voltage of the lines.

The only fundamental benefit to be gained by the use of mixed frequencies for transmission appears to be one of convenience. In some cases the advantage in convenience may be so great as to lead indirectly to an economy in copper. For instance, if one can transmit 40 telephone conversations over the same pair of wires simultaneously, instead of over 40 separate pairs of wires, there would be a distinct economy in copper. But this is not due to a fundamentally lower $I^2 R$ loss, but due to increased transmission voltage and more effective utilization of the circuit. If one telephone message were to stress the line insulation to its limit, it would be impossible to superpose 40 messages; but telephone voltages are very small, and insulation stress is not the limiting feature.

Frederick Bedell: As Mr. Boyajian has clearly pointed out, there is no copper economy in the joint transmission of currents of different frequencies when the two currents supply a common receiver. There may, however, be a saving in certain cases, as discussed in references 16-22, when the two currents, transmitted jointly, supply separate receivers.

Development of Automatic Switching Equipments in the United States and Europe

BY A. H. de GOEDE[1]

Associate, A. I. E. E.

Synopsis.—This paper gives a brief outline of the history and general development of automatic switching equipments in the United States and Europe, as applied to power equipment.

A general review is made of the advantages of automatic equipments, consisting not only of a saving in operating expenses, but also of better operating characteristics as compared with manually controlled stations. The various designing problems, adherent thereto, are pointed out.

A comparison based on personal observation is made between the conditions in the United States and Europe, which accounts for the less rapid development and less extensive applications of automatic equipments in Europe, and a brief review is made of the results obtained in the latter years.

Mention is made of the more recent applications, such as to mercury arc rectifiers. A brief description is also given of supervisory control systems, the development of which has progressed hand in hand with the automatic equipments.

The accompanying illustrations show some typical modern American and European installations.

* * * * *

Introduction

It is interesting to note that the development of certain lines of the electrical industry shows widespread differences in the United States and Europe. The automatic switching equipments for the various classes of electric service form a striking example.

The idea to cut down the operating expenses of electric railways by the use of automatic substations, eliminating the attendants and operating only when needed, found its conception in the United States about 14 years ago. These equipments reached a high degree of reliability within a comparatively short time. After the war period, and after the initial installations had proved their worth, the automatic switching equipments found application on a large scale, not only for electric railways but for practically all kinds of service. In Europe, however, the first trial installations were not made until 1921-1922, and they had not been taken into commercial use on any appreciable scale until about 1924. The tardiness of Europe in using automatic equipments may be explained by the difference in economic and operating conditions as compared with the United States.

Development in the United States

It was only natural that the high cost of labor in the United States should create a demand for unattended stations. The first installation of this kind was tried out in Detroit in 1912 where a synchronous converter for lighting service was remotely controlled from a substation a mile away. The success of this arrangement directed the attention of electric interurban railways to it in an effort to reduce their operating expenses. Owing to the greater distances between substations, as in the case of interurban lines, the remote-control scheme was less suitable and the development of full automatic substations had to be taken in hand. Automatic stations should be designed in such a way that they perform the following duties, which are ordinarily taken care of by an operator in a manually controlled station:

1. Start the machine on load demand,
2. Protect the machine during the starting period,
3. Connect the machine to the system,
4. Protect the machine, when running, and control its output,
5. Take the machine out of service when there is no further demand for it.

How well the early designers of these equipments realized the various problems associated with their functioning is proved by the fact that the first installations of 1914 are still in service.

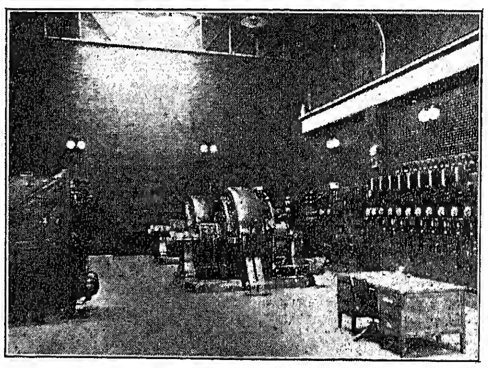

Fig. 1—Automatic Switching Equipment for Two 2000-Kw., 600-Volt, D-c., Synchronous Converters for Railway Service, with Feeders, Combined with Distributor Supervisory Control. (Oak Square Substation of Boston Elevated Railway, Brighton, Mass.)

The success of the very first automatic switching equipments for interurban and city railway service was so striking that a demand developed soon for their application to other fields. After a temporary slackening during the actual war period, this demand became more urgent around 1920, and since that time they have been used extensively for all kinds of electric service, of which may be enumerated their widespread applica-

tion to railway, hydroelectric, lighting, mining and industrial (in particular; steel mill) service.

Hand in hand with the development of automatic control equipments for machines came the design of automatic reclosing a-c. and d-c. feeders in order to derive the maximum benefit from these installations. By selecting the most appropriate machine and feeder control equipments, a most flexible installation can be secured.

The experience obtained with the first installations

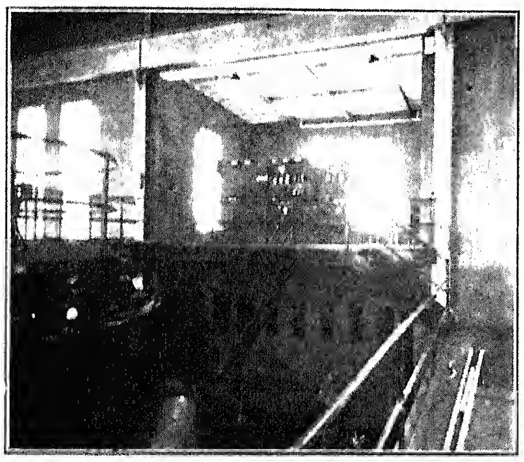

Fig. 2 Automatic Switching Equipment for Two 4600-Volt, A-c., 3000-Kv-a., Waterwheel Driven Generators. (Interior Sugar Island Station, St. Lawrence Valley Power Corporation, Potsdam, N. Y.)

showed that the anticipated saving in operating expenses materialized. The main item was the saving in wages for two or three shifts of substation operators, against which stood a surprisingly small amount for periodic inspection. An appreciable item was also the reduction in power consumption, as the stations are only in operation when there exists a load demand on the system, thus saving the running light losses over considerable periods, especially in the case of interurban lines with infrequent service. Further savings resulted due to the fact that it was now economically possible to install a larger number of small substations throughout a certain territory instead of a few large substations. Not only did this give improvement of service owing to the better holding of constant voltage on the entire system but also a considerable saving in feeder copper was obtained which compensated to a certain extent for the higher initial cost of the automatic substation.

It was soon discovered that not only a saving in operating expenses could be obtained by means of automatic stations but that these equipments had also many other important advantages. In order to secure proper operation, it is essential that an automatic station be provided with a complete set of the well-known protective features which should be designed and arranged in such a way that a certain predetermined function will take place for any anticipated emergency to prevent damage to the machines or attendant equipment. The ordinary manual station has only a few protective devices and depends for the rest on the experience and minute observation of the operator who will never be able, in case a certain trouble develops, to take such immediate positive action as a relay especially installed to perform a definite function in case of just that kind of trouble. All operations in an automatic station occur in a certain predetermined sequence, and each step in the sequence depends upon the proper completion of the previous one, so that faulty operation is excluded under all conditions. This will allow more reliable functioning than when the uncertain human element is present.

In this respect it will be clear that the success of automatic switching equipments depends upon the correct functioning of each individual device. This has been realized by the designers of these equipments since the beginning, and every endeavor has been made to make the devices as perfect as possible. A device must be not only electrically and mechanically strong but in many cases it is also essential that it be quite sensitive at the same time, which offers some unique problems. Furthermore, these devices should operate satisfactorily over a wide range of temperature, as automatic stations are not heated. Special devices have been designed as protective, checking, regulating and sequence relays especially for this kind of service, with due regard to their probable number of operations and duration of life. While in the beginning of automatic station operation there were a few cases of device

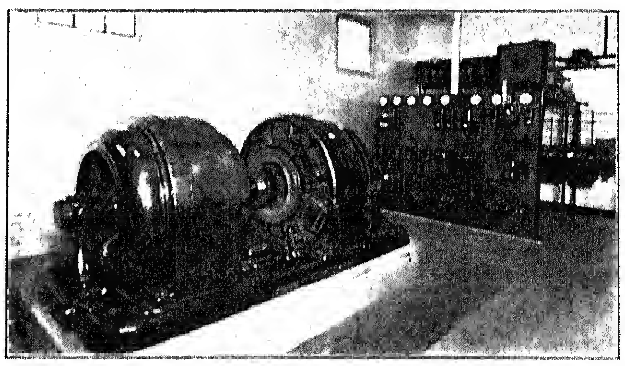

Fig. 3 Typical American Automatic Control Equipment for 275-Volt D-c., 300-Kw. Synchronous Motor Generator Set for Industrial Use

failures, the art has progressed so rapidly that a very high degree of reliability has been reached and device failures rarely happen.

In this way a very high class of regulating equipment has been developed for use in automatic stations, which will allow these stations to operate temporarily at a much higher overload than would be considered safe in case of manual operation. The automatic protective relays will determine exactly when the load has to be reduced in order to prevent damage to the machine and will function to accomplish this. Usually, a d-c. machine will then be adjusted so as to deliver power

up to its limit, to the system at a reduced voltage. As soon as the excessive load demand ceases, the voltage will be brought back to normal. In this respect the load limiting resistors in the circuit of synchronous converters may be mentioned, as well as rheostatic and counter-electromotive force control of the shunt fields of d-c. generators. These arrangements make it possible for an automatic station to deliver power up to the very limit of the machine so that service will be maintained as far as possible.

A further advantage accruing to the use of automatic switching equipments is the fact that smaller buildings of less elaborate design can be used to accommodate these equipments as no sanitary measures have to be taken for the attendant personnel as in manual stations. This makes it also possible to locate substation apparatus in places which would not be considered suitable for manual stations. For example, if the load on an Edison lighting system in the business district of a city increases to such an extent that a new substation becomes necessary, this may be located in the load center and installed in a basement, while in many cases with manual operation a more expensive site would have to be purchased, or the substation would have to be located at some distance from the load center, necessitating expensive cable runs. Another example is formed by the installation of substations with rotating apparatus in residential districts, to which many objections usually are voiced on account of the noise. When using automatic control, it is possible to use an entirely enclosed soundproof building. It will be clear that such "noiseless" substations are only feasible with unattended equipments.

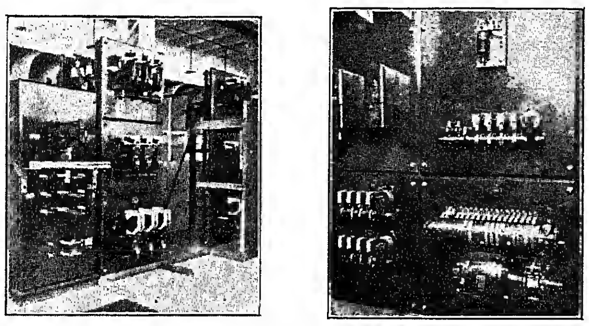

Fig. 4—Two Views of Automatic Switchboard to Control a 500-Kw., 600-Volt D-c. Synchronous Converter at Sevres Substation of the "Societe des Transports en Commun de la Region Parisienne" at Paris, Showing the Extensive Use of American-Made Devices. (Reproduced from *Le Genie Civil* of December 12, 1925)

The automatic switching equipments have also made possible the profitable development of small water power sites. It has been found in many instances that the building of small hydroelectric plants with automatic control was entirely feasible, while their development with manual control was not economically warranted, owing to excessive operating expenses. In some special cases it has been found that the building of several small plants along a river was cheaper than the development of a single high head plant of large capacity, due to the characteristics of the river-bed.

Summarizing the above, some of the most outstanding advantages of automatic switching equipments are the following:

1. No operators required,
   a. Saving in operating expenses,
   b. Freedom from labor trouble,
2. Stations operate only as needed,
   a. Saving in power,
   b. Less wear on apparatus,
3. Continuity of service and better regulation,
4. Reliability,
5. Constant protection with positive action,
6. Possibility of selecting the most economic location for a station,
   a. Saving in feeder copper,
   b. Less expensive sites,
7. Possibility of developing small water power sites.

It is not surprising that because of these paramount advantages of automatic switching equipment, their use has increased rapidly on a progressive scale. While in earlier years automatic equipments were only installed to reduce the operating expenses, it is a notable fact that during the last few years their use is considered in many instances solely based upon their more reliable service accomplishments as compared with manual control. They find more and more application in cases where continuity of service is of the utmost importance, such as in steel mills.

Development in Europe

While the development of automatic switching equipment went ahead with rapid strides in the United States, very little work was done in this line in Europe. During the war period the capital and men were lacking for experiments and investigations which were not directly useful for the progress of the war, so that the development in the electrical industry in general was virtually at a standstill. The principal work consisted of maintaining existing installations in operating condition, while extensions were practically impossible. At the end of the war the load on several systems had increased to such a value that they were operating without any reserve at all.

After the war the demand for electric service increased greatly and the available capital was applied to the extension of the systems. As this had to be done in as short a time as possible to satisfy the demand, and as the industry was still quite disorganized, it is apparent that the time was not very appropriate to try out radical changes in design, and only the more conventional equipments were installed.

Owing to cheaper labor in Europe and the less extensive use of interurban electric railways, the demand for automatic or unattended switching stations was less pronounced. The tremendous success of automatic installations in the United States, however, directed

the attention of European manufacturers to this class of equipment, and the subject was given serious consideration, especially as the post-war depression necessitated the application of the most economical apparatus. In the years 1921-1922 several trial installations were built, practically all for synchronous converters for railway service. Two distinct designs can be noticed:

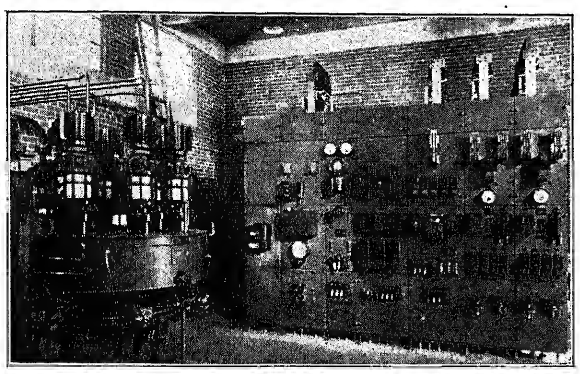

Fig. 5—Automatic Switching Equipment for 1000-Kw., 600-Volt D-c. Mercury Arc Rectifier, Consisting of Two 6-Anode Tanks, for Railway Service, with Feeders, Combined with Selector Supervisory Control. (Chicago, North Shore, & Milwaukee Railroad Co.)

1. Those which were developed by European companies with American connections, and which followed largely the American design, sometimes to the extent of using several devices built in the United States,

2. Those which were developed independently.

Even these latter equipments base their design upon the operating experience obtained in the American stations during several years. The only basic difference is that in many cases the synchronous converter is not self starting, which has never found great favor on the continent owing to the disturbances caused in the a-c. system, frequently of a small capacity. Instead, a special small starting motor is installed on one end of the converter shaft to bring the machine up to synchronous speed before connecting it to the a-c. system.

While it is the universal practise in the United States to raise the brushes from the commutator during the starting period, a few European manufacturers do not follow this procedure. It is claimed that excessive sparking on starting is eliminated by means of a special design of the commutating poles and of the field windings, so that there is no necessity for raising the brushes.

To insure correct polarity on starting, the converter field may be either separately excited or the polarity may be checked and, if necessary, automatically corrected by means of a polarized relay with permanent magnets. Both methods have found extensive use in the United States, and similarly both methods are being followed in European design. The only difference is that in American practise a special single-phase motor-generator set is used for separate excitation (field flashing), while it is the universal practise in Europe to mount an exciter on the converter shaft for this purpose.

After these trial installations had given a good account of themselves, the automatic control equipments for synchronous converters have found commercial application in the last three or four years, when their advantages became more fully appreciated. In the same manner as in the United States, they have been applied not only in order to secure operating economies but have also been used in cases where manual control was less suitable. In this regard mention may be made of a substation, Soho Square Substation of the Charing Cross Electricity Supply Commission, which is installed in the basement of a building in a thickly populated section of London. Incidentally, it may be noted that this substation will ultimately contain five 300-kw. synchronous converters for 210-volt, d-c. lighting service, which are arranged to start and stop automatically in a definite sequence depending upon load conditions of the d-c. system which is a large number of units compared with the usual station in the United States. This shows that faith exists in the reliability of these equipments. Nevertheless, automatic synchronous converter substations have found application only on a very limited scale in Europe when compared with their extensive use in the United States. The value of the load limiting resistors in the machine circuit does not seem to have been generally appreciated in Europe in the beginning. For railway work there have been installed equipments both with and without these resistors. This may be due to less rigid requirements for continuity of service, but still it can be noted that the most recent European installations make more general use of this method of load limiting.

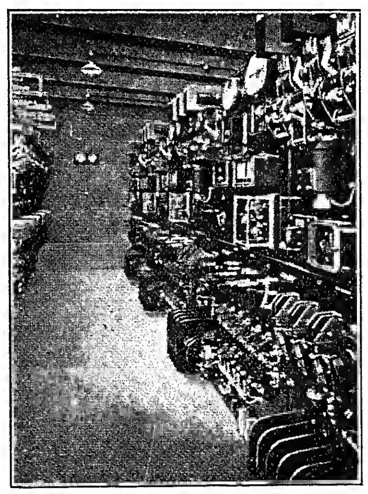

Fig. 6—Typical European Automatic Switchboard to Control four 300-Kw., 210-Volt, D-c. Synchronous Converters at Soho Square Substation of the Charing Cross Electricity Supply Commission at London. (Reproduced from the *Metropolitan-Vickers Gazette*, of December, 1926)

Mercury Arc Rectifiers

At this point attention may be called to the steel enclosed mercury arc power rectifier. Being an American invention, it is remarkable that its development originally progressed even more rapidly in Europe than in the United States. Above a certain definite d-c. output voltage, this apparatus has a very decided attraction as the means of converting alternating current to direct current with the highest efficiency of any known conversion method.

These rectifiers have found widespread application in Europe during the last 8 or 10 years, and after proving their reliability, the step to make them automatically controlled was soon taken. Fundamentally, the automatic switching equipment for a rectifier is simpler than for a synchronous converter as no synchronizing with the a-c. system and no polarity check is necessary. Consequently, automatic control equipments for mercury arc rectifiers have found more general application and on a larger scale in Europe than the equipments for synchronous converters. Only in the last two years a comparatively small number of mercury arc rectifiers has been equipped with full automatic control equipments in the United States. Their application gives some complications which are not known in Europe, especially due to the fact that they are subjected to extreme changes in temperature in many sections of the United States, which may effect the correct operation of the rectifier. Automatic temperature control is therefore necessary, which is not required for European installations. For full automatic equipments the American practise requires also automatic vacuum control, which is not generally furnished with the European equipments. These complications have held back the application of automatic control equipments to mercury arc rectifiers a good deal, but still their use is gradually increasing.

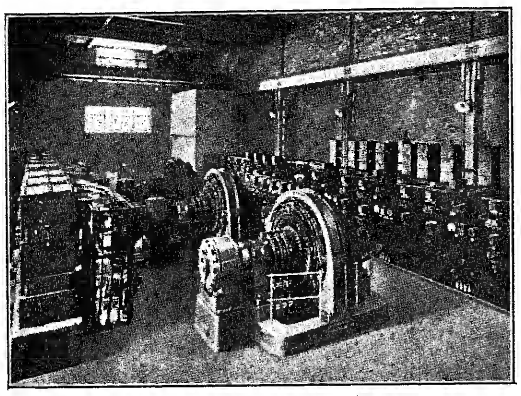

Fig. 7—Typical European Installation of Automatic Switching Equipment for Three 1500-Kw., 600-Volt D-c. Synchronous Converters at Balham Substation of the London Underground Railway, Remotely Controlled. (Reproduced from the *Metropolitan-Vickers Gazette* of November, 1926)

Supervisory Control Systems

The development in the United States has long been concentrated on full automatic operation without any attendance whatsoever, except periodic inspection. In more recent years there seems to be a tendency to go back, not exactly to remote control, but rather to remote supervision. In this case the automatic station is allowed to function automatically by its own devices, but a dispatcher at a central point receives indications of the main switching functions, so that he is at all times fully informed by means of a system of lamps as to what happens in the remote automatic stations. Generally, the dispatcher has control of certain functions, so that he can start or stop a machine or open a feeder at will, regardless of the conditions on the system of which the substation forms a part. This feature is useful in certain emergencies. These supervisory systems have passed the experimental stage and have also reached a high degree of reliability. They allow the control and indication of a large number of separate functions over three or four common line wires, which under certain circumstances may also be used for telephony. The systems operate with a short time delay, which is only 5 or 10 sec. Simpler schemes rely on audible indication and are useful for systems where only a few functions have to be performed. These supervisory systems are based upon the use of devices which have proven their reliability in train signal, telegraph, and automatic telephone service, of course with the necessary modifications for power work. A further refinement of these methods of supervision is the remote metering. Several workable schemes have been developed to transmit various meter readings automatically over large distances from a remote automatic station to a dispatcher. While this supervisory equipment is fairly expensive, many operating companies consider it of the utmost importance, because the dispatcher is constantly informed about the actions of the automatic stations, which will explain why these

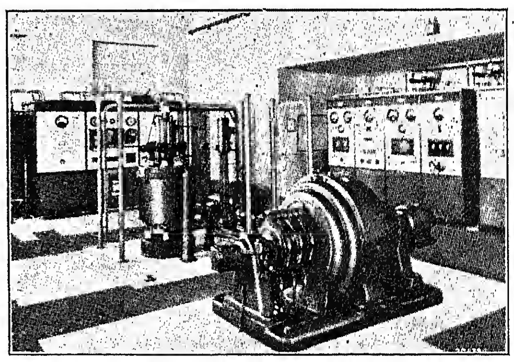

Fig. 8—Typical European Installation of Automatic Switching Equipment for 300-Kw., 800-Volt D-c. Synchronous Converter and 300-Kw., 800-Volt D-c. Mercury Arc Rectifier at St. Legier, Switzerland. (Reproduced from the *Brown Boveri Review*, August 1926)

systems have found a widespread application in the United States during the last few years.

As automatic stations have not yet been in such extensive use in Europe, there has been very little demand for these supervisory systems. A few have been developed, based mainly on automatic telephone devices.

Conclusion

The leading manufacturers in the United States are at present prepared to furnish reliable automatic switching equipments suitable to meet all possible control operations for both a-c. and d-c. machines and for switching operations on a-c. and d-c. networks, in short, for all classes of electric service, with the only exception of generating stations driven by prime movers other than water wheels.

The application of automatic switching equipments in Europe has been on a much smaller scale and covers a smaller scope of work. Practically all installations are for railway and lighting service, with some isolated cases for the other classes of electric service.

Automatic switching equipments for practically every conceivable operating condition have been installed the world over and prove daily their paramount advantages. Their future is assured.

Discussion

Chester Lichtenberg: Since its development in 1914 the automatic station has been a very interesting topic to electrical engineers. The development has been very rapid. For example, in the United States today more than one-third of the entire switchboard output of the large manufacturing companies is automatic switchboard equipment for power stations and substations. Our records indicate that over 2,000,000 kw. of rotating apparatus are under automatic control and over 6,000,000 kw. of feeders and transformers are in automatic station service.

It has been thought that the development of the automatic station would make the attendants more mechanical. This has not been the case. Instead, the personnel of the operating companies who care for automatic stations have been required to use a greater degree of intelligence than those who attend the usual type of substation. It should not be thought, however, that the automatic station is an intricate or complicated collection of devices. It is not. It is a very simple combination of devices quite well known in the control art but so skilfully connected one to another that they perform functions heretofore delegated to human beings. When one considers the problem, this is as it should be because human beings are relatively slow to respond, while the changes in the electrical circuit take place with extreme rapidity. The ordinary human being responds to an impulse in about one half a second while the ordinary electrical device will respond to an electrical impulse in one-tenth or even one one-hundredth of this time.

Sometimes it is thought that the installation of automatic stations will require the engaging of skilled personnel for their maintenance and operation. Experience has indicated that this is not the case because as before stated the equipments consist of quite common control devices although there are more of them than in the usual manually operated station. Operating companies have demonstrated that they have in their employ many who can successfully install, maintain, and operate automatic stations.

Besides, the manufacturers have found that some of the operating companies have employees who can and do suggest improvements in the schemes of operation as a result of their practical experience.

Load-limiting or load-shifting resistors are almost always discussed when automatic stations are considered. These resistors have three functions;

1. To prevent the flow of excessive current between an on-coming machine and the bus.

2. To limit the drain on a machine for continuous service.

3. To shift to adjacent machines the load from a machine which might be overloaded.

Each of these functions is quite important. However, the importance varies with the application and with the type of transforming apparatus. Primarily, load-limiting or load-shifting resistors assist in maintaining service under unusual operating conditions and find here their most advantageous application.

H. S. Knowlton: I should like to ask Mr. Lichtenberg to say a few words about the training of men to maintain and inspect these automatic stations. Probably the designing engineers have provided very thorough instructions in printed form, but is there not a great gap between the ability of the designing engineer to comprehend the details of these automatic plants and that of the average operating man?

K. K. Palueff: It seems to me that the automatic substation has two very important characteristics. First, that there is no need of technical knowledge or training on the part of the operator; and second, that it makes small installations more economical.

The automatic substations will enable us to electrify small waterpower systems. I should like to add that in this country, particularly, the supply of peat was entirely neglected for the reason that the main problem connected with the development of peat was the impossibility of transportation. Peat made in such a manner as to withstand transportation becomes absolutely uneconomical. It seems to me, therefore, that the automatic stations may permit exploitation of the peat bogs in this country as well as in Russia to a far greater extent than at the present time.

E. de Mulinen: (by letter) Mr. de Goede mentions that the first trial installations of automatic switching equipment were not made in Europe until 1921-22. I should like to mention that an automatic converter substation in Basel (Switzerland) has been in successful operation since 1918. Mr. de Goede states that the development in Europe was forced by post-war conditions, but the actual development of automatic equipment was started during the war on account of shortage of labor.

Mr. de Goede mentions that load-limiting resistors are not much used in Europe. It might be said that a drooping characteristic is used in most of the European substations for traction purposes, resulting in a great flexibility in load distribution between the different substations. This scheme protects the converter from high overloads and assures continuity of service without destroying a considerable amount of energy in load-limiting resistors. In this country, about 90 per cent of the traction substations use compound-wound machines which require load-limiting resistors to give the system some flexibility, but when laying out a new system, it will always be found that a drooping characteristic will give the most economical results In this respect, it may be of interest to note that in one of the most recent automatic substations in Chicago—the Grimm

Avenue Substation—no load-shifting resistors are used, as the inherent voltage characteristics of the machines in this substation do not require such equipment.

In saying that automatic vacuum control is not generally furnished with the European automatic rectifier equipments, Mr. de Goede doubtless refers to the first trial installations. After considerable research, Brown, Boveri & Co. has succeeded in bringing out a most reliable vacuum control which has been in commercial use since 1923 and supplied with each automatic rectifier equipment. This type of automatic vacuum control is used with over a hundred automatic rectifiers in Europe and in eight automatic rectifier substations in this country.

A. H. de Goede: Mr. de Mulinen states some of the reasons why load-limiting resistors are in such little use in Europe. It might be said that the service conditions in the United States are usually much more severe, and in many instances it has been proved that during periods of heavy load it was not possible to keep a machine with drooping characteristics on the line, making it necessary to add load-limiting resistors to maintain service.

I was familiar with the fact that the Brown Boveri Company has equipped its automatic rectifier substations with automatic vacuum control during the last two years. However, as stated in my paper, this is still not generally furnished by most of the European manufacturers, while the American practise considers it an essential feature for full automatic operation.

The remarks of Mr. Lichtenberg supplement my paper on some interesting points. Many other points might have been treated more broadly, but in order to keep my paper within bounds, I have only endeavored to give a brief outline of the main advantages of automatic switching equipments, and of what has been accomplished along this line.

The Most Economical Power Factor

A Practical Design Formula for Distribution Circuits

BY H. S. LITCHFIELD[1]

Associate, A. I. E. E.

Synopsis.—The use of power factor corrective devices on distribution circuits is justified, under certain conditions, by rather substantial savings in investment charges and by a reduction in the power losses of the system. The object of the present paper is to develop a practical working formula for calculating the most economical corrected power factor for a distribution circuit. Most economical conditions are assumed when the total of such annual circuit costs as are directly affected by a change in power factor, is a minimum.

The usual methods for computing separately, the saving in $I^2 R$ losses and the decrease in investment charges due to power factor improvement, are inadequate. Particularly in the design of new circuits and extensions has the need for a more accurate method for calculating optimum power factor and conductor sizes been expressed.[2] Since these equations were originally worked out, two other solutions for the most economical corrected power-factor angle have been published, each having been obtained independently of the other. Menjelou[3] obtained his formula in the form:

$$\alpha \sin \theta = 1 - \beta \tan \theta$$

in which θ is the power-factor angle and α and β are constants computed from the circuit costs. Stevenson[4] obtained a similar expression:

$$\sin \theta = \delta - \eta \tan \theta$$

the difference lying in the constants to be evaluated.

The equation developed in this paper reduces to the simple form.

$$\sin \theta = \text{unit cost ratio}$$

That is, the sine of the most economical corrected power-factor angle is determined by the ratio of the annual cost of condenser capacity per reactive kilovolt-ampere of correction to the annual cost (fixed charges plus value of losses) per kilovolt-ampere delivered, of that portion of the supply circuit which is directly affected by the change in power factor. When the unit cost ratio is greater than the sine of the original power-factor angle, it is found that no investment in corrective equipment is economically justified.

The equation is set up in such a form that solutions are readily obtained for the most economical size of conductor as determined by the Kelvin law, and for the required kilovolt-ampere rating of the transformers and condensers. A method is suggested for including generating station costs with those of the individual circuit under consideration.

In evaluating circuit costs, the effects of load factor and the shape of the typical daily load curve upon capital investment and power losses have been worked out after the methods used by Gear and Williams[5] and by Reyneau and Seelye[6].

Equations for evaluating the circuit constants are included in the appendix. Several illustrative examples are worked out.

So long as each community was served by its own generating station, the generator was the most convenient and, in some cases, the most economical source of magnetizing current. But with the elimination of small stations and with the growth of interconnection, the shunting of large blocks of reactive power from one point on the system to another has introduced serious operating complications. Low system power factor limits the availability of installed capacity, adds to the $I^2 R$ line losses, and increases the conductor sizes required to maintain proper voltage regulation. The kilowatt-hour losses on circuits operated at low power factor may run as high as 20 to 30 per cent of the annual input. For a switchboard cost of eight mils, a reduction in line losses from 25 to 15 per cent is nearly equivalent to a saving of one mil per kilowatt-hour at the stations. The economical utilization of the modern generating station is dependent not only upon a favorable base load but also upon the cost of distributing this lower cost power to the consumer. The full value of modern refinements in station design and operation cannot be realized unless there be a commensurate increase in the efficiency of the system of distribution. Certainly, industry cannot hope to obtain full advantage of low cost power made possible by the modern generating station so long as generators, bus structure, cables, substations, lines and transformers must be designed to carry excessive, inductive loads.

Considerable improvement in system power factor usually may be obtained through a more scientific application of the individual induction motor to its load. When loaded continuously between three-fourths and full load rating, a good induction motor should operate at a power factor of from 0.80 or 0.85 to 0.92 or 0.94 lagging, depending on size and speed. The prospective increase in high power-factor heating load will tend to raise the average of the system power factor.

For further improvement, rather substantial investment in corrective devices is necessary. Prices range from six to sixty dollars per reactive kilovolt-ampere of correction. If such large expenditures are to be made in unproductive equipment, it is necessary to know that the largest possible savings are to be effected. How much money can be invested profitably in such improvement? What is the most economical corrected

power factor? The term "most economical" is here used to indicate an economic balance in circuit design for which the total annual cost of supplying a standard power service is a minimum.

In the analysis that follows, a circuit cost equation is set up with θ, the corrected power-factor angle, as a variable. The minimum value is found by equating the first derivative to zero. The general equation includes only the variable circuit costs that are directly affected by a change in power factor. It does not include what may be termed fixed costs that are not reduced by an improvement in the power factor of the circuit. The mathematical correctness of the solution is not changed by the elimination of the fixed costs, since all constant terms drop out in the differentiation.

The equation is developed subject to the following conditions:

a. The value of generating station and outside plant capacity released through power factor correction depends upon its availability for carrying additional profitable kilowatt load. In the design of new circuits, smaller conductors and transformers may be used for a given kilowatt load.

b. The cost[7] of line losses per kilowatt-hour includes fuel cost at the generating station and demand charges prorated over the kilowatt-hour losses for the year.

c. Load is figured in terms of maximum kilowatt demand.

d. Power factor is measured at the time of maximum kilowatt demand at the point where the condenser is to be installed. It is defined as the ratio of kilowatt demand to coincident kilovolt-amperes. The term "power-factor angle" is used as a convenient mathematical convention rather than as a true instantaneous vector relationship.

e. It is assumed that the distribution voltage has been determined by conditions affecting the system as a whole. Existing standards usually determine in a general way the types and ratings of equipment.

f. Construction standards on overhead distribution systems are usually such that the cost of the supporting structure is the same for each of the several possible wire sizes which could be chosen for a given circuit.

g. The cost of spare condenser equipment is not included. This is offset by the reduction in spare transformer and line capacity required for emergency service.

h. Capacity rating of condensers determined by economical considerations: Synchronous condensers to be operated normally at full excitation to obtain maximum corrective effect during working hours, and shut-down during off-peak hours. Static condensers act as a constant capacity connected across the line with losses practically constant. When installed in accessible locations these are usually disconnected during off-peak hours. Annual condenser losses are determined by the number of hours connected.

i. Partial voltage control with capacity rating of synchronous equipment determined by economical formula: In this case condenser and circuit losses should be computed for the actual duty cycle of the condenser throughout the year.

j. Constant voltage control: The rating of the synchronous condenser in this case is determined by the constants of the circuit and by the generator and receiver voltages. The economical power-factor formula does not apply to this condition.

The equation is developed for an overhead line supplying power through a single bank of transformers. The power factor of the load is $\cos \theta_{or}$, lagging. A condenser is to be installed on the low voltage side of the distribution transformer. Kilowatt demand is known, as is also the required full load receiver voltage. It is assumed that the rating of the transformer will be just equal to the resultant kilovolt-ampere demand at the corrected power factor and that the size of the line conductors will be just sufficient to carry the resultant full load amperes at the most economical current density. The annual fixed charges on the investment and the cost of losses for the primary line conductors, transformers, and the condenser are to be set up in an algebraic equation in which the variable is θ, the corrected power-factor angle.

The following symbols are used:

- Q_1 Annual fixed charges on the most economical line conductors per kilovolt-ampere delivered,
- Q_2 Annual cost of line losses per kilovolt-ampere delivered,
- Q_3 Annual fixed charges on transformers per kilovolt-ampere delivered,
- Q_4 Annual cost of transformer iron losses per kilovolt-ampere,
- Q_5 Annual cost of transformer copper losses per kilovolt-ampere,
- K_1 Annual fixed charges on the condenser per reactive kilovolt-ampere of correction,
- K_2 Annual cost of energy losses in the condenser per reactive kilovolt-ampere of correction,
- P Power in kilowatts delivered to the load at the time of maximum demand,
- p Kilowatt loss in the condenser at full load voltage and excitation,
- $\cos \theta_{or}$ Power factor of the load, at the maximum demand,
- $\cos \theta$ Corrected power factor at maximum load,
- M Cir. mils per ampere at full load for most economical line-current density in the conductor,
- Y Annual cost of the circuit, including the condenser; it includes only those costs which are directly affected by an improvement in power factor.

In the appendix will be found a list of additional

7. See reference 6, Chap. IV, for a method of computing the cost of energy losses at any point on the system.

symbols and a detailed mathematical development of the equations for evaluating the K and Q terms, to which reference is made in the following paragraphs.

By the Kelvin[8] law, that wire size is assumed most economical for which the annual fixed charges on the investment in the conductors are just balanced by the yearly cost of $I^2 R$ energy losses. Assuming a current of one ampere, the most economical circular mils per ampere, designated by the symbol M, may be calculated by formula (6) in the appendix. The value of M depends on the cost of copper, the shape of the typical daily load curve, and the cost of energy. It is independent of the ampere load, voltage, phase, spacing, and the length of line. The size of the most economical conductor is then equal to M times the resultant amperes per wire. Multiplying by the length of line and by the unit weight of copper, and by the cost per pound, the cost of one conductor is obtained as in (7). The resultant current may be expressed in terms of kilowatt load, voltage, and power factor. Substituting for the current terms in (7) and multiplying through by the number of conductors and by the annual fixed charge rate yields expression (8). It represents the annual fixed charges on the most economical size of conductors expressed as a function of the resultant power-factor angle θ. The coefficient Q_1 is obtained in expression (9).

The energy loss in the most economical conductor at full load is $I^2 R$ watts. The resistance may be represented by the resistivity per cir. mil ft. times the length of the conductor divided by the area of the conductor in cir. mils. The cross-sectional area equals M times resultant amperes, as in the previous paragraph. Multiplying by the cost of energy and by the number of conductors, expression (10) gives the hourly cost of losses at constant full load.

The actual $I^2 R$ losses of a fluctuating load may be evaluated in terms of loss at full load by means of a special "loss factor" computed from typical daily load curves of the circuit under consideration. The loss factor is found by dividing the sum of the squares of the hourly ordinates of a typical daily load curve by 24 times the square of the annual peak. Descriptions of the method are given in the references[8]. The loss factor multiplied by 8760 hours gives the "equivalent hours" per year that it would be necessary for the annual peak load to continue in order to yield the same energy loss as that given by the actual fluctuating load throughout the year.

The annual cost of losses in the conductors is then obtained by multiplying expression (10) by the equivalent hours. The current term is expressed in terms of kilowatts, voltage, and power factor as before, yielding expression (11). The simplicity of the final result depends in part upon the fact that, by this method of setting up the equation, the cost of losses is expressed as a function of the power-factor angle to the first power rather than to the usual square.

Transformer costs apply to the nearest standard size required for the resultant kilovolt-ampere load. In cost analyses of this sort, where the unit cost varies inversely with the size, it is sometimes desirable to plot the cost per kilovolt-ampere against kilovolt-ampere rating and to obtain the equation of the line passing through the desired points. Under the conditions of the present problem, however, it is simpler to use the unit cost of the nearest standard size. A first approximation may be used and a second value substituted later, if necessary.

The evaluation of the transformer cost coefficients, Q_3, Q_4, and Q_5 is given in expressions (13) (14) and (15). Transformer copper losses are found by multiplying the loss at full load by the equivalent hours defined above. The iron losses are approximately constant and may be represented by loss at the manufacturer's rating times 8760 hr. in a year.

As in the case of the transformers, the unit cost of the condenser is that of the nearest standard size. For static condensers in groups of 30 kv-a., the unit cost does not vary greatly. In the larger sizes of synchronous condensers, the cost per kilovolt-ampere is fairly constant. For the smaller sizes of both types the unit price increases rapidly and it may be necessary to try one or two approximate values. The annual fixed charge rate includes interest, depreciation, and taxes. Where special attendance is required, as with synchronous equipment, the extra expense may be added to the fixed charge rate. Condenser losses are evaluated by multiplying the rated loss at full load voltage and excitation by the hours per year that the equipment is connected to the line. The evaluation of terms K_1 and K_2 is given in expressions (16) and (17).

THE CIRCUIT COST EQUATION

The kilovolt-ampere delivered by the transformers at the corrected power factor are

$$\frac{P + p}{\cos \theta} = (P + p) \sec \theta$$

The annual cost of line conductors and transformers at the resultant power factor is then:

$$(Q_1 + Q_2 + Q_3 + Q_4 + Q_5)(P + p) \sec \theta \qquad (1)$$

The condenser capacity required to raise the original load power factor from $\cos \theta_{0n}$ to $\cos \theta$ is shown graphically by the familiar condenser diagram, Fig. 1. The reactive kilovolt-amperes in leading quadrature to be carried by the condenser are given by the vertical line $D - F$. For static condensers and for synchronous condensers without mechanical load, the losses are comparatively small so that the quadrature difference is usually taken as the approximate condenser capacity required. This quadrature difference, or reactive

8. For Kelvin law, "loss factor" and "equivalent hours," see reference 5; reference 6, Chaps, V. VI; also *Standard Handbook for Electrical Engineers*, Sec. 12, Par. 235-238; Section 13, Fig. 14.

8. loc. cit.

kilovolt-amperes of correction, may be expressed algebraically as

$$P \tan \theta_{or} - (P + p) \tan \theta$$

and the annual cost of condenser capacity as

$$(K_1 + K_2)\, P \tan \theta_{or} - (K_1 + K_2)\, (P + p) \tan \theta \qquad (2)$$

P is the maximum kilowatt load and is assumed constant. The energy loss, p, in static condensers is small, about 0.5 per cent, and is often neglected in calculating the power polygon. For synchronous

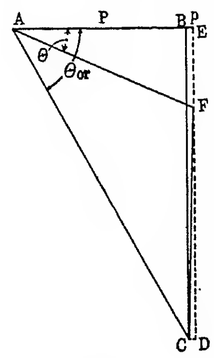

FIG. 1

P	Kilowatt load
p	Kilowatt loss in condenser
$A\ C$	Kv-a. at original load power factor
$A\ F$	Kv-a. at corrected power factor
$D\ F$	Reactive kv-a. correction

For 3 per cent condenser loss, the error in using $D\ F$ for $C\ F$ is less than 0.05 of one per cent

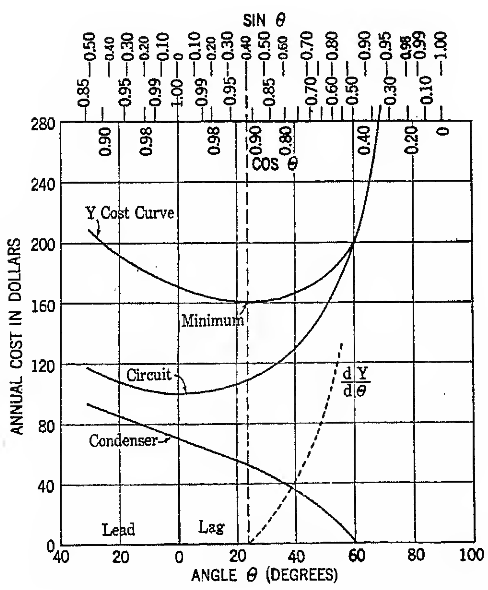

FIG. 2—ANNUAL COST OF CIRCUIT WITH CONDENSER

Drawn for a unit cost ratio of 0.40 and a load power factor 0.50. The minimum point on the Y curve occurs at $\sin \theta_{ec} = 0.40$. Corresponding to a corrected power factor $\cos \theta_{ec} = 0.916$

condensers, losses will be about 1.7 to 3.5 per cent of rating for the larger machines and higher for the smaller units. If p is expressed as a function of θ, the equation becomes unnecessarily complicated. It is simpler, and sufficiently accurate within a limited range of the probable value of θ, to assume a fixed value[9] for p. The first approximation may be corrected later if necessary. θ_{or} is a constant, and θ the only variable.

The annual cost of the circuit, including condenser, for any power factor, $\cos \theta$, is

$$Y = (Q_1 + Q_2 + Q_3 + Q_4 + Q_5)\,(P + p) \sec \theta$$
$$+ (K_1 + K_2)\, P \tan \theta_{or} - (K_1 + K_2)\, (P + p) \tan \theta \quad (3)$$

The minimum point on the cost curve is found by equating to zero the first derivative of Y with respect to θ, and solving

$$\frac{d\,Y}{d\,\theta} = 0 = (Q_1 + Q_2 + Q_3 + Q_4 + Q_5)(P + p) \tan \theta \sec \theta$$
$$- (K_1 + K_2)\,(P + p) \sec^2 \theta \qquad (4)$$

and

$$\sin \theta_{ec} = \frac{K_1 + K_2}{Q_1 + Q_2 + Q_3 + Q_4 + Q_5} \qquad (5)$$

The graphical representation of these cost functions

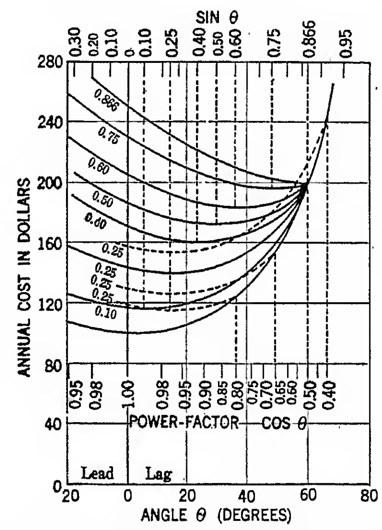

FIG. 3—COMPARISON OF Y-COST CURVES

The number on each curve is the unit cost ratio

in Fig. 2 indicates the variation in total cost as the condenser capacity is increased. The conditions for a minimum[10] are that the sum of the K terms be less than the sum of the Q terms; that the sum of the K terms be positive or equal to zero, and that the sum of the Q terms be positive and greater than zero.

If the sum of the K terms be zero, that is, if condenser capacity could be obtained at no extra expense, $\cos \theta_{ec} = 1.00$ and correction to unity power factor would be justified.

If the ratio of the K terms to the Q terms be equal to the sine of the original power-factor angle, then $\sin \theta_{ec} = \sin \theta_{or}$, and the original power factor is the most economical one. This is illustrated graphically by the upper curve in Fig. 3 marked 0.866. If the unit cost ratio is greater than $\sin \theta_{or}$, the mathematical minimum

9. For percentage error in assuming p constant see appendix B.
10. For test for minimum point see appendix B.

lies in the area of negative values of the condenser cost curve. The physical interpretation of the curves for values of the unit cost ratio greater than sin θ_{or} is that condenser correction is not economical. The lagging power-factor angle is taken as positive.

The conditions under which equation (5) may be used in practical problems are that the sum of the Q terms be positive and greater than zero, that the sum of the K terms be positive or equal to zero, and that the ratio of the K terms to the Q terms lie between zero and sin θ_{or}. Within these limits, the following conclusions are warranted.

A. The sine of the most economical corrected power-factor angle is determined by the ratio of unit annual condenser costs per reactive kilovolt-ampere of correction, to unit annual cost per kilovolt-ampere delivered, of that portion of the supply circuit directly benefited by the improvement.

B. Correction to unity is economically justified only if corrective capacity can be obtained at no additional expense.

C. If the unit cost ratio is found to be equal to, or greater than, the sine of the original load power-factor angle, investment in corrective equipment is not economically justified.

D. For a given unit cost ratio, the most economical power factor is the same, irrespective of the power factor of the load.

Conclusion D is illustrated by the dotted curves in Fig. 3 where each of the four total cost curves drawn at a unit cost ratio of 0.25, for load power factors 0.80, 0.65, 0.50, and 0.40, has its minimum value at sin θ_{rc} = 0.25 corresponding to the corrected power factor, cos θ_{rc} = 0.986.

Conclusion D is based on a constant unit cost ratio within the range of values considered. This condition is met in the case of a distribution substation with supply lines, built to a standard maximum current rating. Local power load is served, up to the limit of circuit capacity, by radiating branch feeders either at the same or at reduced voltage. The circuit cost per kilovolt-ampere of its capacity is known, and the average unit price of the static condensers, to be located at the load ends of the radiating branches, is fixed by the manufacturer's quotation. The unit cost ratio is therefore practically constant and a common most economical power factor for the circuit as a whole is determined by equation (5). Sufficient condenser capacity is installed at the end of each branch, whatever its original power factor, to raise the corrected power factor to the most economical value. This result, based on economic considerations, is in agreement with the best operating characteristics of the circuit. If all the condenser capacity be placed at the ends of the branches, but each corrected to a different power factor, circulating currents will be set up between the branches which tend to offset the desired savings.

General Application

In the design of a circuit to serve a definite kilowatt load, the unit cost ratio tends to decrease as the size of the condenser is increased, and the required line and transformer capacity becomes less. This is due to the variation in cost per kilovolt-ampere of condensers and transformers with a change in size. The correct relationship is given by the unit cost ratio at the minimum point on the total cost curve. In the usual case, standard sizes of equipment will not agree exactly with the most economical sizes of conductors, transformers, and condensers as calculated by the formula. The flatness of the cost curve near the minimum point, however, indicates that this value is not critical. With static condensers, it is quite practicable to install just the capacity required, since these are built up in small units.

The formula has been derived for the particular case of an overhead feeder. Similarly, it may be developed for distribution circuits in general, both overhead or underground, by introducing appropriate Q terms. The criterion for including a given cost is whether or not a saving can be effected in that particular item by improving power factor. The cost of the supporting structure should be included in the case of parallel circuits, when a reduction in the number of paralleled conductors can be effected after correction, due to the reduced ampere capacity required to supply the same kilowatt load. This applies also to the cost of ducts in an underground system, when fewer cables will be required after correction. The cost of stringing wire or running cable should be included if the labor charge for the larger size is materially higher than for the smaller. The unit annual costs per kilovolt-ampere of circuit capacity applying to cables, switches, bus structure, and substation electrical equipment in general should be evaluated as Q terms if an actual saving can be made. In including cost at the sending end, such as step-up transformers, the cost per kilovolt-ampere should be increased by a factor covering per cent line loss between that point and the condensers.

The sine relationship between unit condenser and circuit costs may be used also in making power factor improvement calculations in industrial plants. The method of computing optimum rating of static condensers within the consumer's plant is the same as for outside feeders. Where over-excited synchronous[11] motors or internal corrective motors of the synchronous-induction[12] type[13] are used, the power, p, consumed by the motor is included as a part of the useful load, P. The cost[2] properly chargeable to power factor improvement is the difference between the price of the synchronous

11. *Electric Journal*, March 1926, p. 99.

12. H. Weichsel, *A New Alternating-Current General-Purpose Motor*, presented at the Midwinter Convention of the A. I. E. E. New York, February, 1925.

13. Underhill, "Power Factor Wastes," McGraw-Hill. JOURNAL of the A. I. E. E., October 1926, p. 949.

motor and that of a lower priced induction motor of equivalent rating. The correction in reactive kilovolt-ampere is the sum of the power component in leading quadrature of the synchronous motor and the lagging component of the equivalent induction motor. The cost per reactive kilovolt-ampere of correction, term K_1 in the equation, is thus determined. Further correction may be justified when the rate schedule contains a special power factor clause.

In making a basic cost study of the power factor problem on a utility system preparatory to working out new power rate schedules, the use of the sine formula is suggested as a means for determining the optimum consumer power factor upon which the schedule of penalties or bonus is based. In this case the cost of correction at the motor is credited with savings on the central station system back to the generator, in addition to savings within the industrial plant. Direct comparison may be made between the over-all savings obtained by consumer correction and those resulting from the use of condensers on the lines of the central station.

Generating Station Costs

Excess generating station costs chargeable to low lagging power factor include (a) fixed charges on generating capacity which could be released for profitable kilowatt load, (b) excess electrical losses due to increased excitation requirements and the reactive current component in station bus and transformers, and (c) lower steam economy due to the necessity for operating turbines below normal power rating or for floating spare units on the line as condensers. Figures for determining excitation losses are usually obtainable from the manufacturer's design data. Other losses must be worked out for each individual station from daily operating data and special tests.

The evaluation of station costs is not within the scope of the present paper. The following method is outlined for segregating that portion of the station costs directly affecting the distribution circuits.

Case I: Generating capacity insufficient to supply kilowatt demand at existing power factor, necessitating the purchase of a new generator or additional power from an outside source. It may be assumed that it would be cheaper to release existing generator capacity up to the limit of the horse power rating of the turbines by installing a large synchronous condenser at the station. The larger units have the lowest cost per kilovolt-ampere. Let the annual fixed charges, including routine maintenance, be K_3 and the cost of losses K_4 dollars per reactive kilovolt-ampere per year.

The problem is to determine how much of this corrective capacity could be installed more profitably at the load end of the distribution circuit. The annual unit cost of the load end condenser has been evaluated as $(K_1 + K_2)$ dollars per reactive kilovolt-ampere per year and is greater than $(K_3 + K_4)$. Due to load diversity between feeders, additional capacity is required at the load end than at the station. Let D = the ratio of coincident reactive kilovolt-ampere demand at the station peak to the sum of the reactive demands of the individual feeders. One reactive kilovolt-ampere of condenser correction out on the line saves $D\,(K_3 + K_4)$ dollars per year in station condenser costs, at the same time releasing generating capacity for profitable kilowatt load. The difference in the annual unit costs of the two condensers, representing the additional cost of load end correction, applies to the distribution circuit. Equation (**5**) in its general form is then:

$$\sin \theta_{ec} = \frac{(K_1 + K_2) - D\,(K_3 + K_4)}{Q_1 + Q_2 + Q_3 + Q_4 + Q_5 + Q_6 + \ . \ . \ .} \qquad \textbf{(5a)}$$

the additional Q terms representing cost of cables, substations, et cetera, as previously noted.

Case II: Spare generator capacity available, station economy reduced by inefficient operation at low power factor. It is assumed that the expense of a station condenser is not justified. Term K_3 is not included since no immediate saving in annual fixed charges on generating equipment will be made. The excess cost of operating the station at low power factor, compared with the cost of generating the same kilowatt-hours in salable energy at unity power factor, represents the cost of using station generators as condensers. The excess cost throughout the year divided by the reactive power component at the station peak demand gives K_4, the annual cost per reactive kilovolt-ampere of correction at the station. The numerator of equation (**5a**) is then $(K_1 + K_2) - D\,K_4$.

The method does not apply to distant hydroelectric or steam stations operating at leading power factor. The sine formula does not apply to transmission lines[14] of such length and voltage that charging current, corona loss, conductor material, tower spacing, and other special factors enter into the problem. The correct rating of condensers for long lines is usually determined by the requirements for voltage control and system stability.

The sine formula may be used in the design of the individual distribution circuits of the network supplied by a transmission line, as in Case I for the generators. Thus, if it is found economical to correct the power factor at the load ends of the individual circuits of the distribution network from 0.70 to 0.90, the size of the synchronous condenser required to control transmission line voltage is considerably reduced.

The annual saving at the most economical power factor depends upon the power factor of the load and the unit cost ratio. In Figs. 2 and 3, the difference in the height of the ordinate to the total cost curve at the original power factor, and the ordinate at the minimum

14. Kirsten and Loew, *The Line of Maximum Economy*, presented at the Pacific Coast Convention of the A. I. E. E., September, 1925.

point indicates the saving effected. For a load power factor of 0.50 and a unit cost ratio 0.4, the saving at the economical power factor, 0.916, is about 20 per cent, but would be only about 15 per cent if corrected to unity. For a unit cost ratio of 0.5, there would be a saving of 14 per cent if corrected to 0.866, but only 7 per cent at unity power factor. The percentage annual saving at the most economical corrected power factor has been plotted against unit cost ratio in Fig. 4. These curves show in a general way the conditions

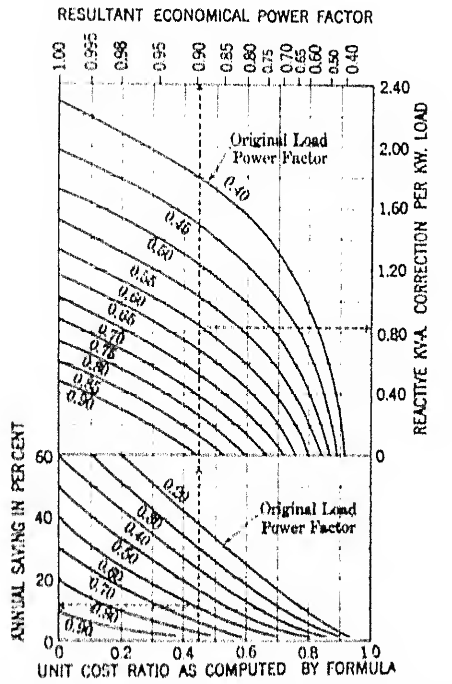

FIG. 4 WORKING DIAGRAM FOR USE IN PRELIMINARY CALCULATIONS

Calculate unit cost ratio from K and Q terms. The dotted projection lines indicate use of chart. Final figures should be worked out accurately for the actual prices and ratings of equipment used.

under which substantial savings may be expected.

The upper set of curves in Fig. 4 gives the required correction in reactive kilovolt-amperes for any power factor.

CONCLUSION

An annual cost equation has been developed for an overhead distribution circuit supplying a lagging power factor load partially corrected by a condenser. An economic balance in circuit design is obtained when the sine of the corrected power factor angle equals the ratio of the unit annual cost of correction to the unit annual cost of that portion of the supply circuit in which an actual saving is effected by power factor improvement. For this value of θ_{cc}, the total annual cost of the circuit is a minimum, and $\cos\theta_{cc}$ is the most economical corrected power factor. Comparison is made on the basis of the most economical conductor sizes and transformer ratings equal to the resultant load. If the unit cost ratio is equal to, or greater than, the original load power-factor angle, correction is not economically justified.

Application of the formula may be extended to distribution circuits in general, both overhead and underground. A method has been outlined for working out the comparative advantages of power factor correction at the generating station and at substations, feeder load ends, and the motors. This requires a careful study of load diversity and of the effect of each type of condenser upon the shape of the load current curve and therefore upon $I^2 R$ losses.

The equations and methods here given have the definite advantage that they may be applied equally as well to the design of new circuits and extensions as to the selection of optimum condenser ratings for existing circuits.

Although the present discussion has been limited to the cost element of the power-factor problem, it should be understood throughout that applications to specific cases should always be made in accord with practical operating requirements, and with those more intangible attributes connoted by the term "electric service."

Appendix A

Supplementary List of Symbols and Working Formula. In addition to the symbols already defined, the following list is given for use in evaluating the K and Q terms. It represents circuit design data ordinarily available to the distribution engineer.

C_{cu} Cost of conductor in dollars per lb. of actual copper, actual price of bare wire. For insulated wire, multiply charging out price by ratio of weight per 1000 ft. insulated wire to weight 1000 ft. bare wire of same size A. W. G.

C_e Cost in dollars per kilowatt-hour of generating and distributing energy to supply losses.

C_{con} Cost of condenser equipment in dollars per kilovolt-ampere.

C_T Cost of nearest standard size of transformer to carry the resultant load, in dollars per kilovolt-ampere.

g Rate of annual fixed charges; includes interest, depreciation, insurance, and taxes.

U_{1fe} Decimal ratio of watts iron loss in transformer to the volt-ampere rating.

U_{1cu} Decimal ratio of watts copper loss in transformer at full load to the volt-ampere rating.

U_{con} Decimal ratio of kilowatts required to operate the condenser at full load to the kilovolt-ampere rating.

l Length of line in feet, one way.

N Number of conductors with respect to relative size.

N' Number of conductors carrying full current.
For 3-phase, 3-wire . . . $N = 3$, $N' = 3$

w Weight of conductor in lb. per 1000 cir. mil ft.
For copper, $w = 0.00303$ lb.

ρ Resistivity of conductor per cir. mil ft.

H 8760 hr. in a year.

f Load factor.

fH Hours use of demand, yearly.

F Loss factor[8], computed from typical daily load curve

$$F = \frac{\text{sum of squares of hourly ordinates}}{24 \times (\text{peak load})^2}$$

$F\,H$ Equivalent hours[8] per year at constant full load to produce the same kilowatt-hours in $I^2 R$ line losses as occur with the actual fluctuating load. Analogous to "hours use of demand."

h Hours per year that condenser is connected to the line.

E Receiver voltage, phase voltage at full load.

I_{ec} Amperes per wire at full load at the resultant economical power factor, for a 3-phase line,

$$I_{ec} = \frac{1000\,(P + p)}{\sqrt{3}\,E \cos \theta_{ec}}$$

$$\frac{l\,w\,I_{ec}\,M}{1000 \text{ ft.}} = \text{Weight of one conductor.}$$

$$\frac{\rho\,l}{I_{ec}\,M} = \text{Resistance of one conductor.}$$

The K and Q terms are set up for a 3-phase, delta-connected line. Similar expressions may be worked out for 3-phase, 4-wire and 2-phase, 3- or 4-wire circuits. The economical circular mils for one ampere are calculated from the Kelvin law.[8]

$$M = 5500 \sqrt{\frac{F\,C_e}{g\,C_{cu}}} \tag{6}$$

The area in circular mils of the economical size of conductor is $I_{ec}\,M$. If the line drop for this size proves too great, calculate M from the allowable regulation.

$$\text{The cost of one conductor} = \frac{C_{cu}\,l\,w\,M\,I_{ec}}{1000} \tag{7}$$

The annual fixed charges on N conductors, substituting for I_{ec},

$$= \frac{g\,C_{cu}\,N\,l\,w\,M}{1000} \times \frac{1000\,(P + p)}{\sqrt{3}\,E \cos \theta_{ec}}$$

$$= \frac{g\,C_{cu}\,N\,l\,w\,M\,(P + p) \sec \theta_{ec}}{\sqrt{3}\,E} \tag{8}$$

and

$$Q_1 = \frac{g\,C_{cu}\,N\,l\,w\,M}{\sqrt{3}\,E} = \frac{0.00525\,g\,C_{cu}\,l\,M}{E} \tag{9}$$

$$Q_1 \text{ per mile} = \frac{27.72\,g\,C_{cu}\,l\,M}{E} \text{ dollars per mile per year} \tag{9a}$$

The $I^2 R$ losses in kilowatt at full load, for one conductor

$$= I_{ec}^2 \frac{\rho\,l}{I_{ec}\,M} \times \frac{1}{1000}.$$

The cost of losses in N' conductors at C_e dollars per kilowatt-hour

$$= \frac{C_e\,\rho\,l\,N'}{1000\,M} \times I_{ec} \tag{10}$$

dollars per hour at constant full load. When the load fluctuates, the $I^2 R$ losses vary as the square of the current. The annual cost of loss for a fluctuating load may be approximated by multiplying loss at full load by the "equivalent hours," $F\,H$, defined above. The annual cost of line losses

$$= \frac{C_e\,\rho\,l\,N'\,F\,H}{1000\,M} \times I_{ec} = \frac{C_e\,\rho\,l\,N'\,F\,H}{1000\,M} \times \frac{1000\,(P + p)}{\sqrt{3}\,E \cos \theta_{ec}}$$

$$= \frac{C_e\,\rho\,l\,N'\,F\,H}{\sqrt{3}\,E\,M}\,(P + p) \sec \theta_{ec} \tag{11}$$

and

$$Q_2 = \frac{C_e\,\rho\,l\,N'\,F\,H}{\sqrt{3}\,E\,M} = \frac{160826\,C_e\,l\,F}{E\,M} \tag{12}$$

$$Q_2 \text{ per mile} = \frac{849.16\,C_e\,F\,10^6}{E\,M} \text{ dollars per mile per year} \tag{12a}$$

Transformer prices and losses are those of the nearest standard capacity actually required at the resultant power factor

$$g\,C_T\,(P + p) \sec \theta_{ec} \tag{13}$$

and

$$Q_3 = g\,C_T$$

Transformer iron losses may be assumed as practically constant through the year. Transformer iron loss

$$= U_{TFe}\,C_e\,H\,(P + p) \sec \theta_{ec} \tag{14}$$

$$Q_4 = 8760\,U_{TFe}\,C_e$$

Transformer copper losses vary as the square of the current. Annual losses in kilowatt-hours may be approximated by multiplying loss at full load by the "equivalent hours," $F\,H$. The annual cost of copper losses in the transformer

$$= U_{TCu}\,C_e\,F\,H\,(P + p) \sec \theta_{ec} \tag{15}$$

and

$$Q_5 = 8760\,U_{TCu}\,C_e\,F$$

Annual condenser costs are divided into fixed charges and cost of losses. The unit fixed charges are

$$K_1 = g\,C_{con} \tag{16}$$

For synchronous condensers, an estimated percentage should be added to the annual fixed charges, g, to cover the cost of routine maintenance.

The yearly losses may be approximated by multiplying loss at full load excitation by the hours use $= U_{con}\,h$ per kv-a. The unit annual cost of losses will be

$$K_2 = U_{con}\,C_e\,h \tag{17}$$

Appendix B

Test for Minimum. If a root of the first derivative of Y with respect to θ yields a positive result when substituted in the equation of the second derivative, a minimum is indicated at that point.

Let K = sum of K terms and Q = sum of Q terms. Taking the second derivative of (**3**) and substituting the value of θ from (**5**)

$$\frac{d^2 Y}{d\,\theta^2} = \frac{Q^2}{\sqrt{Q^2 - K^2}}$$

The expression is real and positive when Q is positive and > 0, K is positive or $= 0$, and $Q > K$. Negative values of K and Q terms have no physical significance in the present problem. Lagging power factor is taken as positive.

Accuracy of Results. For the purpose of calculating the power polygon in equations (**3**) and (**4**), the value of p, kilowatt loss in the condenser, was assumed a constant. The error thus introduced is practically negligible. In a typical numerical example, for a load of 1000 kw., the loss in the condenser required to correct the power factor from 0.50 to 0.85 was 3 per cent, or 33 kw. The assumption that the condenser loss would be the same for corrected power factors ranging from 0.75 to 0.95 introduced a maximum error of less than 0.9 of one per cent of the total kilovolt-amperes. Since plus errors in calculating condenser kilovolt-amperes offset minus errors in required transformer kilovolt-amperes, even these small errors tend to cancel out in evaluating the total cost, Y.

In equations (**1**), (**2**), and (**3**) and in Figs. 2 and 3, a constant unit cost per kilovolt-ampere is assumed for transformers and condensers. In the usual case, however, the unit price of the larger sizes tends to decrease with increase in rating. If necessary, this condition could be expressed mathematically by plotting cost per kilovolt-ampere against kilovolt-ampere rating and writing the equation of a line passing through the required points. Introducing these expressions into equation (**3**) would tend to complicate the problem unnecessarily. The location of the minimum point of the Y cost curve is all that is required, and this can be determined accurately from the simple formula in one or two trials. No error is involved when the conditions of formula (**5**) are satisfied.

In the application of the formula to practical problems, it may be desirable to design the circuit for a corrected power factor slightly above or below the calculated value in order to make the most advantageous use of standard sizes of wire, cable, transformers, and condensers. In the design of new circuits, probable growth in load may dictate the use of larger wires and transformers than are immediately required. Where static condensers are used, provision may be made for adding additional units as required, thus maintaining economical operation during the period of growth and increasing the ultimate kilowatt capacity of the circuit.

Instability in Transformer Banks

BY KING E. GOULD[1]

Associate, A. I. E. E.

Synopsis.—*This paper considers the instability which sometimes occurs in banks of transformers supplying a capacity load when certain harmonics in the primary current are suppressed, either by the type of transformer connections or by a resonant circuit in series with the primary of the transformer, and the similarity between the several unstable circuits is pointed out.*

Curves showing the triple-frequency voltage distortion as a function of the capacity load have been included for two of the unstable circuits. For one case, oscillograms taken during the instability are shown.

An explanation, substantiated by actual analyses, has been brought forward for the simplest unstable circuit, consisting of three branches connected in Y across a three-phase line with balanced, sinusoidal line voltages, with the neutral unconnected, each branch of the Y consisting of an iron-cored reactance in parallel with a capacity. This explanation is extended to the other cases, two with experimental evidence as justification, and the third by analogy only.

INTRODUCTION

In 1915 Mr. L. N. Robinson published a paper[2] concerning the unstable condition which sometimes occurs when a Y-connected capacity load is supplied by a Y—Y-connected transformer bank with the secondary neutral closed but the primary neutral open. The phenomenon was evidently closely associated with the voltage distortion which occurs with this and similar transformer connections, and which has been studied by many investigators[3]. No very satisfactory explanation of this unstable condition, however, has ever been advanced so far as the author knows, and the principal object of this paper is to advance an explanation substantiated by considerable analytical proof and experimental observation.

Mr. Robinson suggested that the instability might be due to a "reversing transformer leg," but this theory has been disproved by oscillograms which show that the line voltages and currents are balanced during some of the unstable conditions, and by hysteresis loops observed during instability, which were found to remain symmetrical with respect to the two axes.

Mr. R. P. Shaw investigated this phenomenon[4] and took oscillograms and very complete data throughout both the stable and the unstable ranges of line voltage and capacity load. He also investigated a quite similar case of voltage distortion and instability which occurs when a capacity is inserted in the delta of a Y-delta-connected bank of transformers, primary neutral open. Two of his curves showing the third harmonic induced voltage as a function of the capacity load have been included in this paper.

EXPERIMENTAL WORK

Three identical transformers, each of 1½-kv-a. rating at 100 volts, 60 cycles, the ratio of transformation being unity, were connected Y—Y to supply a Y-connected, balanced capacity load of 12.5 μf per phase. The secondary neutral was closed while the primary neutral was open. The transformers were supplied by a 5-kv-a., 60-cycle alternator of very good wave form for balanced loads, direct-connected to an 8-hp., d-c. motor. Under these conditions, the transformers, emitted "grunts" or "beats" which sounded like a solid body, such as a wooden mallet, striking the laminations, and all the meters with the exception of the line voltmeter oscillated badly. The line voltage was about 200 volts, as indicated by a dynamometer type meter, and oscillated but slightly, as the change in load over a beat had but little effect upon the terminal voltage of the alternator.

This instability persisted with a wide range of capacity loads. Mr. Shaw, who worked with the same apparatus, records instability with a capacity load of as high as 40 μf. per phase. With any given line voltage, stability would occur with either a very high or a very low value of capacity, the maximum values of capacity which would produce instability being increased as the voltage was increased.

The instability was not due to the alternator supplying the transformers, as was proved by Mr. Shaw by connecting them to a large alternator, and also by taking oscillograms of the alternator field current, which was found to be perfectly regular. Mr. Robinson had also noted this instability under conditions differing widely enough to indicate that it was not due to the power source.

Fig. 1, taken from Shaw's work, shows the variation of third-harmonic induced voltage with the size of the capacity load, throughout the lower, stable range of capacity and part of the unstable range, where measurements were possible. These voltage readings were taken with a thermocouple heater element, in series with a high resistance, inserted in one corner of a delta formed with an auxiliary winding on each transformer, as shown in Fig. 2. Multiples of the third harmonic appeared in this voltage also, but they were small, as indicated by analyses of the wave form.

Mr. Shaw also experimented with a quite similar unstable condition produced by connecting the pri-

maries of the transformers as before, in Y with the neutral unconnected, and the secondaries in delta, with a capacity inserted in one corner of this delta as shown in Fig. 3. The third-harmonic induced voltage was measured across one corner of an auxiliary delta as before. As was to be expected, the capacity necessary to produce instability in this latter case was about one-third that in the Y - Y connection, as the third-harmonic voltages induced in the secondary windings add up directly to make the voltage across the capacity three

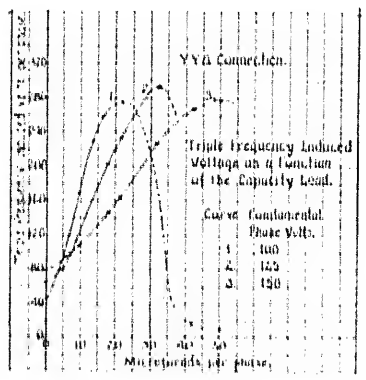

Fig. 1

times the third-harmonic phase voltage. Fig. 4, due to Mr. Shaw, shows the third-harmonic phase voltage as a function of the capacity inserted in the delta, and is similar to Fig. 1 except that the capacity has been reduced to about one-third its previous value. Mr. Shaw records that the instability commenced in the Y-delta-delta case with a capacity of from 2 to 4 $\mu f.$, which corresponds to from 6 to 12 $\mu f.$ per phase in the Y - Y

Fig. 2

delta connection. That the Y - Y connection and the Y-delta connections are essentially the same so far as the third harmonic and its multiples are concerned is evident from a comparison of Figs. 5 and 6, which represent the same circuit except that in Fig. 6 the leakage reactances of the transformer windings have been neglected.

As the removal of the primary neutral connection produced instability in an otherwise stable circuit, it seemed evident that the instability must be due to the third harmonic and its multiples, introduced by the varying permeability of the iron cores of the transformers. The existence of the Y-delta instability confirms this hypothesis.

As it was well established that the unstable condition which sometimes occurred in some star-connected transformer banks was due to the suppression of the third harmonic and its multiples in the primary current, it was conceived that by means of a series filter, the partial suppression of the harmonics in the primary current of a single-phase transformer supplying a capacity load might produce an unstable condition.

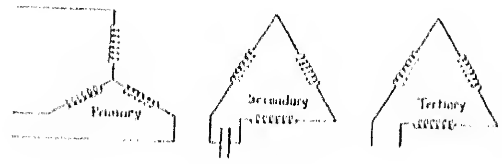

Fig. 3

Accordingly a circuit was set up as shown in Fig. 7, the transformer being one of those used in the three-phase case. The filter circuit consisted of a capacity in series with two identical air-core inductances which were mounted so that the mutual inductance between

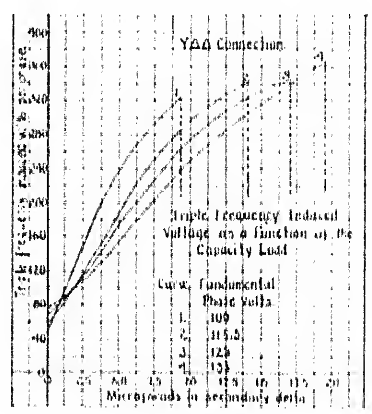

Fig. 4

them could be varied. This filter circuit was adjusted for resonance at 60 cycles, the combined impedance being 12 ohms, while the capacity and the inductance each had an impedance of 203 ohms at 60 cycles.

With this arrangement, with 110 volts at 60 cycles

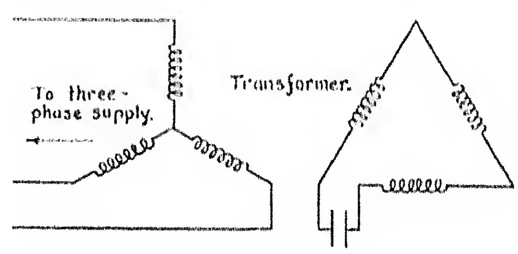

Fig. 5

impressed upon the circuit and with a capacity of 13.5 $\mu f.$ placed across the secondary of the transformer, the circuit was found to be distinctly unstable, even worse than the three-phase case, although the two instabilities were quite similar. This single-phase instability occurred over a considerable range of capacity either

side of 13.5 $\mu f.$, but the beats seemed most violent at about this value of capacity. A great enough change of capacity in either direction would produce stability, the voltages and currents at the stable condition with high values of capacity being low, as in the three-phase case. By changing conditions, such as the voltage, frequency, or capacity load, the beats could be varied continuously from less than one per sec. to so many that nothing could be heard but a hum. In general, the beats were more violent the longer they were.

The beats were adjusted to about five per sec., so

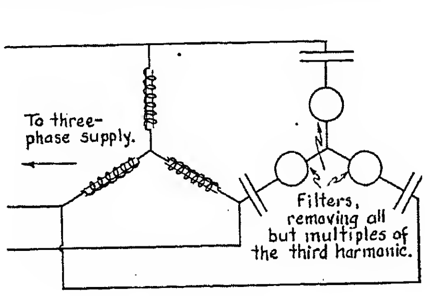

Fig. 6

that each one included about 12 cycles, and simultaneous oscillograms long enough to show the wave form over a complete beat were taken. These are shown in Fig. 8. The oscillations were not very violent

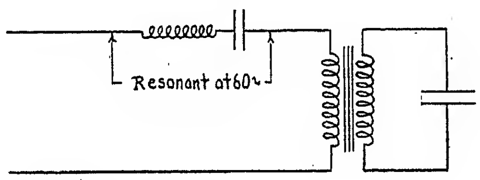

Fig. 7

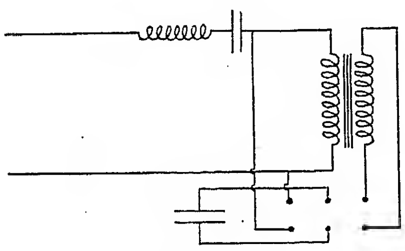

Fig. 7-A

in this case, but a beat of longer period was not used because of the length of film required. It will be noted that a beat does not include an integral number of cycles.

By means of the two-dimensional oscillograph[5], an examination of the hysteresis loops of the transformer during instability was made. The hysteresis loops could be thrown upon a ground glass screen and viewed very well indeed. An attempt was made to photograph the series of loops during the unstable condition, but with no success, as the point of light traversed a given path but once, and was too faint to record this path. The loops thrown upon the screen brought out one fact—that the loops increase and decrease in size, but they always remain symmetrical with respect to the two axes.

It seemed possible that the unstable condition might not depend upon leakage reactance of the transformer windings, so a switch was arranged to shift the capacity load from the secondary to the primary, as shown in Fig. 7A. The unstable condition was established, and the capacity suddenly switched from the secondary to the primary of the transformer. No change could be detected in the frequency or violence of the beats. Thus it was proved that leakage reactance of the transformer windings is not a contributing cause of the instability.

In view of the fact that the single-phase instability

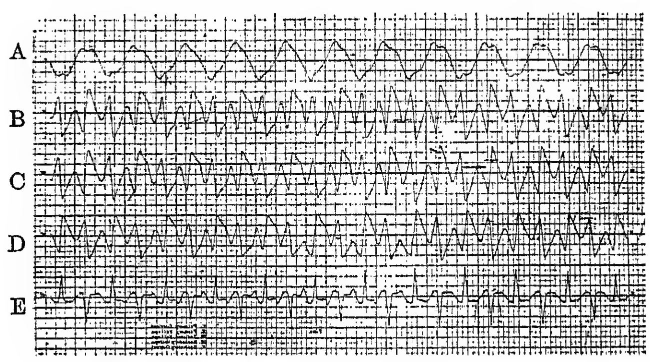

Fig. 8

A. Primary current
B. Primary voltage
C. Induced voltage
D. Secondary voltage
E. Secondary current.

occurred with the capacity across the primary of the transformer, it seemed probable that the unstable condition would occur if an iron-cored reactance and a capacity of the proper size were connected in parallel, and three such branches were connected in Y across a three-phase line of the proper voltage, the neutral being unconnected. Accordingly, the three transformers used before were connected in Y, the primary neutral open, and with a capacity of about 12.5 $\mu f.$ in parallel with each primary, as shown in Fig. 9. This combination was connected across a three-phase supply with a line voltage of 200 volts, at 60 cycles, and distinct beats occurred in each transformer, just as in the case with the capacity load across the secondary of the transformer.

Explanation of Instability

Of the circuits found to be unstable, the one shown in Fig. 9 is most easily analyzed, as nothing but odd multiples of the third harmonic can appear in the phase voltage under stable conditions with sinusoidal, balanced line voltages, and the third harmonic and its

5. E. L. Bowles, Discussion, Trans. A. I. E. E. 1923, p. 346.

multiples in the exciting current must be equal in magnitude and opposite in phase to the respective harmonic currents through the capacity. All multiples of the third harmonic above the third itself seemed, from actual analyses, to be comparatively small and hence were neglected. The effect of the third harmonic in the phase voltage upon the third-harmonic exciting current was determined as follows.

A fundamental flux density of 10.2 kilogausses was assumed, corresponding to a fundamental (60-cycle) phase voltage of 100 volts. Various amounts of

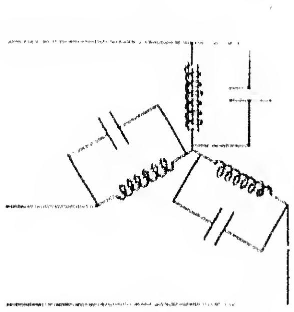

Fig. 9

third harmonic were introduced "in phase" with the fundamental; that is, so that the resultant flux wave was of the form, $A \sin w t + B \sin 3 w t$, and the resultant flux wave was drawn. This was done with the third-harmonic flux from 12 per cent to 60 per cent of the fundamental. From Mr. P. A. Blackwell's series of hysteresis loops[6] for one of the transformers, the magnetization curve was drawn as shown in Fig. 11. From this curve, the exciting current corresponding to each resultant flux wave was determined, and each of these was analyzed for the third-harmonic current.

When the third-harmonic flux was "in phase" with

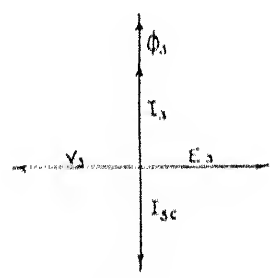

Fig. 10

the fundamental flux, the resultant flux wave was, of course, always symmetrical with respect to the 90-deg. (fundamental scale) ordinate. As there is only one value of current corresponding to each value of flux density, using the magnetization curve, the exciting current was symmetrical, also, with respect to the 90-deg. ordinate. Thus no cosine component of the third harmonic could appear in the exciting current;

6. M. I. T. thesis, 1924, Unstable Effect in Three-Phase Transformer Bank with Capacity Load.

in other words the third-harmonic current is in phase with the third-harmonic flux. From Fig. 10, it will be seen that this is a condition which must be fulfilled if the third-harmonic exciting current, I_3, is to be in phase opposition to the current through the capacity. In Fig. 10, ϕ_3 is the third-harmonic flux which produces the induced voltage E_3, while V_3 is the third-harmonic impressed voltage which causes the current I_{3c} to flow through the capacity. The resistance and leakage reactance of the transformer winding are neglected.

Thus it will be seen that the phase relation of the third-harmonic exciting current remains correct if the magnetization curve is used. Moreover, the third-harmonic exciting current increases more rapidly than the third-harmonic current through the capacity, after the maximum flux density becomes high, so that the two will become equal in magnitude. Hence the saturation curve cannot produce instability by making

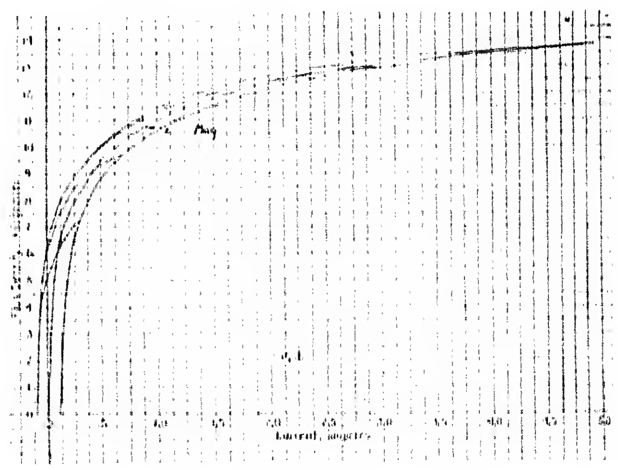

Fig. 11

it impossible for the two third-harmonic currents to become equal in magnitude and opposite in phase.

As the use of the saturation curve would not indicate instability, the exciting current was determined from the hysteresis loops shown in Fig. 11 and taken by Mr. P. A. Blackwell for one of the transformers. For any desired maximum flux density, a loop similar in shape to the ones shown was interpolated. It was assumed that each secondary hysteresis loop was thin enough to practically coincide with the portion of the main hysteresis loop where it started. Loops taken by Mr. W. M. Gilman[7] indicate that this assumption introduces but little error.

The third-harmonic flux density was varied, in steps of 12 per cent, from zero to 60 per cent of the fundamental flux density, as before, but each value of third harmonic flux density was introduced at 20-deg. (fundamental scale) intervals. The resulting exciting current waves were analyzed for the third harmonic by means of

7. M. I. T. thesis, 1925, Quantitative Analysis of Transformer Harmonics.

the Woodbury analyzer[8], which was quite satisfactory for waves with a cyclic length as long as was used, 12 inches. Fig. 12 shows a sample wave, the third-harmonic flux being 48 per cent of the fundamental, and introduced so that the resultant flux wave was of the form, $[A \sin w\,t + 0.48\,A \sin 3\,(w\,t + 20°)]$.

The magnitude of the third-harmonic exciting current, I_3, was plotted against the third-harmonic flux, ϕ_3, for given angular displacements between the fundamental and the third-harmonic fluxes, as shown in

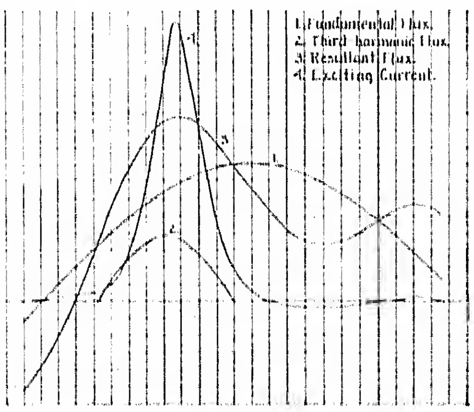

FIG. 12

Fig. 13. This angle, which we shall call $\theta_{3\phi}$, is the fundamental angle by which the zero point of the third-harmonic flux wave lags the zero point of the fundamental flux wave, both zero points being those at which the slope is positive. Thus the flux wave is expressed as $A \sin w\,t + B \sin 3\,(w\,t + \theta_{3\phi})$. The intersections of the curves of I_3 against ϕ_3 with a line which repre-

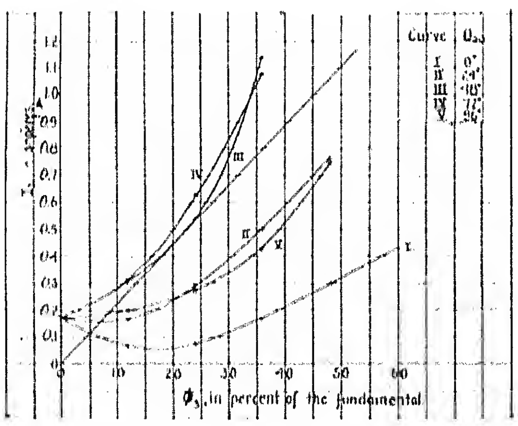

FIG. 13

sented I_3 against ϕ_3 for a capacity of 6.5 μf. gave values of ϕ_3 and $\theta_{3\phi}$ at which the magnitude of the third-harmonic exciting current was correct for this value of capacity. These values of ϕ_3 and $\theta_{3\phi}$ were plotted as shown in Fig. 15, curve I.

The angle, θ_{3I}, by which the third-harmonic current lags the fundamental flux (that is, the fundamental angle by which zero point of the third-harmonic current lags the zero point of the fundamental flux, both zero points being those at which the slope is positive), for constant values of third-harmonic flux, was plotted against the lag of the third-harmonic flux behind the fundamental flux shown in Fig. 14. As this third-

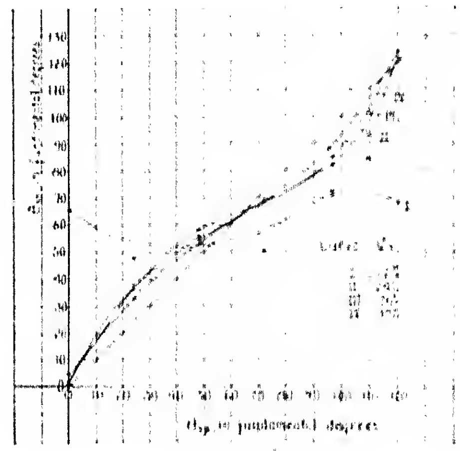

FIG. 14

harmonic current must be in phase with the third-harmonic flux in order to be in phase opposition to the third-harmonic current through the capacity, the angles θ_{3I} and $\theta_{3\phi}$ must be the same so that the intersections of the curves of Fig. 14 with a straight

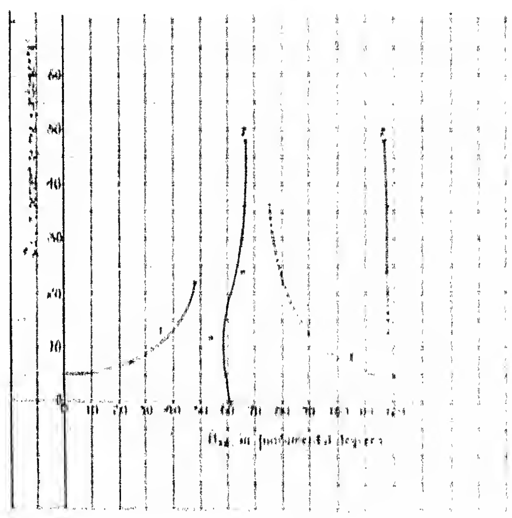

FIG. 15

line through the origin and with a slope of unity gave values of ϕ_3 and $\theta_{3\phi}$ at which the phase of the third-harmonic exciting current was correct. The locus of the point at which the phase was correct is shown in Fig. 15, Curve 2.

It should be noted that the part of Curve 2 which lies at $\theta_{3\phi}$, equal to about 117 deg., is actually discontinuous downward, stopping at a value of ϕ_3 somewhere between 12 per cent and 24 per cent. The portion between these two points is shown dotted, as it is not known

8. F. S. Dellenbaugh, Jr., A. I.E. E. Journ., Jan. 1923. p. 58.

exactly where the curve stops. For each value of ϕ_3 below 12 per cent, there is only one value of $\theta_{3\phi}$ at which the phase of I_3 is correct. Also, it should be noted that the "phase correct" curve at $\theta_{3\phi}$ equal to about 60 deg. approaches 61 deg. as a limit, $\theta_{3\phi}$ at ϕ_3 equal to zero being indeterminate.

It will be seen from Fig. 13 that the magnitude of the third-harmonic exciting current is never correct for values of $\theta_{3\phi}$ between 48 deg. and 72 deg., as all the $I_3 - \phi_3$ curves for this range of $\theta_{3\phi}$ lie entirely above the straight line which is drawn for the 6.5-$\mu f.$ condenser. As this straight line is tangent to the curve for $\theta_{3\phi}$ equal to 48 deg., the left-hand "magnitude correct" curve becomes vertical at this value of $\theta_{3\phi}$, and for increasing values of ϕ_3, $\theta_{3\phi}$ will decrease. Similarly, the right-hand "magnitude correct" curve becomes vertical at some value of $\theta_{3\phi}$ greater than 72 deg., and for increasing values of ϕ_3, $\theta_{3\phi}$ increases. The dotted line added to the "magnitude correct" curve is to show that it is definitely known that the curve never crosses a vertical line erected at $\theta_{3\phi}$ equal to 72 deg.

Thus, in Fig. 15, there is no intersection between the "magnitude correct" and the "phase correct" curves, which means that with a fundamental phase voltage of 100 volts and a capacity of 6.5 $\mu f.$ per phase, the magnitude and phase of the third-harmonic exciting current never become correct at the same time, at least over the range of third-harmonic voltage considered; that is, up to about 150 per cent of the fundamental. This seems a reasonable cause of the instability, as under stable conditions the third-harmonic exciting current and the third-harmonic current through the capacity must be equal in magnitude and opposite in phase.

It would seem probable that with higher values of third-harmonic voltage, no intersection of the "magnitude correct" and "phase correct" curves would occur. In Fig. 13, it looks as though the straight line for 6.5-$\mu f.$ capacity would not intersect the $I_3 - \phi_3$ curves for $\theta_{3\phi}$ near 120 deg., which would mean that no intersection would occur along the "phase correct" curve near $\theta_{3\phi}$ equal to 120 deg. Moreover, analyses of oscillograms and Mr. Shaw's measurements have not shown a third-harmonic voltage so great as 150 per cent of the fundamental for this value of capacity.

If, in Fig. 13, the straight line is given a greater slope — that is, the capacity is increased far enough — this line will intersect the $I_3 - \phi_3$ curves corresponding to $\theta_{3\phi}$ in the range about 60 deg., and hence an intersection of the "magnitude correct" and the "phase correct" curves would occur along the "phase correct" curve near $\theta_{3\phi}$ equal to 60 deg. Moreover, no matter how much more the capacity is increased, there will always be an intersection in Fig. 15, with $\theta_{3\phi}$ near 60 deg., and hence always a stable point.

If the capacity is decreased far enough, the $I_3 - \phi_3$ line for the capacity, in Fig. 13, will intersect the $I_3 - \phi_3$ curves for $\theta_{3\phi}$ near 117 deg., at values of ϕ_3 great enough to produce an intersection of the "phase correct" and "magnitude correct" curves near $\theta_{3\phi}$ equal to 120 deg. At very low values of capacity, the straight line, Fig. 13, becomes tangent to the curves for $\theta_{3\phi}$ equal to 120 deg., and of course for smaller capacities than this, the magnitude never becomes correct, according to the curves. For such a small capacity, however, higher multiples of the third harmonic may have appreciable effect upon the third-harmonic exciting current, or there may be instability which, due to the small current through the capacity, is unnoticeable.

According to the analysis described above, there appears to be a wide range of capacity at which the unstable condition occurs, although an insufficient number of $I_3 - \phi_3$ curves have been plotted to determine the limits of this range of capacity. Experimentally it was found that 8.5 $\mu f.$ per phase would produce instability, the fundamental phase voltage being 100 volts at 60 cycles, while with four $\mu f.$ per phase no instability could be detected. Lack of suitable capacity prevented more accurate determination of the range of instability. According to the curves of Figs. 13 and 15, it seems likely that instability would occur at four $\mu f.$, which indicates that the lower limit of capacity which will produce instability is actually greater than that indicated by this analysis, due possibly to the stabilizing effect which is possible by the introduction of odd multiples of the third harmonic in the phase voltage.

As the circuit analyzed is equivalent to a Y—Y-connected transformer bank supplying a Y-connected capacity load, with the secondary neutral closed but with the primary neutral open, neglecting the leakage reactances of the transformer windings, and as experiment has shown that the instability is essentially unchanged by switching the capacity load from the primary to the secondary (taking due account of the ratio of transformation), the above explanation should apply to this latter type of circuit also. Moreover, as the circuit analyzed is equivalent, so far as the third harmonic and its multiples are concerned, to a Y-delta-connected bank of transformers with a capacity inserted in one corner of the delta, and with no primary neutral, again neglecting the leakage reactances of the transformer windings, the above explanation seems valid in this case also. Figs. 5 and 6 illustrate the similarity of the circuit analyzed and the above y-delta connection.

Results and Conclusions

1. An unstable condition, quite similar to the one which may occur in some star-connected transformer banks, may be produced with a single-phase transformer supplying a capacity load, by partial suppression of all higher harmonics in the primary current by means of a filter circuit. Stability will be produced if any of the conditions, as voltage, frequency, or size of the capacity load, are changed far enough in either direction.

2. Hysteresis loops traced upon a ground glass screen by the two-dimensional oscillograph during this unstable condition increased and decreased in size, but always remained symmetrical with respect to the two axes.

3. Both the single-phase and the three-phase instability existed with the capacity load connected across the primary. Thus leakage reactance cannot be a contributing cause of the instability.

4. Under the cause of the three-phase instability developed herein, the saturation curve cannot alone produce instability. Hysteresis, as well as non-linearity of the magnetization curve, is necessary.

5. There is considerable evidence that the three-phase instability (Y-connected branches of capacity and iron-cored inductance in parallel, with neutral unconnected) is due to the inability of the third harmonic and its multiples in the phase voltage to adjust themselves so as to make the third-harmonic exciting current and its multiples equal and opposite to the respective harmonics in the current through the capacity. As these conditions must be fulfilled during steady-state operation, this failure constitutes a reasonable cause of the instability. Hysteresis is necessary to produce instability, as mentioned above; non-linearity of the magnetization curve alone is not sufficient.

It has been shown, by drawing the exciting current wave from the hysteresis loops and the voltage waves, that when the iron-cored inductance and a certain capacity are connected in parallel, with three such branches connected in Y and with no neutral connection, across a three-phase supply with a certain value of balanced, sinusoidal line voltage, the third-harmonic phase voltage cannot adjust itself to make the third-harmonic current through the inductance equal and opposite to that through the capacity. This analysis neglects all multiples of the third harmonic above the third itself.

The lower limit of capacity which will produce instability, as indicated by this analysis, is somewhat less than the actual limit as indicated by experiment. This would seem to be due to the stabilizing effect produced by the introduction of higher odd multiples of the third harmonic in the phase voltage, these harmonics appearing only in order to produce stability.

6. The above explanation covers the instability which occurs when the capacity is connected across the secondaries of the transformers, Y—Y, with no primary neutral connection, as the two circuits are equivalent, neglecting leakage reactance of the transformer windings. It also covers the case of Y-delta-connected banks, with the primary neutral unconnected, when a capacity is inserted in the secondary delta, as this circuit is similar, in so far as the third harmonic is concerned, and neglecting leakage reactances, to the circuit for which the analysis was made.

7. It seems probable, although no proof has been advanced, that the single-phase instability is due to the inability of all the harmonics in the voltage impressed upon the inductance and capacity in parallel, to adjust themselves so as to make each harmonic in the exciting current equal and opposite to the corresponding harmonic current through the capacity, assuming that the filter circuit is perfect. The cause of this instability then becomes quite analogous to that of the three-phase case.

Discussion

V. M. Montsinger: I was very much interested in Mr. Gould's paper because it gives a possible explanation of the same kind of phenomena that I observed on some single-phase transformers a few years ago.

In 1914, I presented discussion for a series of papers on transformer connections, etc., and in this discussion, showed how condenser capacity, connected either across an opening in the delta of a Y-delta connected bank, or across the legs of the delta, intensified the harmonic voltages. Fig. 4, as given in Part I of the A. I. E. E. Transactions, for 1914 p. 782, shows that at about 45 or 50 kilolines per sq. in. core density, the harmonic voltages suddenly increases to 200 per cent of the fundamental voltage. Upon further increasing the density, the harmonic voltage decreases and then increases again; in fact, as the core density increased, there were three points at which the harmonic voltages were intensified.

Fig. 6, shown on p. 783, gives results of similar tests made on a three-phase core-type transformer, and these curves demonstrate that no intensification of the harmonic voltages occurred at any point as the core density was increased—the maximum intensification being in the order of 15 to 20 per cent of the fundamental.

One point I wish particularly to emphasize is that while we have these dangerous harmonic voltages in single-phase transformers, we do not have them in three-phase core-type transformers. The reason for this obviously is due to the fact that in single-phase transformers, the third harmonic voltages in the three legs, which are in phase and flowing towards the neutral of the "Y" connection, have a return path through the iron core leg external to the windings; while in three-phase core-type transformers, the harmonic voltage flux must return through the air.

I should like very much to have Mr. Gould's comments on how this difference in phenomena between single-phase and three-phase core-type transformers lines up with the conclusions that the contributing cause of this intensification is leakage reactance.

K. E. Gould: I have done no work with the three-phase transformer, and the present paper considers only three single-phase transformers star-connected. The statement that the leakage reactance of the transformer windings is not a contributing factor in the instability is based on the fact that in changing the capacity from the secondary to the primary, there was practically no difference in the instability which seemed to me conclusive evidence that the leakage reactance is not a contributing cause.

This statement that leakage reactance does not cause instability, was made particularly in consideration of work that Mr. Shaw did at M. I. T. in 1924. He gave a very good explanation of the instability, showing that there were two conditions—two points at which the transformers could operate—due to the interaction of the capacity, and the leakage reactances of the transformer windings, particularly in the Y-delta case, where the capacity is inserted in one corner of the delta. However, as soon as it was discovered that the instability still existed with only the iron-core reactor in parallel with the capacity, it seemed evident that the instability was not due to what Mr. Shaw called a resonance effect between the capacity and the leakage reactance of the transformer windings.

An Instrument for Measuring Short-Circuit Torque

BY G. W. PENNEY[1]
Associate, A. I. E. E.

Synopsis. *The torque produced by a short circuit or other transient will produce a corresponding acceleration of the rotor. If the rotor is not connected to a load the acceleration of the rotor will be directly proportional to the torque. A small instrument is described which can be attached to the end of the shaft of the machine to be tested. This instrument records the instantaneous acceleration of the rotor, the corresponding torque being calculated. The acceleration is measured by two separate methods. The first method gives points on an acceleration—time curve and the second gives a continuous record of the torque. The acceleration is recorded on the oscillogram so that by using a six element oscillograph a simultaneous record can be obtained showing both the acceleration and the short-circuit currents. The mechanism for closing the short circuit at the desired point of the voltage wave and the method of checking the accuracy of the instrument are also described. A record from an actual short-circuit test is shown. The results of the tests will be discussed in a later paper. The instrument can also be used for measuring sudden shocks on motors and other rotating machinery.*

INTRODUCTION

IN order to design machines to withstand all possible operating conditions and yet not waste material, it is necessary to know the magnitude of the greatest forces which may act on the machine under the worst possible conditions. At the instant of a short-circuit surge, or when synchronized out of phase, enormous forces may act on a machine. The end windings are inherently rather weak mechanically and usually these are the first parts to be injured by a short circuit. These failures are caused by local magnetic forces, but in a few instances, the resultant torque of the machine has caused failure. One of the first large vertical shaft generators of low reactance sheared off the foundation bolts and turned through a considerable angle. In another case, a 6000-kv-a. frequency changer set had the frame supporting foot broken off and the holding down bolts stretched when the set was connected to the line out of phase.

These failures show the enormous forces produced by short circuits and other transients. In order to make machines sufficiently strong to withstand these abuses to which they are frequently subjected and yet not waste material, the maximum torque which may be developed under abnormal conditions must be known. Because of its transient nature, this torque is very difficult to calculate or measure. Methods thus far developed for calculating short-circuit torque are rather questionable because the assumptions which must be made do not accurately represent the actual conditions.

So far as the writer is aware, the only previous attempts to actually measure this torque have been by recording the oscillations of the rotor, using the torsiograph or similar instrument giving a space—time curve of the movement of the rotor or by measuring the voltage generated by a small generator connected to the shaft of the machine short circuited[2]. The determination of torque from a space—time record is very uncertain because the torque is proportional to the second derivative, *i.e.*, curvature of the space—time record. As is discussed later, this is very unsatisfactory for this purpose. The measurement of the voltage generated by a small direct-connected generator is much better but this method requires taking the slope of the record which is not entirely satisfactory. This paper outlines an analysis of the general problem of measuring torque produced by short circuits and other transient phenomena and describes the instrument which was developed. The instrument was designed to be attached to the end of the shaft of a machine and gives a record on the oscillogram of the instantaneous acceleration of the rotor which is proportional to the instantaneous torque provided the machine is not connected to an external load. If it is desired to measure the torque developed when the machine is short circuited while running under load, the test must be arranged so that the torque developed by the machine short circuited can be determined from the acceleration of its rotor and the known characteristics of the connected load or driving motor. The instrument was designed for the one purpose of measuring the acceleration of the rotor produced by a sudden pulsating torque. It was intended to give an accurate record of the first torque cycle and a fairly accurate record of succeeding torque cycles. It was designed for torque frequencies not exceeding 120 cycles and accelerations of 500 radians per sec. and above. It can be readjusted for measuring lower accelerations provided the frequency is reduced. In addition to studying short circuits, it may be useful

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

2. The torque developed by a short circuit was measured by H. Rikli, (*Bulletin Association Suisse des Electriciens* No. 5, 1925). He measured the voltage generated by the exciter which was operated on open circuit with its field supplied by storage batteries. The torque was of course proportional to the rate of change of voltage. If the torque developed had a sinusoidal form, it would be fairly easy to determine the rate of change of voltage, but with the irregular torque developed by a short circuit, it is very difficult to measure the peak acceleration.

for studying shocks on rolling mill equipment and similar applications.

Selection of Type of Instrument

There are many methods which might be used to measure the torque produced by a short circuit. Perhaps the most obvious method would be to mount the stator on trunions and attempt to measure the torque. This would require large, clumsy, and expensive apparatus, and since the torque is of a pulsating nature, it would be extremely difficult, if not impossible, to measure this torque accurately, for any known method of measuring such a large pulsating force would allow some motion of the stator and any such motion absorbs force in the inertia reaction of the stator, so that the torque measured would not be the same as the actual torque developed.

Another method of attack is to measure the effect on the rotor. If the rotor is sufficiently rigid so that it can be regarded as a single mass, the acceleration of the rotor will be directly proportional to the torque applied (assuming that the rotor is not connected to any other device). This general scheme was adopted since it requires only a record of the acceleration of the rotor and therefore lends itself to a small instrument which may be readily attached to any machine.

The pulsating nature of the torque produced by a short circuit is the major difficulty in measuring the torque accurately. For instance, if an attempt were made to measure the actual force acting on either the stator or the rotor a very slight movement would absorb a large force in the inertia reaction, resulting in a large error in the recorded force. For example, the stator of a representative 20,000-kv-a., 60-cycle generator has a moment of inertia of $\frac{2,600,000}{g}$. Then if this stator were mounted on trunions and perfectly free to move and if a sinusoidal torque of 60-cycle frequency and having a peak value equal to the normal torque of the machine were acting on the stator, the amplitude of the resulting movement would be only 0.00002 radians. At an 80-in. radius, the total movement (double amplitude) would be only 0.0032 in. This movement of 0.0032 in. assumes a sinusoidal torque whose average value is zero so that it has no tendency to produce continuous rotation and with the stator mounted on trunions, the only effect is to produce this torsional oscillation of 0.00004 radians total movement which absorbs the full pulsating torque in the inertia reaction of the stator. This is merely given as an example of the enormous force required to produce a very small oscillation of a stator or rotor at 60-cycle frequency. If an attempt were made to measure the torque developed during short circuit by measuring the force exerted by a stator mounted on trunions, it is evident from the above discussion that the allowable movement of the stator is very small. The problem is further complicated by the probability of resonance[3]. The same general difficulty applies to other methods of measurement, so that in any method of measurement, the flexibility of the instrument must be carefully considered for any slight relative movement permitted may result in very large errors. It is much easier to control the natural frequency in a small instrument which measures the acceleration of the rotor than in a large device for measuring force, so that the small instrument should be more accurate and reliable as well as cheaper and more convenient.

There are several possible methods of measuring the acceleration of the rotor. One method would be to obtain a space — time curve showing the instantaneous position of the rotor as a function of time. The second derivative of this record (*i. e.*, the curvature) would then give the acceleration. But in this method any vibration of the recording mechanism would indicate a torque which did not exist. In general, the tendency is to exaggerate errors when a record must be differentiated. A record of instantaneous speed could be obtained, but this would have to be differentiated to get the acceleration so that excessive accuracy would be required in the speed — time record in order to obtain a reasonably accurate record of acceleration. Thus, to secure an accurate record as well as to save time in interpreting the record, the instrument should measure acceleration directly.

The acceleration could be measured electrically by generating a voltage proportional to the rotor speed and impressing this voltage across a condenser. The charging current would then be proportional to the acceleration of the rotor. This method is possible, but to secure sufficient current to give a reasonable deflection on the oscillograph, the apparatus must be rather large or amplification must be used. There is considerable chance for error due to e. m. fs. induced by stray fields at the time of short circuit and by the variation in drop across the brushes which must be used to collect the current. The most serious disadvantage is that it does not lend itself to a small instrument and the calibration is neither as convenient nor as accurate as in the device adopted.

The general scheme of measuring the force required to drive a small flywheel is believed to be the most accurate method available for measuring the acceleration of the rotor. It is very convenient since it can be incorporated in a small instrument which can be attached directly to the shaft of a machine, and since it can be calibrated statically by applying a known torque to the flywheel, the corresponding acceleration being calculated from the moment of inertia of the flywheel.

3. The torque transmitted to the foundation by a stator mounted with some flexibility is discussed by Mr. Soderberg in an article published in the April, 1924 issue of the *Electric Journal* (p. 160). This article covers the steady state conditions. For a transient such as a short circuit, the solution is much more complicated.

The Instrument

The instrument decided on combines two separate devices for measuring the acceleration of the rotor. The first merely gives eight points on the acceleration-time curve and the second gives a continuous record of the acceleration. These devices are in a single, very rigid casting which can be attached to the end of the shaft of the machine to be tested. The acceleration is recorded on the oscillogram giving a simultaneous record of acceleration and of short-circuit current. Figs. 1 and 2 show two views of the instrument attached to a small 1200-rev. per min. alternator.

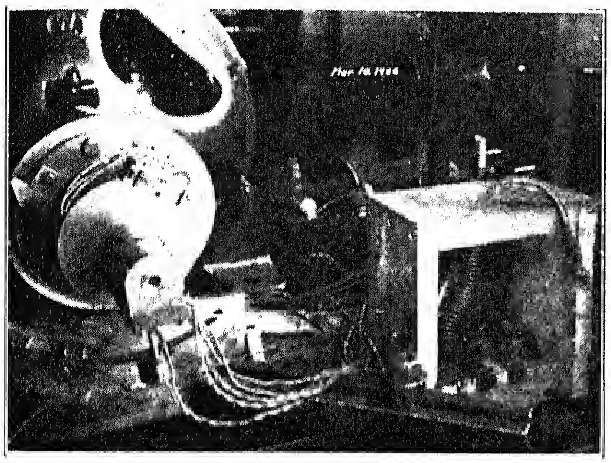

Fig. 1 Illustration of the Instrument Attached to the Shaft of a 100-Kv-a. Generator

The device which records points on the acceleration time curve consists of several small disk flywheels mounted on and free to rotate on the instrument shaft. Fig. 3 is a cross-section of the instrument showing one of the disk flywheels and also shows the wiring diagram for a group of flywheels. Each disk flywheel (a) has a projection (b) on its periphery which engages with a stop (c) on the body of the instrument. This stop also serves as an electrical contact. The flywheel projection is held against this stop by a spring (d) as shown in Fig. 3. The projection on the flywheel is made of hard

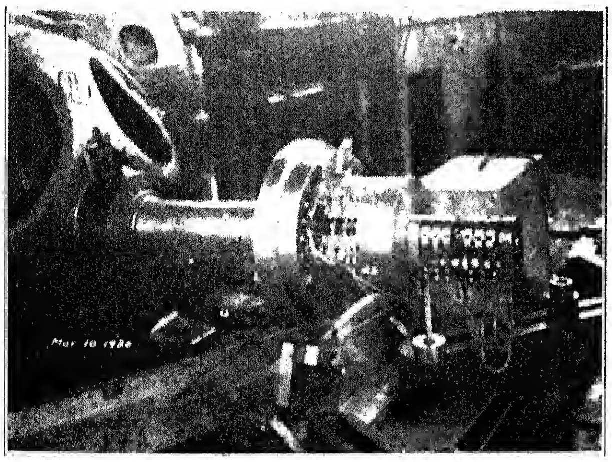

Fig. 2 Illustration of the Instrument

rubber with a brass insert for a contact, so that current is carried through the spring, brass insert, and stop, being entirely insulated from the flywheel disk.

When the instrument is accelerated in a clockwise direction, the inertia reaction of the flywheel will tend to open the contact, but the spring will hold the contact closed until the acceleration force exceeds the spring force. As soon as this point is reached, the contacts will start to separate thus breaking the circuit and recording the time at which the acceleration reaches a value corresponding to the spring setting. By using several flywheels with different spring settings an acceleration-time curve can be plotted.

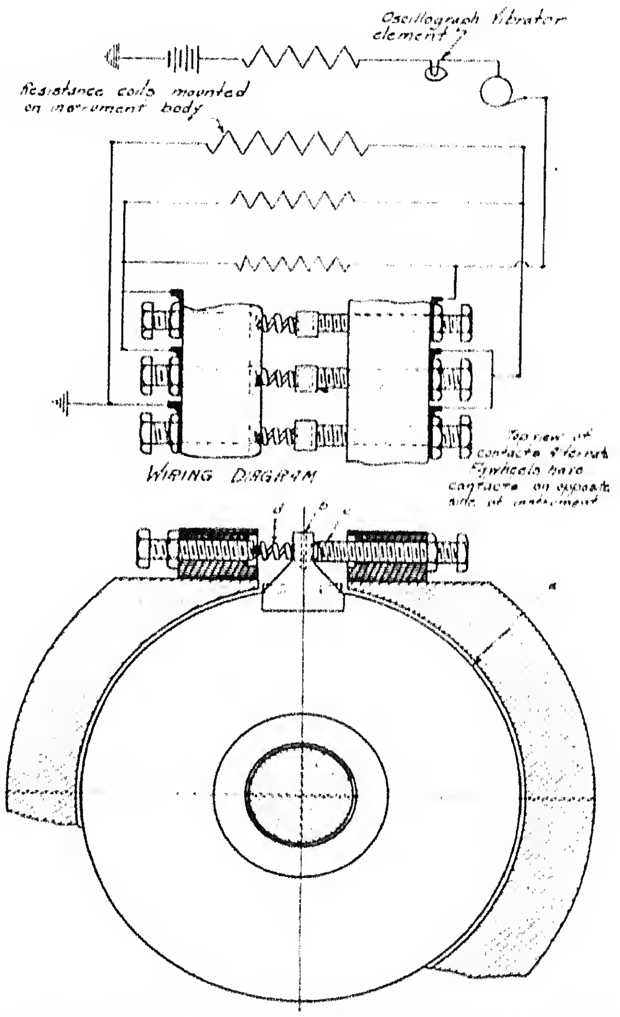

Fig. 3 Cross-Section Showing Disk Flywheel and Contact

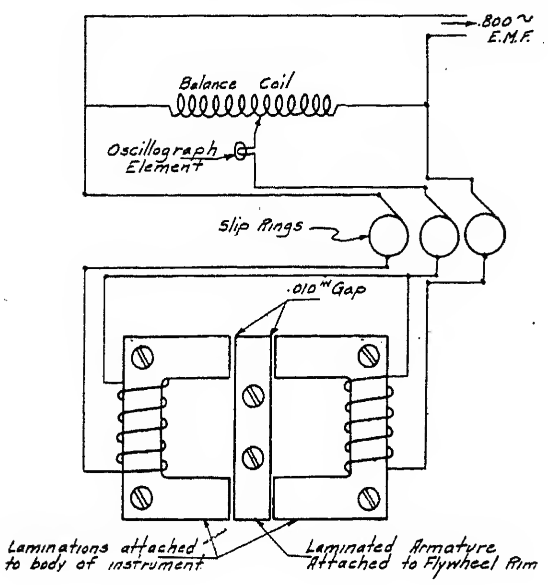
This shows a disk flywheel and its contact. The time at which the contact opens shows when the acceleration reaches a certain value. The instrument includes eight of these flywheels. The wiring diagram shows the connection for recording the action of several contacts with one oscillograph vibrator element.

It is evident that at the instant when the contact pressure becomes zero, the contacts will start to separate very slowly at first and then more rapidly. If an appreciable separation of the contacts is required to break the circuit, a considerable time lag will be introduced. Fig. 5 shows the calculated rate of separation of contacts. It is evident that if a record of the instant

when the pressure becomes zero, can be obtained, the instrument is accurate, but if a separation of one 1/1000 of an inch is required, a considerable error is introduced. A resistance is connected across the contact so that opening the contact will merely produce a slight decrease in current and by using a small current



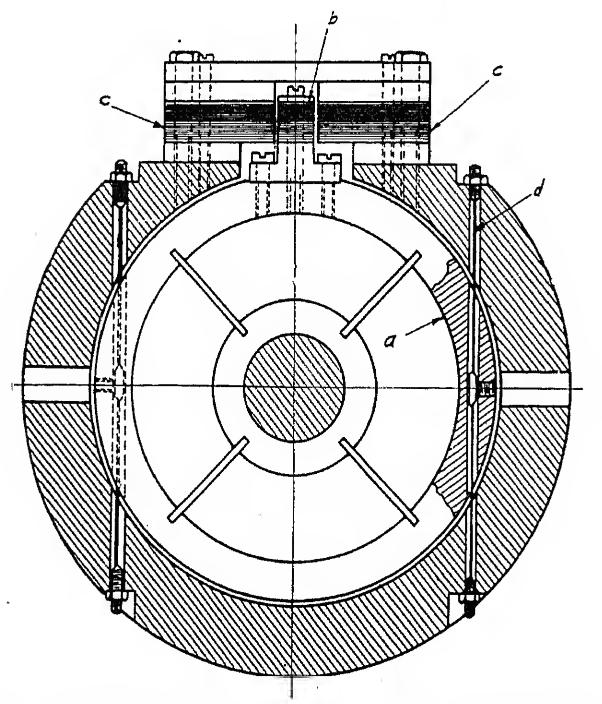


Fig. 4—Cross-Section Showing Magnetic Accelerometer

The instrument combines two independent devices for measuring acceleration. This is a cross-section showing the device which gives a continuous record of the acceleration. The wiring diagram is shown above.

and low voltage, and making the circuit as nearly non-inductive as possible, the contact separation required is reduced to a minimum. As described later, a calibration test was made which showed that in this circuit a change in the current can be observed almost at the instant when the contact pressure becomes zero.

Eight of these flywheels are mounted on the instrument shaft. Each flywheel is 5¼ in. in diameter and ⅜ in. thick at the hub, so that the axial space required is only three inch. The flywheels are connected in groups as shown in the wiring diagram (Fig. 3). In this way, several contacts are connected in series, each contact being shunted by a resistance. When any contact opens, there will be a certain decrease in the current. The values of resistance are chosen such that if the contacts open in the normal order, the steps in the current record will be approximately equal, but if they open in any other order, the steps will be unequal and the contact which opens can be determined from the value of resistance shunting the contact. In this way, a group of flywheels requires only one slip-ring and one oscillograph vibrator element.

In this device there is considerable time lag in the closing of the contacts and severe chattering after they

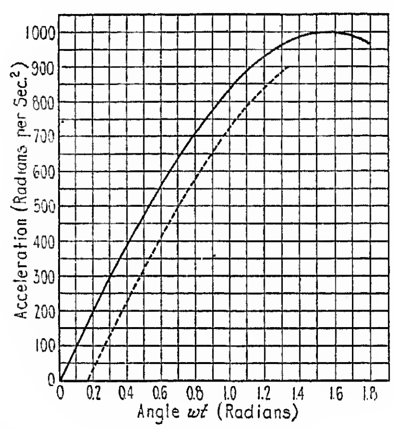

Fig. 5—Calculated Opening of Contacts

Full line shows the assumed sine-wave acceleration.
The dotted line shows the acceleration that would be recorded if a contact separation of 0.0001 in. were required to give a perceptible change in current. Actual tests showed a negligible time lag indicating that for the circuit used, the contact separation required to give a perceptible change in current was very much less than 0.0001 in.

close so that the record is of no value after the first torque cycle, but in a short circuit the main point of interest is the first torque cycle, so that for this purpose this instrument is very satisfactory.

The device which gives a continuous record of the torque consists of a flywheel rim mounted from a rigid hub with spokes which are flexible in a tangential direction. Then when the instrument is given an angular acceleration, the inertia reaction of the flywheel rim will deflect the spokes producing a relative tangential movement between the flywheel rim and body of the instrument. A magnetic device measures this relative movement which is proportional to the acceleration. Fig. 4 is a cross-section of the instrument showing this device for giving a continuous record of the acceleration. The flywheel rim (a) carries a laminated armature (b). Two sets of U-shaped laminations (c) are attached to the body of the instrument. Any relative tangential movement between the flywheel rim and

body of the instrument will increase one air-gap and decrease the other. Each set of U-shaped laminations carries a coil. The two coils are connected in a bridge circuit with a balance coil and oscillograph vibrator element as shown in the wiring diagram (Fig. 4). An 800-cycle e. m. f. is impressed across the coils. The balance coil can be adjusted to give approximately zero current for the neutral position of the armature.

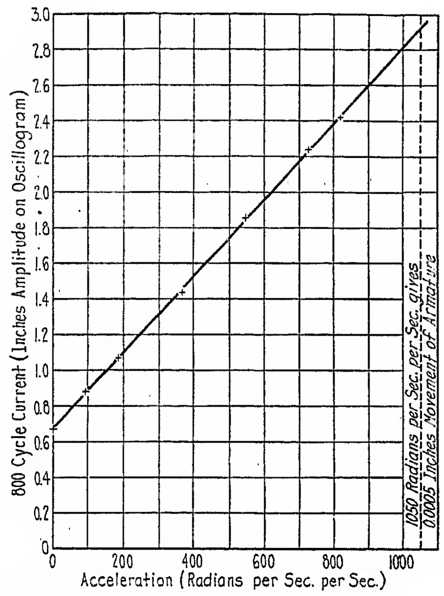

Fig. 6—Calibration of Magnetic Accelerometer

Then any movement of the armature will decrease the inductance of one coil and increase that of the other, causing a current to flow in the oscillograph element. With negligible resistance, saturation, and leakage flux,

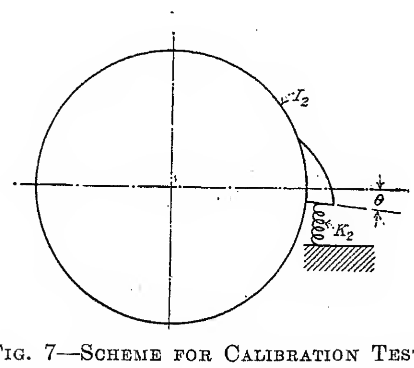

Fig. 7—Scheme for Calibration Test

The instrument rotates at a known velocity and a projection on the flange strikes the spring "K_2" at $\theta = O$.

the oscillograph current will be proportional to the movement of the armature. For the oscillograms shown in Fig. 9, the only attempt to balance the resistance was by constructing the resistances approximately equal. To reduce the initial current further, the resistance and reactance should be balanced separately.

In an ideal instrument, the motion of the flywheel rim should be exactly the same as the motion of the body of the instrument so that the acceleration of the flywheel rim will be the acceleration which it is desired to measure. This would require the measurement of force without permitting relative movement. Practi-

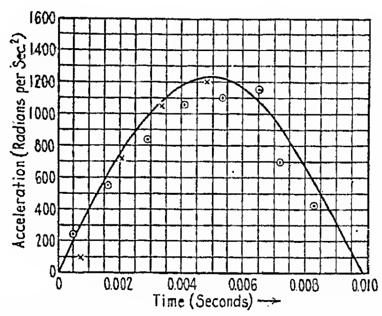

Fig. 8—Results of Calibration Test of Accelerometer

Points indicated by "x" are the points recorded by the disk flywheel contacts

cally, it is sufficient to have the motion of the flywheel rim substantially the same as the motion of the instrument. The error corresponding to a given relative movement is discussed in Appendix I.

In Appendix I, it is shown that to obtain a given accuracy a certain natural frequency of the flywheel is required, and for a given natural frequency and acceleration, the relative movement between the flywheel rim and the body of the instrument is fixed. If the error is to be small, the relative movement allowable is very

D—Field current
E—Current in short-circuited phase

small. In this instrument, the natural frequency of the flywheel is 400 cycles per sec. so that for an acceleration of 1000 rad./sec.² which is a fairly high value of acceleration, the corresponding relative movement between

flywheel rim and instrument body is only one-half mil.

Since this one-half mil of relative movement is between two parts rotating at high velocity and subject to severe vibrations at the instant of short circuit, very careful design is required to insure an accurate measurement. The instrument as constructed gives a 2-in. amplitude on the oscillogram for an armature motion of ½ mil, or a magnification of 4000 times. This gives a very satisfactory method of measuring the acceleration of the rim since the relative movement is so small that the motion of the flywheel rim is practically the same as the motion of the shaft.

This ½ mil of allowable movement does not mean that the absolute position of the flywheel rim must be located with any such accuracy. It does require however, that there be no relative movement permitted between the flywheel rim and body of the instrument except the elastic tangential movement of the flywheel rim which is proportional to the acceleration. To accomplish this, the flywheel rim is carried on flexible spokes so that the flywheel and body of the instrument behave as one piece of metal having the proper flexibility to permit a slight relative tangential movement, but with sufficient rigidity in other directions so that all other relative movements are negligible. The magnetic instrument must then measure minute relative tangential movement with accuracy. To accomplish this, the air-gaps are set as nearly alike as possible and the final balance obtained with the balance coil adjustment. Then a very slight movement of the armature can give a very large oscillograph deflection.

A slight torsional vibration of the flywheel rim will sometimes occur, but with the high natural frequency of the flywheel (400 cycles) this can readily be distinguished from other effects. Serious trouble might occur if there was a tooth pulsation or other disturbance having a frequency the same as the natural frequency of the flywheel. For this reason, it is desirable to be able to change the natural frequency of the instrument. It is also desirable to have a means of changing the sensitivity of the instrument. Both of these objects are accomplished by the auxiliary springs (*d* in Fig. 4), which give additional stiffness to the flywheel system. Each spring is merely a piece of piano wire stretched between two parts of the instrument body and with its midpoint attached to the flywheel rim. It is so arranged that the size of wire can be readily changed. For the small movement required, this gives the stiffness required in a very light spring.

The amplitude of the current recorded by the oscillograph is a measure of the movement of the armature from its neutral position. If this current is adjusted to be zero in the neutral position, a movement in either direction will produce an increase in the amplitude of the recorded current, but since the direction of the first acceleration of a short circuit is known, this is satisfactory. With negligible resistance, saturation, and leakage flux, the amplitude of the current recorded should be proportional to the movement of the armature. The instrument used can be set to give a slight initial deflection and a straight line characteristic in one direction, but not quite a straight line characteristic in the reverse direction. In this case, the main point of interest is the first torque peak, so that this adjustment was used. Fig. 6, shows a calibration curve for the instrument. The magnification can be increased by increasing the voltage applied to the instrument.

Method of Calibrating the Instruments

The moment of inertia of each flywheel can easily be determined so that the torque corresponding to a given acceleration can be calculated. To calibrate the disk flywheel springs, a torque is applied to the flywheel rim using a spring balance. The torque is gradually increased until the contact opens as shown by watching the deflection in the oscillograph. Each spring can then be adjusted to give the desired value of torque required to open the contact.

In practise, the springs are adjusted roughly to cover the desired range and the torque required to open each contact measured and recorded as the calibration for that contact.

To calibrate the instrument which gives a continuous record, a known torque is applied by hanging scale weights from the flywheel rim and measuring the corresponding deflection in the oscillograph. By doing this for several values of torque, an acceleration deflection curve can be plotted. This calibration curve is shown in Fig. 6. The method of calibration is very simple, so that if desired it can be checked before and after a test to be sure that nothing is out of adjustment.

By calibrating the instrument in this way, the oscillograph and acceleration measuring instrument are calibrated as a unit so that all errors are eliminated except those due to the difference between rotating and stationary conditions. Two of these errors which must be considered are the variation in contact drop at the slip-rings and any e. m. f. which might be induced by stray fields at the instant of short circuit. The effect of a slight change in contact drop is negligible since the reactance of the circuit is large compared to the resistance, so that a change in resistance will result in a change in phase angle, but only a very slight change in impedance.

Any currents induced by stray fields will have a low frequency compared to the 800-cycle e. m. f. supplied to the instrument, so that an induced current will merely shift the zero line and not affect the amplitude of the 800-cycle record so that an induced current will not give an appreciable error. There is usually considerable lateral vibration at the instant of short circuit, but this does not produce angular acceleration in an accurately balanced flywheel.

As a check on the operation of the instrument in actually recording pulsating acceleration, a calibration

test was made in which a sine-wave acceleration of known frequency and magnitude was imparted to the instrument by rotating the instrument and allowing a spring to engage with a projection on the periphery of the instrument. This method is discussed in Appendix II. Fig. 8 shows the agreement between the calculated acceleration and the acceleration as measured by the instrument. The agreement between the records was considered very close for measurements of this kind.

Closing the Short Circuit

The torque developed by a short circuit varies with the point of the voltage wave at which the short circuit occurs. In order to measure the maximum possible torque, it is necessary to close the circuit at the proper point of the voltage wave. To accomplish this, a switch is arranged to be tripped at a given position of the rotor. The switch is designed to close quickly (1/100 of a sec.) so that a small percentage of variation in the time required for the switch to close will give only a very small error in the time at which the switch closes. The position of the rotor at which the switch is tripped is adjustable. In making a test, one short circuit must be made with a known setting of the tripping mechanism. The point at which the switch is closed is noted on the oscillogram and the tripping device set ahead or back the required number of degrees to close the switch at the desired point of the voltage wave.

The switch shown in Fig. 1 was improvised using an ordinary knife switch. It is closed by very heavy springs and has a rubber bumper to absorb the shock at closing. The tripping device consists of a projection on the flange of the shaft coupling which engages with a very light phosphor bronze dog. This phosphor bronze dog can be moved in an arc of a circle to engage at the desired position of the rotor. This arc is graduated in degrees to facilitate setting the dog. This device can be seen at the bottom of Figs. 1 and 2. The dog is made as light as possible and is connected to the catch of the switch by a piece of small piano wire. These parts are very light, for if heavy, they would cause a serious jar of the instrument at the instant of short circuit which might destroy the accuracy of the record. A certain amount of flexibility is also essential to prevent breaking the parts due to the high speed at which they engage.

This device can be depended upon to close the circuit with less than 10 deg. variation from the desired position of the voltage wave, which is less than one-half thousandth of a second error. Prior to closing the short circuit, a piece of small fuse wire holds the phosphor bronze dog sidewise in a position where it will not engage with the rotating projection. A hand operated switch is used to start the oscillograph. This switch also connects 110-volts, d-c. power, directly across this small fuse wire, blowing the fuse and releasing the dog. Then as soon as the rotor reaches the proper position, the main switch will be tripped closing the circuit at the desired point of the voltage wave. In this way, closing the circuit and taking the record are controlled automatically so that all the operator has to do to take a record is to close a small instrument switch.

Conclusion

Some tests have been made and these have shown remarkable agreement between the two separate methods of recording the torque. This fact, together with the calibration test, shows quite conclusively that the instrument is very accurate. Fig. 9 shows an oscillogram taken of a short circuit, the circuit being closed slightly off zero voltage. The armature current and acceleration of the rotor are recorded simultaneously. Fig. 10 shows the torque developed by a single-phase short circuit. A discussion of the results of the tests will be given in a later paper.

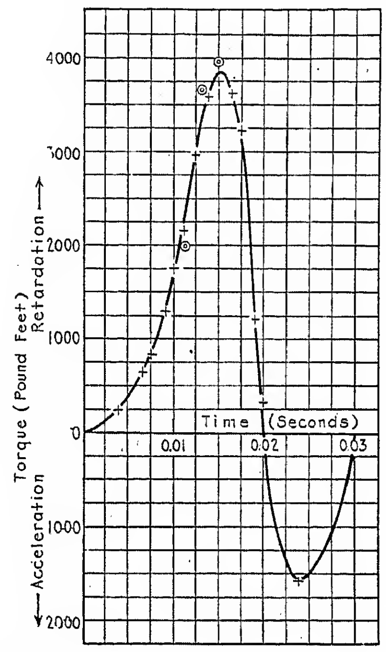

Fig. 10—Torque—Time-Curve for a Single-Phase Short Circuit

Points shown by dot and circle (⊙) show acceleration as recorded by opening of contacts

Points indicated by cross "+" show acceleration recorded by magnetic instrument (peaks of 800-cycle current)

The means of measurement used are old devices, merely redesigned and combined for the particular purpose desired. The idea of measuring linear acceleration by a mass held against a contact by a spring has been used frequently, and its adaptation to angular acceleration was suggested by Mr. Soderberg several years ago.

The idea of measuring small movements by the variation in inductance resulting from the change in air-gap has been used in many instruments and experiments. The magnetic device used for measuring the movement of the flywheel rim in this instrument was copied from an instrument built four years ago by Mr. J. G. Ritter, for measuring railway track stresses.

The author is indebted to many men in the Westing-

house organization for valuable suggestions and ideas used in designing the instrument and wishes to take this opportunity to thank them, particularly Mr. C. R. Soderberg, Mr. J. G. Ritter, Mr. J. W. Legg, and Mr. C. J. Fechheimer.

Appendix I

In measuring the acceleration of a rotor by measuring the force required to drive a small flywheel, the flywheel should have exactly the same motion as the shaft, but since any known device for recording the instantaneous force allows a slight relative movement of the parts, the error due to this relative movement between flywheel and shaft must be considered.

Let

α_F = Acceleration of flywheel in rad./sec.^{2}

α_R = Acceleration of rotor of machine in rad./sec.^{2}

δ = Relative angular movement between rotor and flywheel.

K = Spring constant of device driving flywheel (pound-inches per radian).

I = Moment of inertia of flywheel.

$\alpha_R = \alpha_F$ + relative acceleration between rotor and flywheel.

$$\alpha_R = \alpha_F + \frac{d^2\,\delta}{d\,t^2} \tag{1}$$

But

$$K\,\delta = I\,\alpha_F \tag{2}$$

or

$$\delta = \frac{I}{K}\,\alpha_F$$

Then assume that

$$\alpha_R = A \sin \omega\, t$$

Then

$$\alpha_F + \frac{I}{K}\,\frac{d^2\,\alpha_F}{d\,t^2} = A \sin \omega\, t$$

or

$$\frac{d^2\,\alpha_F}{d\,t^2} + \omega_c^2\,\alpha_F = \omega_c^2 A \sin \omega\, t$$

where

$$\omega_c = \sqrt{\frac{K}{I}}$$

This gives

$$\alpha_F = C_1 \cos \omega_c\, t + C_2 \sin \omega_c\, t + \frac{1}{1-\left(\frac{\omega}{\omega_c}\right)^2} A \sin \omega\, t \tag{4}$$

In this solution $\left[A \frac{1}{1-\left(\frac{\omega}{\omega_c}\right)^2} \sin \omega\, t \right]$ represents the steady state condition and $C_1 \cos \omega_c\, t + C_2 \sin \omega_c\, t$ represents the transient condition which will be damped out by friction. Thus in the steady state condition, α_F, which is the acceleration measured, is equal to the actual acceleration of the rotor (α_R) multiplied by the factor $\left[\frac{1}{1-\left(\frac{\omega}{\omega_c}\right)^2} \right]$. So that $\left[\frac{1}{1-\left(\frac{\omega}{\omega_c}\right)^2} \right]$ represents a fundamental error in this method of measurement. The smaller the value of $\frac{\omega}{\omega_c}$ can be made, the smaller will be the error. If $\frac{\omega}{\omega_c} = \frac{1}{4}$, the measured value will be 6½ per cent high.

Any mechanical device for continuously recording force can be regarded as having a certain flexibility and as measuring the deflection due to the action of a force on this flexibility. Then if the value of ω_c is fixed by the allowable error, and if a given acceleration must be measured, the corresponding relative movement between rotor and instrument flywheel is fixed.

For, from equation (2)

$$K\,\delta = I\,\alpha_F$$

or

$$\frac{K}{I} = \frac{\alpha_F}{\delta}$$

or

$$\omega_c = \sqrt{\frac{\alpha_F}{\delta}} \tag{4}$$

or

$$\delta = \frac{\alpha_F}{\omega_c^2} \tag{5}$$

In designing this instrument, a natural frequency of 400 was used and the instrument designed to measure an acceleration of 1000 rad./sec.^{2} with accuracy.

Using equation (5)

$$\delta = \frac{1000}{(400 \times 2\,\pi)^2} = 0.00016 \text{ radian}$$

The radius of the measuring device was approximately 3 in. so that 0.00026 multiplied by 3 = 0.00048 in., which the instrument must be able to measure with accuracy. This is a very small movement to measure accurately but it cannot be increased without increasing the size of the instrument or the fundamental error considered above.

The factor of error $\frac{1}{1-\left(\frac{\omega}{\omega_c}\right)^2}$ derived above applies only to measuring a steady sinusoidal acceleration. For measuring irregular accelerations, the factor will not be exactly the same, but the error will still be a

function of the ratio of the acceleration frequency to the natural frequency of the instrument and the factor derived above will give a good approximation to the magnitude of the error to be expected.

Appendix II

As has been mentioned, the method used to calibrate the instrument was to rotate it at a known speed, but running free, and let a projection on the flange strike a very light, stiff spring. To rotate the instrument, it is mounted in a lathe but instead of driving it by a lathe dog a string is used having just sufficient strength to overcome friction. Then when the projection on the flange strikes the spring, the string breaks, allowing the instrument to move under the influence of the spring force and its own inertia. As shown below, this imparts a sinusoidal acceleration to the instrument.

Assumptions and symbols:
Friction negligible
Mass of spring negligible
Initial velocity $= \omega_0$
θ = Angular position of instrument
I_2 = Moment of inertia of instrument
K_2 = Spring constant (inch pounds per radian) of the spring used to stop the instrument
t = time/
At $t = 0$ the projection of the flange of the instrument strikes the spring.

Then

$$I_2 \frac{d^2 \theta}{d t^2} + K_2 \theta = 0 \tag{5}$$

$$\theta = A \cos \sqrt{\frac{K_2}{I_2}}\, t + B \sin \sqrt{\frac{K_2}{I_2}}\, t \tag{6}$$

Where A and B are constants of integration.

At $t = 0$, $\frac{d^2 \theta}{d t^2} = 0$ so that $A = 0$

At $t = 0$, $\frac{d \theta}{d t} = \omega_0$

This gives

$$\omega_0 = B \sqrt{\frac{K_2}{I_2}}$$

or

$$B = \omega_0 \sqrt{\frac{I_2}{K_2}}$$

Then the acceleration of the instrument is

$$\frac{d^2 \theta}{d t^2} = \omega_0 \sqrt{\frac{K_2}{I_2}} \sin \sqrt{\frac{K_2}{I_2}}\, t \tag{7}$$

This equation holds only during the time when the spring is in contact with the projection on the instrument, which is from $t = 0$ to $\sqrt{\frac{K_2}{I_2}}\, t = \pi$. Or in other words the sinusoidal acceleration continues for only one-half a cycle.

From this it is evident that the acceleration imparted to the instrument in this manner has a frequency determined by the inertia of the instrument and the stiffness of the spring used. This frequency used for checking the instrument should be approximately the same as the frequency which the instrument is to measure. For any given frequency the magnitude of the acceleration is determined by the initial speed of rotation.

A piece of piano wire in tension was used for the spring. This gave a very light spring combined with the required high spring constant.

Fig. 7 shows the schematic arrangement for the test. Fig. 8 shows a plot of the results of this test as compared to the calculated acceleration. The agreement between calculated and test results is within the accuracy with which the oscillogram could be read.

Reduction of Transformer Exciting Current to Sine-Wave Basis

BY G. CAMILLI[1]

Associate, A. I. E. E.

Synopsis.—*As a sequel to an earlier investigation and development of a method for the reduction of core-loss measurement to sine-wave basis, this paper describes two methods developed for the reduction of exciting current to sine-wave basis.*

The first method consists of making two measurements at wave shapes as widely different as possible, setting the voltage in each case by means of the flux voltmeter. The current corresponding to sine-wave voltage is obtained by extrapolation from the observed values of currents and form factors. Although the method might be considered to some extent empirical, it is found to yield an accuracy within one per cent even under extremely unfavorable conditions.

The second method utilizes as before the flux voltmeter for setting the voltage but uses a "crest ammeter" (developed for this purpose) for reading the instantaneous maximum values of the corresponding currents. Measurements are made at 100 per cent, 86.6 per cent and 50 per cent voltages. These data determine the fundamental, third and fifth harmonics of the exciting current corresponding to sine-wave voltage and hence the exciting current itself, because these harmonics are the only important components in determining the effective value of the exciting current.

Theory of the crest ammeter is given, and its applicability (in conjunction with the flux voltmeter) to the determination of d-c. saturation curves by means of a-c. tests in magnetic investigations is indicated.

INTRODUCTION

It is well known that the no-load losses, that is, the iron loss and exciting current, of a transformer are dependent upon the wave shape of the excitation voltage. While the Institute rules provide that the efficiency rating of transformers must be based on sine-wave operation, it is known how difficult it is to obtain sine-wave voltage on a commercial scale for the testing of transformers. Some scheme that will reduce core loss and exciting current tests to a sine-wave basis is therefore a necessity, much more important now than it was some years ago, due primarily to the increased kv-a. capacity of transformers. This may be seen better by considering the fact that while the kv-a. capacity of transformer units has steadily increased, the kv-a. capacity of generating units used for testing them has not increased proportionately, and therefore the core-loss load on generators in testing departments is a much larger percentage of the generator capacity than was formerly the case, with the consequence that wave distortion is much larger.

In a paper presented to the Institute a year ago,[2] the writer described a new and accurate method for the reduction of transformer core-loss measurements to sine-wave basis, utilizing a flux voltmeter developed for that purpose by the writer. The accuracy of the meter and method was checked and endorsed by the Bureau of Standards,[3] and it is understood that a number of research laboratories besides the Bureau of Standards have already adopted the scheme.

Since the successful solution of the problem of the reduction of the core-loss component of the no-load loss measurements to sine-wave basis, the writer studied the problem of the reduction of the exciting current component of the no-load measurement to sine-wave basis.

Two different methods were developed for the reduction of exciting current measurements to sine-wave basis, as follows:

Method I. In core-loss measurements, setting the voltage by the flux voltmeter,[2] the maximum flux density and therefore the maximum value of the exciting current are those corresponding to sine-wave voltage regardless of the wave shape of the test voltage. The effective value of the exciting current, however, will be variable with the wave shape of the test voltage.

To apply a wave-shape correction to the observed effective value of the exciting current, it would be necessary to have some applicable measure of wave distortion. Now, form factor is one kind of a measure of wave-shape distortion and is given in a simple way by the flux voltmeter, and therefore it occurred to the writer that some simple relation might exist between form factor and effective value of the exciting current. Thus, indicating the values of form factors by F, and the values of the exciting current by Y, we may write as a general equation between these two variables:

$$Y = a + b\,F + c\,F^2 + d\,F^3 + \ldots + f\,F^n$$

Equations of this type are frequently used in engineering problems and are very convenient whenever it is found that the terms above the first or second power are negligible. Tests were therefore made to determine what approximation could be used, and it was found that all terms above the first power could safely be ignored; that is, the exciting current corresponding to sine-wave form factor may be extrapolated as a straight line function of the form factor.

$$\text{form factor} = 1.11 \times \frac{\text{A-c. Voltmeter reading}}{\text{Flux Voltmeter reading}}$$

In a dozen test cases, the error was not more than 1 per

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Pittsfield, Mass., May 25-28, 1927.

cent. With no correction applied, the error would have been up to 20 per cent, making the exciting current that much too high.

Method II. In the foregoing, it was mentioned that in using the flux voltmeter the maximum flux density and therefore the maximum value of the exciting current are determined. Consequently, if a transformer is tested at various voltages, observing the voltage on a flux voltmeter and the current on a crest ammeter (to be described below), points of the *B-H* curve of the transformer are obtained. Having the *B-H* curve, the effective current corresponding to sine-wave voltage can be calculated.

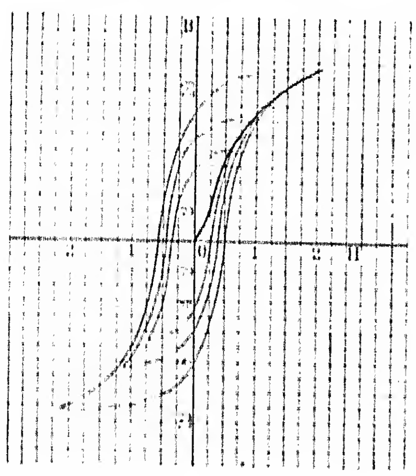

Fig. 1—B-H Curve by Means of the Crest Ammeter

It may appear at first as though this would be a very laborious method, but it is extremely simple. Three readings, *viz.*: one taken at full voltage, one at 86.6 per cent voltage, and one at 50 per cent voltage (by the flux voltmeter), enable us to determine the fundamental, third-harmonic and fifth-harmonic components of the exciting current corresponding to sine-wave voltage, and, since these are the only important harmonics, their resultant gives the total effective current for sine-wave voltage. In this method, the higher harmonics are not entirely neglected, because they appear partially in the first, third, and fifth harmonics by modifying their values. For greater accuracy, a larger number of readings and correspondingly larger number of harmonics may be included, but this appears to be hardly necessary. When a large number of points is taken, it becomes unnecessary to bring in the harmonics at all, as the r. m. s. value of the exciting current for sine-wave voltage may be calculated by taking points equi-distant in time. The harmonic idea is useful in obtaining a greater accuracy from a few points than would otherwise be possible.

The *B-H* curve obtained by observing simultaneous values of B_{max} and I_{max} will be recognized to be the locus of the tips of the symmetrical hysteresis loops for various densities, as shown by the heavy line in Fig. 1, and therefore, intermediate between the ascending and descending branches of the loop for maximum (normal density). The error which this introduces into the exciting current calculation is that of ignoring the power component of exciting current corresponding to hysteresis loss, which ordinarily may be neglected in the value of the exciting current. The exciting current thus obtained lacks, therefore, the hysteresis loss component; and therefore, if desired, this component may be added to it as determined by the core-loss test. This refinement, however, appears to be hardly necessary, because tests show that exciting currents obtained by this method err on the safe side; that is, results obtained by the three-point method are a little larger than those obtained by direct sine-wave tests.

Crest Ammeter. The principle underlying the functioning of the crest ammeter is as follows: In an air-core reactor, the maximum flux density, and consequently the maximum value of the current, is proportional to the arithmetical average value of the reactive voltage across it.

The proof of the theorem may be seen in the following way: Let e be the instantaneous voltage drop in the inductance of the circuit and i the current through it. By elementary theory:

$$e = L \frac{d\,i}{d\,t} \qquad (1)$$

where L is the inductance of the circuit, a constant. From (1) it follows that

$$e\,d\,t = L\,d\,i \qquad (2)$$

$$e \int d\,t = L \int d\,i \qquad (3)$$

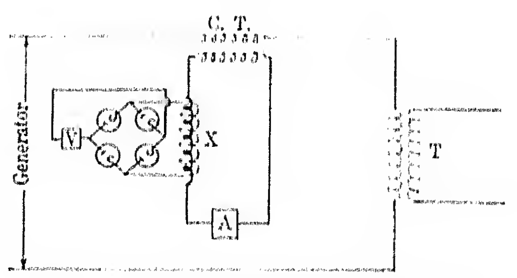

Fig. 2—Use of the Crest Ammeter

$$\int_{t1}^{t2} e\,d\,t = L \int_{I\ \text{lowest value}}^{I\ \text{highest value}} d\,i \qquad (4)$$

But

$$\int_{t1}^{t2} e\,d\,t = \text{area of half-cycle} = e_{avg}\,(t_2 - t_1) \qquad (5)$$

And

$$L \int_{I\ \text{lowest value}}^{I\ \text{highest value}} d\,i = L \text{ times maximum change in current.} \qquad (6)$$

Therefore, substituting (5) and (6) in (4),

$e_{avg}\ (t_2 - t_1) = L$ times the maximum change in the current.

Since the maximum change in current is twice the maximum value of the current, e_{avg} is proportional to the maximum value of the current.

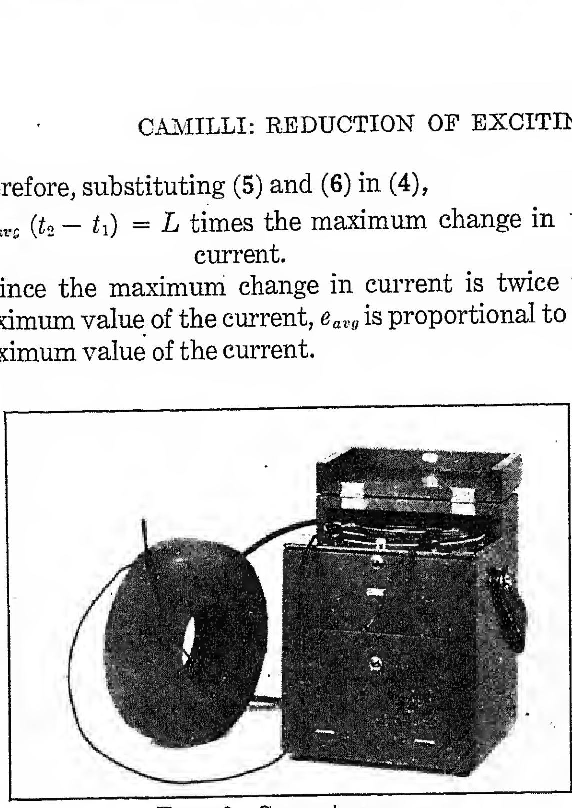

FIG. 3—CREST-AMMETER

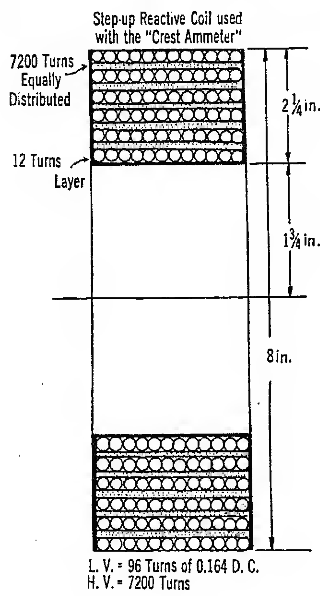

FIG. 4

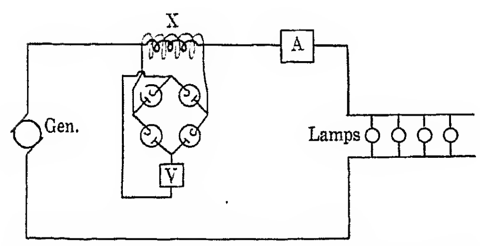

FIG. 5—CALIBRATION OF THE CREST AMMETER

The arithmetical average voltage drop across the reactor can be measured by means of the flux voltmeter, so that the flux voltmeter shunted by a reactor becomes a crest ammeter.

The scheme of the apparatus and its connection to the circuit may be seen from Fig. 2 in which T is the transformer under test, $C\ T$ is an ordinary current transformer, A is an ordinary a-c. ammeter, X is the air-core reactor, and V is a flux voltmeter.

Fig. 3 shows a view of the outfit. Fig. 4 shows the details of the air-core reactor.

Fig. 5 shows how the calibration of the crest ammeter may be made. A sine-wave generator is used for this purpose connected to a non-inductive load.

The calibration is made by comparing the readings in the voltmeter V and the ammeter A. The calibration of this instrument corrects also for the slight error introduced into the readings by the fact that the shunt reactor cannot be of zero power factor required theoretically, but must have some little resistance.

B-H CURVES BY A-C. TESTS USING CREST AMMETER AND FLUX VOLTMETER

Usual methods for obtaining the *B-H* curve of a specimen require the use of direct current and laboratory instruments and methods unsuited for commercial test. It will be evident from the foregoing discussion of the crest ammeter that *B-H* curves (not hysteresis loops) can be obtained by very simple and convenient commercial a-c. tests by men with no particular laboratory training, using the crest ammeter and the flux voltmeter, two sturdy portable meters.

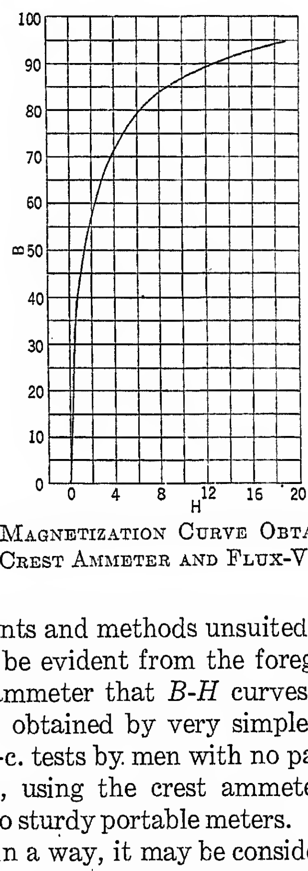

FIG. 6—D-C. MAGNETIZATION CURVE OBTAINED BY THE USE OF THE CREST AMMETER AND FLUX-VOLTMETER

Although, in a way, it may be considered a disadvantage that hysteresis loops cannot be obtained by these simple tests, on the other hand troubles from residuals, and need for proper demagnetization, etc., attendant on d-c. tests, are entirely avoided in the a-c. tests.

Fig. 6 shows the magnetization curve of a 2000-kv-a. transformer obtained by this method.

TEST DATA

Method I. In the tests tabulated below a given transformer was tested on two or more generators of widely different wave shapes, or on the same generator but connected to different voltage diagram, so as to obtain

the exciting current for at least two different form factors.

The values so obtained were plotted in rectangular coordinates, and by extrapolation the exciting current for a sine-wave form factor was obtained.

As a check, the same transformer was tested with the best generator available and the two results were compared and are tabulated below. (See Table I.)

The data in Table II are taken from the records of an earlier core-loss investigation[4] and illustrate the fact that the exciting current is a function of the form factor and increases with it.

Method II. In using this method, a given transformer is tested at three different voltages: *viz.*, 50 per cent, 86.6 per cent, and 100 per cent (set by the flux voltmeter), and value of the current corresponding to each voltage is measured by the crest ammeter. With the help of these data the effective value of the exciting current is calculated. (See Appendix B.)

As a check to the value of the current obtained by this method, six transformers were tested also with the best wave shape available, and the results are compared below.

4. G. Camilli, *A Flux Voltmeter for Magnetic Tests*, JOURNAL A. I. E. E., Oct. 1926.

ACKNOWLEDGMENT

The writer is indebted to Mr. Boyajian for his personal interest and consultation in this investigation.

APPENDIX A

In using Method I, instead of graphical extrapolation, calculation may be made by slide rule as follows:

Calling the value of current I_1 at form factor F_1 (for instance, the higher form factor), and I_2 at form factor F_2 (the smaller form factor), the value of exciting current I at sine wave may be expressed by:

$$I_{sine\ wave} = I_1 - \frac{(I_1 - I_2)\,(F_1 - 1.11)}{F_1 - F_2}$$

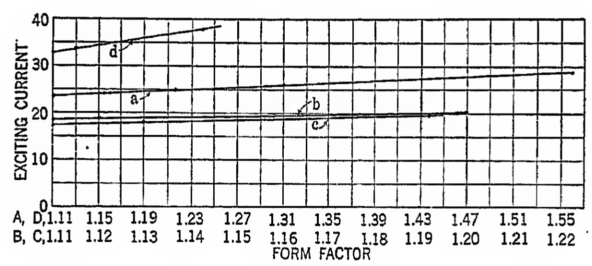

FIG. 7—METHOD NO. 1 FOR THE REDUCTION OF THE EXCITING CURRENT TO SINE-WAVE BASIS

APPENDIX B

In using Method II (the crest ammeter method), the effective value of the exciting current is found from the peak values of the exciting current corresponding to 50 per cent, 86.6 per cent, and 100 per cent rated voltage of the transformer. The following method gives in a simple way the fundamental, third and fifth harmonics by means of which it is possible to calculate the effective value of their resultant. Example:

Let A be the value of I_{max} corresponding to 100 per cent voltage.

Let B be the value of I_{max} corresponding to 50 per cent voltage.

Let C be the value of I_{max} corresponding to 86.6 per cent voltage.

Then

$$\text{3rd harmonic} = \frac{A - 2B}{3} = I_3$$

Item	Rating	Exciting current by crest ammeter	Exciting current by conventional method, a-c. ammeter	Exciting current at sine-wave voltage	Error of conventional method, per cent	Error of crest ammeter method, per cent
(1)	*H*-60-2000-*C*-73,000-2520	79	93	78.3	19	0.9
(2)	*H*-60-667-*C*-33,000-2300/4000 Y	7.97	8.9	8.03	11	0.85
(3)	*H*-60-3333-*C*-13,200 Y-2300/4000 *Y H* 480	61.8	65.1	61.5	6	0.5
(4)	*H*-60-2000-*C*-69,300-2400/4160 Y-*K D H*	47.7	48.0	47.3	1.4	0.8
(5)	*H*-60-2000-*C*-2300-23,000	23.3	23.5	23.5	0	0.85
(6)	*H*-60-4000-*C*-23,000-4200/7260 Y	16	17.8	16	10	0

$$\text{5th harmonic} = \frac{A - (I_3 + 1.15\,C)}{2} = I_5$$

$$\text{1st} = A - (I_3 + I_5) = I_1$$

From which

$$I_{\text{effective for sine wave}} = \sqrt{\frac{I_1^2 + I_3^2 + I_5^2}{2}}$$

Discussion

Aram Boyajian: For the benefit of those who are not intimately familiar with transformer problems I wish to say that the reduction of core loss and exciting current to a sine-wave basis is not quibbling over laboratory precision. The reduction of the core loss to a sine-wave basis involves wave-shape errors of from zero to 20 per cent, and the reduction of exciting current to a sine-wave basis involves errors of from zero to 50 per cent. The leading manufacturers of the country use methods to reduce core loss to sine-wave basis, and possibly some of them use methods to reduce the exciting current also to sine-wave basis. These methods greatly lessen but do not completely eliminate the possible errors mentioned, due to the fact that the bases of all the methods used in the past have been imperfect. Mr. Camilli therefore has undertaken to develop methods which will have a better basis and will be entirely reliable. I think he has succeeded surpassingly well.

K. K. Palueff: With the tests made by various manufacturers under different conditions, it is impossible to adjudge the comparative characteristics of different transformers, and it seems to me that the methods described by Mr. Camilli will give a very fine basis on which to decide whether the magnetizing current really is 2 per cent or 4 per cent.

I should like to take exception to Mr. Camilli's statement in the first paragraph of his paper wherein he says that the testing facilities, in regard to the capacity of the generators, are not increasing in proportion to the transformer kv-a. capacity. That isn't our case here in the General Electric Company. For the last five years, our testing capacity in generators has increased from 3000-kv-a. to 25,000-kv-a. units, and at the present time we are equipped to test the largest transformer we have yet built, or are going to build for several years to come, with a generator which will give very good agreement with that of the perfect sine-wave generator.

Research

Annual Report of the Committee on Research*

To the Board of Directors:

1. The Training of Research Workers

There is, perhaps no more important problem at this time than that of the training of research workers and engineers. The popular appreciation of research is increasing. This is good because the chief stimulus of research is a certain state of mind akin to, but more than, curiosity and inquisitiveness which without doubt can be developed in the proper atmosphere. It was a similar state of mind, a dissatisfaction, a desire to go where others had not gone and see what others had not seen that actuated our pioneer ancestors and resulted in America. It would thus seem that the right material should be available; but more than material and popular appreciation is required to create the necessary state of mind. Are our colleges doing their part? As was pointed out in the report of this Committee last year, indications are that they are not. As a gage on the research in electrical engineering at colleges, Dr. F. E. Terman, of Stanford University, has made a statistical study of research papers presented by college professors and their students. The following is quoted from his report which appeared in the April 22, 1927 of *Science:*

"The summary of this survey shows that the electrical engineering schools of our country produce about one-eighth of the electrical and radio research that is reported in the pages of the national engineering societies. This represents about eleven articles a year. Of these eleven articles coming from the colleges each year, approximately seven come from four universities. There is a total of several hundred. Apparently not over a dozen technical schools are making much effort, if any, in the way of research. Over half of the university research in electrical engineering is the work of eight men.

This is the situation, and it now remains to consider the consequences of this condition. University research in electrical engineering is primarily significant as an indication of the situation which exists today in the education of electrical engineers. The laboratories of the big electrical companies make technical progress assured even without university research, but the country's supply of technically trained young men can come only from the university."

These facts are disconcerting. In correcting this condition, it must be kept in mind that true research workers are more than mere readers of instruments and collectors of data and cannot be turned out mechanically.

It is not a mere matter of money and apparatus; atmosphere and inspiration are necessary. These must be supplied. There is, perhaps, something still to be done by the industry in further recognition of the research worker in a monetary way.

2. Active Research

This Committee serves as the Advisory Committee on Electrical Engineering to the National Research Council. At the request of that Council, the Committee on Research has been instrumental in establishing in the National Research Council, a Committee on Electrical Insulation. This has given work of a definite character to the Committee on Research and a small group of its members has been active in this connection.

The Committee on Insulation, largely made up of members of the Committee on Research, has already made two reports; the second of which is a comprehensive review of the literature and present information on the subject of dielectric absorption, and has suggested channels for further research in this field. As a result, a number of researches are now under way in different universities; one of these, in Johns Hopkins University, is of special interest on the present occasion, as it is being supported by a generous fund guaranteed by Engineering Foundation.

A third report of this Committee on Dielectric Strength of Solid and Liquid Dielectrics is being presented at this meeting.

Research on cable insulation, under the auspices of the N. E. L. A., is under way in several colleges. Part of this work Influence of Residual Air and Moisture on Impregnated Paper Insulation has already been presented to the Institute by Doctor Whitehead.

3. Stimulation of Research

All divisions of electrical engineering offer wide opportunity for experimental study, development, and research. It is the special duty of our Committee to encourage and stimulate research, to keep in touch with the results accomplished, and to see to it that the members of the Institute and others interested are informed.

To do this, the Committee asks its members to report on all matters of the following natures that come to their attention:

1. New experimental work about to be undertaken. Information assists in co-ordination and often prevents duplication.

2. Important results of completed research. Information is necessary for our annual report.

*Committee on Research:

W. A. Del Mar,	Harold Pender,	R. W. Sorensen.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

3. Suggestions of important problems for research. The Committee has frequent opportunities for suggesting promising problems for experimental attack.

4. Any method or occasion which suggests itself for obtaining important research papers for the Institute.

President Chesney has done much to stimulate research in his inspiring talks at our various Sections in the United States and Canada. While he has pointed out clearly the necessity of pure research and adequate support of our colleges, he has not let us forget that the work cannot go on by research alone. Combined with this research spirit of adventure, there must be the spirit of cooperation and willingness of standardization at the proper time. Strange as it may seem, research and standardization must go together if the maximum prosperity is to be attained. It is well, in closing, to place the engineer by quoting from President Chesney's Chicago talk:

"The electrical engineer's hopes and aspirations turn him to the future. His spirit is essentially the spirit of progress, and, while he reveres the accomplishments of the past in which figures of men were more conspicuous than events, the changing conditions of modern day civilization still leave him the embodiment of progress. Complacent satisfaction with things as they are has ever been foreign to his nature; he is constantly striving for improvement."

F. W. PEEK, Acting Chairman.

Discussion

F. C. Caldwell: There are two types of minds that are particularly adapted to the training for research,—on the one hand, the student who is distinctively scientific, who has the real research spirit, the desire to know, the scientific curiosity,—on the other hand, the inventor, the man who has ideas that seem, to him at least, to be inventions of importance.

The man of the first type is interested only moderately in the money side of his work. The man of the second type usually has in mind that financial return his invention will bring to him and often vastly over-estimates its money value.

Such a student needs to have impressed upon him the real situation with regard to invention and development, the problems and the difficulties involved and the value of team work in this connection. He may thus come to appreciate the advantage of working cooperatively in an organization rather than trying to play a lone hand.

The other student, the one who is of the scientific research type, wants to know that he will earn a good living, assuming a reasonable degree of success, and that he will not have to worry too much about the cost of living, if he trains himself for and devotes himself to research.

Recently one of the large electrical organizations sent us a curve showing the average salaries which the graduates of our institution were earning at various intervals after leaving college It was a very interesting curve, and quite encouraging. It showed that for a man who was satisfied with a comfortable living, that was a good organization to join; little prospect of making a fortune, but an opportunity to live a comfortable life.

It would be interesting if we could have such a curve for research workers. A curve like this, if it shows such an upward slope as I believe it will, should be very encouraging to would-be research workers.

Another point,—often when a university teacher does develop some research ability, he is taken out of teaching work and absorbed by industry. That is a real difficulty, but we certainly would not want to eliminate it. The loss of such men from education is a hard problem to solve. Perhaps there is no solution for it, until the time comes, if it ever does, when teachers will be paid salaries commensurate with those that the same men get in industry.

R. W. Sorensen: The educational problem in our engineering colleges up to the present time has been largely with undergraduate students whose college life is limited to four years. A few engineering colleges are extending their courses to five and in some instances to six years. This seems to indicate that in the near future there will be available in the colleges graduate students who will have the required preparation and time to do research work.

Just at present the scientists are ahead of the engineering students in their ability to raise finances for pure research work as compared to applied research work or engineering research work.

In those colleges with which I am acquainted a pure scientist research teacher may have one course to teach, and usually that is just a lecture course, or perhaps he has only a few research men with whom he holds conference regarding their research problems. Engineering teachers for the most part have to devote about half their time to teaching; some of them also have to devote a large share of time to administrative work to keep a department going, in addition to being expected to try to get in a bit of personal research work and at the same time inspire students' work of a research type.

In engineering as well as in pure science we must find a way to make available a large number of fellowships which capable men may make use of while doing research work and studying for a Ph. D. degree in engineering. At the present time the few available fellowships of this nature make it necessary for engineering students who are not members of fairly well-to-do families to find all kinds of outside work in order that a few dollars may be earned to keep soul and body together.

Another factor is, only a few of the industries of today have expressed a willingness to pay for increased engineering training beyond that required to obtain a Bachelor's degree. I think it can well be said the few who have been liberal in paying men who have been worthy of doing graduate work have found the increased pay a profitable investment. Another factor is that engineering research men have been directed toward commercial problems because of larger pay frequently given to commercial men.

If colleges are to undertake engineering research problems they must also give considerable attention to the study of patents, how to obtain them, and the ownership of patents resulting from research work in college laboratories. It is my opinion that for the best results, patents thus developed should be the property of the educational institution where the work is done, but the institution must, on the other hand, do as the industries have done, recognize patentable features resulting from research work as worthy of being the basis for financial compensation to the workers who make it possible to obtain patents. Inasmuch as educational institutions have limited funds available for taking out patents, industries, who after all will get the return by manufacturing the goods, must be very liberal in assisting the educational institutions in developing and patenting new devices.

In fact, the whole problem is intricate and requires a great deal of study, but that study is inevitable because our technical problems are reaching a state where they can be analyzed and extended further only by engineers who have a thorough understanding of modern physics and mathematics; that is, the engineering profession has become so thoroughly a language of physics and mathematics that four years of training is insufficient for the man who wishes to be in the forefront of technical progress. To make it possible for colleges to turn out such men the industries and colleges must work out a new plan for financing men qualified to do graduate work. The colleges must see to it that they admit to graduate work only men peculiarly fitted for it.

Some criticism has been made regarding the number of papers coming from our college research laboratories. I am quite convinced, however, that the colleges are producing results commensurate with the amount of money spent in their laboratories equal to that in the industrial laboratories. Our own experience has been such as to indicate that often research problems useful to industries can be carried on by students in a college laboratory as well as by a man in an industrial laboratory for much less money than the industry would require should they use the same man for the same work in one of their own laboratories.

R. E. Hellmund: I think the subject of research in colleges is a very timely one to discuss. The reason why I believe so is that there are relatively few students coming from the colleges with the intention of taking up research work or design work which is similar to research. I have for many years interviewed most of the students coming to the Westinghouse Company to take up engineering work, and until recently the large majority of them showed a preference for application work and but very few came with the idea of going into design or research.

We, of course, have given this a good deal of thought, because a manufacturing company is primarily in need of design engineers. The usual idea that the compensation may be the reason for the existing condition can hardly apply because the salaries of research and design engineers are in general the same as those of application engineers. I believe the real reason is that the colleges do not instill into the students a desire to do this kind of work. I have found, for instance, that in some schools the students during their senior year do a number of design calculations for induction motors, generators, transformers, etc. They are given formulas for this purpose, and in using them make numerous mistakes. Because of their inexperience, they do not discover such mistakes until well toward the end of their calculations, and as a consequence they are obliged to carry through the slide-rule work many times. As a matter of course, they become thoroughly disgusted with the work and make up their minds that this is not the kind of thing they wish to do all their lives.

With the realization by the schools that it is impossible to give the students a complete knowledge of design, there has for several years been a tendency to eliminate design activities entirely and merely equip the students with a fundamental knowledge. This point of view has also found support with the representatives of the industries, who felt that if the student had a thorough knowledge of fundamentals, the industry could teach him the particular design knowledge required. This may be true, but it must not be overlooked that even the fundamental knowledge is merely a tool and that the real function of the research man and the designer is to create. In other words, all the fundamental knowledge is of no use if the design engineer does not have the desire and ability to create, and I therefore do not believe it is safe to keep a student in college for four years merely absorbing knowledge and without continually fostering in him the desire to create something himself. Unless this is done, the student is not properly developed for his future work, nor will he be interested in design or research work upon entering industry.

It is, of course, impossible to teach all varieties of design and research during the limited time of a college course. However, I consider it essential to keep the student engaged in some kind of design work throughout the entire course, without any attempt to cover the entire field. Starting with the simplest kind of problems, more difficult ones may follow later, and care should be taken at all times to utilize and apply in this connection the knowledge acquired in the fundamental studies.

I fully agree with the previous discussors that additional financial resources are desirable in connection with the research work of the schools, but I also believe that a great deal can be accomplished simply by keeping the student interested in design and research work and continually fostering in him a desire to exercise his creative ability.

W. A. Del Mar: There is one observation I should like to make about training of research men which I believe has never come up in the discussion between the engineers and educators; that is, the importance of training men in manual dexterity, both for making instruments and experimental "set-ups," and for their manipulation.

Success in research work depends very largely upon the dexterity of the worker in making, assembling, and using apparatus. The man who depends entirely upon ready-made commercial instruments or who has to wait for the commercial concerns to make his instruments will not get very far in research work.

There is one other point in connection with training of research men, and the development of research mentality. I do not think there is a single research mentality. We need two different types of men in the research laboratory, one having reliability in making measurements, and the other having extraordinary coordinating power, bringing together the results of tests and uniting them together into something new. I think these are two entirely distinct types and ought to be recognized as such by the educators.

J. Tykocinski-Tykociner: (communicated after adjournment) Research becomes more and more the result of cooperation instead of the effort of a single individual. With the growing complexity of engineering problems, the number of individuals participating in the solution of a particular problem will naturally increase. This development, conspicuous in the industrial laboratory, will have to be met also in the colleges. The development of theory, experiment, and equipment forms the three special divisions of research activities in which the individual research workers will have to specialize according to their natural aptitude. The type of student gifted in theoretical formulation of problems finds ample opportunities of preparing himself and developing for research work. Originality and knowledge of mathematical methods is all that is required for his future success.

However, the gifted experimenter, whose chief aim is to apply his creative faculties to the development of new methods of investigation, the design of new apparatus, and to the surmounting of innumerable difficulties presenting themselves in the course of research work, finds himself limited by the lack of talent to do things requiring skilled manual work. An inventor of new scientific methods and devices will rarely be sufficiently skilled in mechanics to produce the actual experimental apparatus and precise measuring instruments he requires. In fact he will find in most cases that there is no mechanic available at the college who could do all the work he needs. If he can get the mechanic to do work on his apparatus, he will find him a dutiful craftsman but without initiative or understanding of the real needs for which the apparatus is to be built. Colleges as well as industries must face the fact that the old generation of good mechanics adapted for the varied auxiliary research work is vanishing and that the present sources for supplying trained men are inadequate. Continued progress in research calls for the creation of an efficient professional body of mechanics especially trained for research work. The research mechanic of the immediate future will regard his vocation as a fine art and he will acquire all the knowledge, training, and skill in a special department of an engineering school to be created for this purpose. The research mechanic will actively cooperate with the theoretical investigator and with the experimenter. His aim will be to produce and to improve the equipment required for the solution of the various problems. All three must have an understanding for one another's part of the common work. The work of each must be regarded as an equivalent contribution. Each of them will participate with his particular ingenuities for a common achievement. Cooperation of this kind and the organization of special courses for education and training research mechanics seem to me to be the factors which will further research and which should be stimulated at the present stage of development.

Electrophysics

Annual Report of the Electrophysics Committee*

To the Board of Directors:

The general views of the chairman of the committee will be found in the editorial entitled *Relationship between Physics and Electrical Engineering*, in the JOURNAL for February, 1927. This editorial may be considered as part of this report. During the year, some of the members of the committee volunteered to watch new developments in the following topics: Ferro-magnetism, theory of mapping of fields, short-time phenomena, high-voltage research, insulation and dielectrics (solid, liquid, and gaseous), arcs and discharges, short-wave propagation, atomic physics, spectroscopy, quantum theory, and surges. This list will give an idea of the scope of interest in electrophysics. Several manuscripts submitted to the Institute were read and passed upon by the committee.

The committee has felt that a constant influx of new ideas from the field of pure physics to Institute membership should be carefully maintained, in order that the profession might promptly take advantage of new discoveries, methods of measurement, and theories. As a partial realization of this endeavor, the committee desires to report as follows:

1. It has obtained permission from your Board to invite two members of the American Physical Society to sit with the committee. It is hoped that this arrangement will actually go into effect after August first.

2. It has obtained permission from the editor of *Physical Review* to publish in our JOURNAL abridgments of any papers appearing in the *Review*, with the usual credit. This will make it possible to note important articles immediately after their publication.

3. It has arranged with Professor K. T. Compton of Princeton University to write a paper on *The Nature of the Electric Arc* for presentation at this convention. It is hoped that another prominent physicist may be secured to address our next Winter Convention and that such addresses may become a regular practise in the future, at least at Winter Conventions.

PAPERS PRESENTED

The following papers and articles, which appeared in the JOURNAL during the period covered by this report, will give an idea of the range of topics in electrophysics covered. While not all of these papers were presented under the auspices of the Electrophysics Committee, they all lie within the scope of the committee's interests. The pages refer to the JOURNAL.

1926

Temperature of a Contact and Related Current-Interruption Problems, J. Slepian, October, p. 930.

Measurement of Transients by the Lichtenberg Figures, K. B. McEachron, October, p. 934.

The Space Charge That Surrounds a Conductor in Corona at 60 Cycles, J. S. Carroll and H. J. Ryan, November, p. 1136.

Coolidge's Cathode Ray Tube, November, p. 1143.

Vacuum Switching Experiments, R. W. Sorensen and H. E. Mendenhall, December, p. 1203.

1927

Frequency Measurements with Cathode Ray Oscillograph, F. J. Rasmussen, January, p. 3.

Maxwell's Theory of Layer Dielectrics, F. D. Murnaghan, February, p. 132.

A New Electronic Rectifier, L. O. Grondahl and E. H. Geigher, March, p. 215.

Space Charge and Current in Alternating Corona, C. H. Willis, March, p. 272.

Oil Breakdown at Large Spacings, D. F. Miner, April, p. 336.

Graphical Determination of Magnetic Fields, A. R. Stevenson, Jr., and R. H. Park, Winter Convention. E. E. Johnson and C. H. Green, June, p. 583.

ELECTRICAL DISCHARGES IN GASES

Disruptive Discharges. Using a development of Townsend's theory of ionization by collision, it has been proved possible to design electrode shapes of high-voltage spark-gaps so as to obtain minimum electrode size. "No time-lag" electrodes so designed are much smaller than corresponding "no time-lag" spheres, (Rogowski and Rengier, *Archiv. f. Elektrotech.*). A study of time lag of spark-over of gaps has shown that in many cases the duration of the lag is a matter of chance and must be dealt with statistically, (McEachron, A. I. E. E. JOURNAL; Braunbek, *Zeitsch. f. Physik*). The influence of the state of electrode surfaces on time lag has been confirmed, (Burawoy, *Archiv. f. Elektrotech.*). The Townsend theory of ionization by collision seems to be inadequate for explaining the shortness of the time lag, (Rogowski, *Archiv. f. Elektrotech.*). Progress has been made in the theory of lightning, (Simpson, *Proc. Roy. Soc.*; Dorsey, *Frank. Inst. Jl.*); experimental work has been done aiming to discover the manner of striking of lightning, (Peck, *Frank. Inst. Jl.*).

Corona. Progress is being made toward a rational theory of corona, and the influence of space charge in

*Committee on Electrophysics:

V. Karapetoff, Chairman
Carl Kinsley, Secretary
Oliver E. Buckley, V. Bush, J. F. H. Douglas, Charles Fortescue, Carl Kinsley, W. B. Kouwenhoven, K. B. McEachron, R. A. Millikan, J. H. Morecroft, Chester W. Rice, J. Slepian, Harold B. Smith, Irving B. Smith, J. B. Whitehead.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

the discharge is being taken into account, (Carroll and Ryan, Jl., A. I. E. E.).

Arcs. An improved equation for the volt -ampere characteristic of an arc, with one constant of the equation directly related to the boiling point of the anode, has been developed, (Nottingham, *Phys. Rev.*). Experimental and theoretical evidence has been produced for the existence of cold cathode arcs, (Newman, *Phil. Mag.;* Slepian, *Phys. Rev., Frank. Inst. Jl.*).

Miscellaneous. Important formulas have been theoretically derived and experimentally confirmed for the properties of electrodes immersed in gaseous electrical discharges, (Langmuir and Mott-Smith, *Phys. Rev.*). Cathode rays due to very high voltages have been brought outside the vacuum tube, and have produced strange phenomena, (Coolidge, *Frank. Inst. Jl.*).

Short-Time Phenomena

Much progress has been made in developing instruments for the determination of the characteristics of short-time electrical phenomena. Through the use of the modern cathode ray oscillograph of the Dufour type, it is now possible to determine the relationship between time, voltage, and current for any device operating under transient conditions, such as a lightning arrester.

Heretofore, it has only been possible to calculate wave fronts, and such calculations were of course limited to the assumptions made and frequently gave results considerably in error because of the presence of unsuspected oscillations. The cathode ray oscillograph has been used successfully for transients whose crest voltage was attained in one ten-millionth of a sec.

The propagation of waves over circuits and effects of reflection points, the breakdown of insulation, and other similar problems, are being actively studied with the help of this oscillograph. It is also being used to study the effects of lightning on transmission circuits, and gives for the first time an opportunity for the determination of the character and form of transients due to lightning.

For the purpose of making field studies of transients and transmission lines,' surge recorders based on Lichtenberg figures have become of very great importance. The magnitude, polarity, and frequency of occurence of disturbances have been determined for many systems. These data have added greatly to our knowledge of phenomena for which there were only few quantitative data in the past. The measurements cover a very wide range of voltage, having been made on practically all ratings, from telephone circuits to 220-kv. transmission systems.

The surge recorder is also very useful in the laboratory as a device for measuring the potential of transients, without drawing appreciable energy from the test circuit. Many investigators, both here and abroad, are now studying the phenomena of lightning with renewed interest, and considerable benefit is certain to come from these studies.

Ferromagnetism

During the past year notable advances have been made in our understanding of ferromagnetism, principal among which may be noted:

1. Studies of single crystals of iron and of nickel have shown remarkable magnetic properties different from those obtained in multi-crystalline materials. The principal contributors in this field have been Honda, Webster, Gerlach, and Sucksmith.

2. Studies of magnetostriction in permalloy by McKeehan have indicated that this phenomenon plays a much more important role in ferromagnetism than had previously been appreciated, and that hysteresis is very definitely related to magnetostriction. Work by Wedensky and Simanow and by S. R. Williams confirms the existence of such a relation.

3. Studies have been made on the magnetic properties of iron and magnetite at radio frequencies by Wait. His results throw doubt on the results previously reported by Arkadiew and his collaborators.

4. Studies of the specific heat of ferromagnetic metals by Sucksmith and of the closely related magneto-caloric effect by Weiss throw some light on the relations between thermal and magnetic energy.

A very notable contribution to the literature of ferromagnetism which is of particular interest to electrical engineers is Thomas Spooner's book on the properties and testing of magnetic materials.

High-Voltage Research

In the realm of high-voltage research, steady progress has been made. Corona has been studied up to potentials of 1,000,000 volts. Spark-gap measurements have been extended to 2,000,000 volts. The past year saw the first 220-kv. transmission system in the East put into operation (in Pennsylvania).

The use of the ground wire seems to find increasing favor as a means of decreasing the number of serious impulses occurring on transmission systems during lightning storms. Laboratory tests have shown quantitatively the benefits to be derived from the use of the ground wire under various conditions. The shielding of buildings and other structures from the effects of lightning has also been studied.

Several high-voltage laboratories are now available for research and test purposes, the latest being the new 2,000,000-volt Ryan Laboratory at Stanford University.

General Progress in Electrophysics

With the discovery of X-rays and radioactive substances, some 30 years ago, the progress in physics has been phenomenal, and it is not possible even to enumerate briefly the important contributions which have been made within the last year or two, especially

in the domain of our knowledge of the fine structure of spectral lines. These contributions follow the trend of ideas, previously established, with respect to the individual electronic orbits which determine the atomic and molecular structure of matter and the ultimate nature of various forms of radiation and other forms of energy.

An authoritative and monumental work on modern physics is now appearing under the title, *Handbuch der Physik*, edited by Geiger and Scheel, in 24 large volumes (Springer, Berlin). Scores of prominent physicists are contributing to this work. Numerous special books are also available on branches of physics of interest to our profession, such as X-rays, spectroscopy, ionization, dielectrics, photoelectricity, molecular structure, radiations, chemical physics, etc.

Those who wish to get a bird's-eye view on modern developments in physics should read Darrow's "Introduction to Contemporary Physics" (Van Nostrand) and his serial articles in the current issues of the *Bell System Technical Journal*. See also R. A. Millikan, "The Last Fifteen Years of Physics," *Amer. Philos. Soc. Proc.*, 65.2, pp. 68-78, 1926.

By following certain portions of *Science Abstracts*, Section A, one may readily keep in touch with the progress of any particular branch of physics in which one is interested. For work done in this country, the abstracts of papers presented before the American Physical Society and published in its bulletin should be consulted. This bulletin appears separately and is also subsequently reprinted in the *Physical Review*. Publications of the National Academy of Sciences, Franklin Institute, American Philosophical Society, Bell System, etc., will also be found useful.

VLADIMIR KARAPETOFF, *Chairman*.

Discussion

R. W. Sorensen: The 1927 Pacific Coast Convention papers will include reports of work done in a study of the characteristics of lightning and devising means of protecting oil reservoirs against lightning strokes. One of the two papers to be presented at that time is the result of work done in the research laboratories of California Institute of Technology, a group of people who wish protection for oil-storage reservoirs providing funds for this definite piece of research work. These funds have been used up and certain protective plans for oil reservoirs prescribed, but there remains much to be done in making a comprehensive study of lightning and protection against it. Also this is one of the types of problems which, if properly financed, could well be carried out by one or more college staffs. Research on such a problem should not be limited to one or two laboratories and their respective groups of research men, but we should have a number of field observation crews and a number of laboratory groups making studies about lightning. It is my hope that a way will be found for men interested in the subject of lightning and provided with high-voltage equipment to do experimental work at our colleges in order that we may train students for this kind of work by permitting members of the faculty and student body to have a part in the work.

I am much encouraged by the work already done. Observers are coming more nearly into accord as to what lightning phenomena are and how to protect against the destructive nature of lightning; but may I, in closing, urge that a comprehensive program be financed in such a way as to enable several college laboratories, as well as the high-voltage laboratories maintained by industrial organizations, to have a part in carrying out these investigations.

A. I. E. E. Standards

Annual Report of the Standards Committee[1]

To the Board of Directors:

The Standards Committee has continued actively the revision of the Standards of the Institute, both as to form and content. In 1922, the Institute published its Standards in a volume of nearly 200 pages, divided into 26 chapters, with an appendix in which are reprinted the Rules for Electrical Machinery of the International Electrotechnical Commission. Soon after this edition was issued the Standards Committee was reorganized by the Board, and a revision was begun which involved the splitting up into separate sections the existing Standards, rearranging the material, and bringing together into separate complete compilations, the definitions, service conditions, rating, heating, dielectric tests, markings, and other requirements applicable to any particular type of apparatus or brand of the art.

Thirty sections have been definitely projected of which 23 have been issued; 7 are in preparation. Of the 23 issued 2 are reprinted without change from the 1922 edition of the Standards, but one of these sections is now in a revised report form for comment and criticism, and will shortly be issued. Five of the revised Standards have been approved as American Standards by the American Engineering Standards Committee, and other sections are now before that committee for consideration. A complete list of Standards adopted and in preparation is given below as an appendix to this report.

The revised form of the Standards has justified itself in the ease with which revisions may be made in the published sections. The sections are published in comparatively small editions, and revisions are readily made and a new edition printed without much expense or difficulty. Several of the Standards have been revised in this way. Monthly lists of the Standards available are published in the JOURNAL of the Institute.

The Standards Committee is charged with the coordination of all the standardization activities of the Institute. The Committee has made recommendation to the President and Board of Directors upon all cases of representation of the Institute upon Sectional Committees working in accordance with the procedure of the American Engineering Standards Committee; upon acceptance of and requests for sponsorship by the Institute; and has cooperated very closely with the United States Committee of the International Electrotechnical Commission. The cooperation of the committee with the technical committees is being made closer and more effective. The chairman of each technical committee, or a member of the committee designated by the chairman, is a member of the Standards Committee. Several of the Standards have been formulated by technical committees and accepted by the Standards Committee, and in other cases subcommittees of technical committees have been made the working committee on specific standardization projects.

By direction of the Board, certain Standards have been translated into the Spanish language under the very able supervision of Past President Mailloux. The translation of 19 of the standards has been completed and 13 have been published by the Bureau of Foreign and Domestic Commerce of the U. S. Department of Commerce. By July 1, it is expected that all of the translated sections will be in print. The Spanish edition is printed in the same style and in the same size as the English edition. The translation has been received with interest by engineers in Spanish-speaking countries of South America. The Institute is very much indebted to the Bureau of Foreign and Domestic Commerce for the excellent manner in which the Spanish text has been published, and for the fine cooperation that exists between the Bureau and the Standards Committee. American electrical manufacturers will no doubt find this Spanish edition of considerable value in business relationships in Spanish-speaking countries.

The committee has cooperated to the fullest extent with the American Engineering Standards Committee, the International Electrotechnical Commission, and the Standardization activities of other organizations. In the formulation of Institute Standards, the committee has endeavored to enlist the fullest cooperation of all other organizations interested in electrical standardization. Standardization work as now organized in the electrical field, is somewhat complex, and there is of necessity a certain amount of unavoidable overlapping. It is believed, however, that very good progress is being made as represented by the present Standards of the Institute.

High-Frequency Measurements

Report of Committee on Instruments and Measurements

To the Board of Directors:

Three branches of the field of electrical measurements in which the demands of industry have stimulated new, improved and more precise methods and means of measurement are: electric power and energy, dielectrics, and high frequency. The first two items were covered in the report of the committee for 1925-26 and in the symposium on dielectric measurements conducted at the Niagara Falls Regional Meeting of the Northeastern District, May, 1926.

High-Frequency Measurements

This year's activity has been focussed on the matter of measurement of high-frequency quantities arising principally in the field of carrier telephony and radio. The committee, functioning largely through a subcommittee consisting of Messrs. H. M. Turner, Chairman, E. D. Doyle, Melville Eastham, W. N. Goodwin, Jr., and B. W. St. Clair, arranged for the presentation of a series of papers at the Pittsfield Regional Meeting of the First District (May 25-28, 1927).

A list of these papers and a résumé of the information in these papers are included as part of this report under the heading "Symposium on High-Frequency Measurements."

Electrical Measurement of Physical Values

The committee has also continued, through a subcommittee of one, (namely Mr. P. A. Borden), the extension of the bibliography of articles in other periodicals dealing with the application of electrical methods to the measurement of other than purely electrical quantities. This bibliography is submitted as part of this report.

Remote Metering

There has been formed this year a new subcommittee to survey the field of distant indications of electrical quantities. This committee consists of Messrs. E. I. Rutan, R. T. Pierce, and P. A. Borden, and it will report at a later date.

A. E. Knowlton, *Chairman.*

Symposium on High-Frequency Measurements

The following article consists of a résumé of a series of fifteen papers dealing with measurements at high frequencies. The study of this subject, the preparation of these papers and their presentation, will constitute the major activity of the Committee on Instruments and Measurements during the year 1926-27. The papers are to be presented at the Regional Meeting in Pittsfield, Mass., May 25, 1927. Complete copies may be obtained from Institute headquarters. The papers are as follows:

1. *Notes on the Use of a Radio-Frequency Voltmeter,* by W. N. Goodwin, Jr.

2. *Substitution Method for the Determination of Resistance of Inductors and Capacitors at Radio Frequencies,* by C. T. Burke.

3. *Condenser Shunt for Measurement of High-Frequency Currents of Large Magnitude,* by Alexander Nyman.

4. *Radio-Frequency Current Transformers,* by Paul MacGahan.

5. *Methods for the Measurement of Radio Field Strengths,* by C. R. Englund and H. T. Friis.

6. *The Quantitative Determination of Radio Receiver Performance,* by H. D. Oakley.

7. *High-Frequency Measurements of Communication Lines,* by H. A. Affel and J. T. O'Leary.

8. *Methods of Measuring the Insulation of Telephone Lines at High Frequencies,* by E. I. Green.

9. *High-Frequency Measurement of Communication Apparatus,* by W. J. Shackleton and J. G. Ferguson.

10. *Impedance of a Non-Linear Circuit Element,* by E. Petersen.

11. *Empirical Analysis of Complex Electric Waves,* by J. W. Horton.

12. *A New Thermionic Voltmeter,* by S. C. Hoare.

13. *The Oscilloscope: A Stabilized Cathode Ray Oscillograph with Linear Time Axis,* by Frederick Bedell and H. J. Reich.

14. *Sensitivity Characteristics of a Low-Frequency Bridge Network,* by P. G. Edwards and H. W. Herrington.

15. *Microammeter Indication of High-Frequency Bridge Balance,* by H. M. Turner.

The committee feels that these papers reflect the latest development in the methods of measurement of quantities associated with frequencies ranging from those just above power and ordinary telephone frequencies through those used in radio communication.

The instruments commonly employed in measurements at ordinary power frequency have very definite limitations when used at the higher frequencies. Also it is a matter of common knowledge that measurements of circuit properties under the higher frequencies cannot in general, be made satisfactorily by direct determination of current and voltage drop in a series arrangement. Much of the progress in the field of high-frequency measurements has been in the direction

Committee on Instruments and Measurements.

of bridge modifications, adaptation of the electron tube to measurement circuits, and also the improvement of thermocouple type instruments.

Instruments for Radio Frequencies

A shielded thermocouple type voltmeter for radio frequencies was described by L. T. Wilson in the 1924 Transactions. The current consumption varies from 2 to 8 milliamperes for the conductive circuit of the instrument and a quadrature component for shield-charging of the same order of magnitude. Subsequent investigation during the development of the instrument have shown that in order that the inherent precision of the instrument shall be realized, the effect of inductance and capacitance in the connections must be avoided by observance of careful technique. Thus in measuring the effective resistance of a reactor, the low-potential section of the measuring circuit should be carefully grounded and the high-potential section kept short and clear of solid dielectrics and consequent stray loss.

In measuring the R and L of a broadcast tuning coil, for example: It is connected in series with a 500-m. m. f. condenser, a 100-milliampere ammeter and a 1.2-ohm resistor (say 2 in. of 0.0065-in. manganin) the latter serving as conductive coupler with an oscillator 10-watt or larger. The drop across the resistor as indicated by the voltmeter will be of the order of three volts when the measuring circuit is tuned to sharp resonance. The effective resistance of the coil is less than E/I by the amount of milliammeter and condenser resistances. The inductance of the coil is computed from the resonance formula and the capacity setting of the condenser. The frequency error of this device is about 1 per cent for frequencies of the order of 1500 kilocycles. (See paper No. 1.)

Circuit constants of capacitors and inductors are, in one method, of a substitution type, found by resonating them in a series circuit and using as an indicator a crystal in series with a d-c. microammeter, the combination shunted across a small inductance in the series circuit.

The resistance of an inductor is found in the value of a non-reactive resistor substituted for the inductor in a circuit tuned in both cases to resonance by adjustment of a capacitor having negligible equivalent series resistance. The inductance is found in terms of the quotient of difference and product of the capacities required for resonance. Similarly, the capacitance and resistance of a capacitor are found in terms of the change in resistance and capacitance between resonance with and resonance without the capacitor in question. (See paper No. 2).

In the measurement of high-frequency current of more than 10 amperes the hot wire instrument is not feasible because the size and resistance tend to become prohibitive. The thermocouple ammeters for larger ranges than 100 amperes become very expensive on account of considerations of skin effect and size of heating element. Iron-cored current transformers are satisfactory up to 500 kilocycles but for much higher frequencies the difficulties in design increase.

A method has been developed which employs a hot-wire or thermocouple ammeter in series with a relatively small condenser and the combination in parallel with a large condenser shunt. The error due to the thermocouple resistance need not exceed 0.5 per cent with frequencies up to 6000 kilocycles and satisfactory commercial measurements are feasible up to 60,000 kilocycles. Unit assembly of the shunt condenser readily permits the provision of several current ranges,—say 50, 100, 200 amperes, the thermocouple instrument in each case having a 0.25-ampere rating. Care must be taken to avoid losses from resonance of the closed circuit at some harmonic of the fundamental. The absolute calibration of the arrangement presents difficulty even by means of a calorimeter ammeter because of the uncertainty about high-frequency resistance and effect of distributed capacity. The condenser shunt is apparently entitled to greater confidence than a direct thermal determination. (See paper No. 3).

For the measurement of large currents at high frequency, there are also available current transformers of the through-type with secondary rated at one ampere; the indicator is usually a thermocouple type ammeter. (See paper No. 4.)

Radio Field-Strength and Receiving Sets

The vacuum tube used as detector, amplifier, and voltmeter is the basis of sensitive comparator methods for determining radio field strengths at frequencies below 1000 kc. in the customary unit of micro volts per meter. The loop-antenna is employed in preference to the open-antenna and no indirect evidence has appeared which places in doubt the value of equivalent effective height computed for the loops used. Both the $I R$ drop and mutual-inductance voltage methods are employed for introducing into the antenna the sinusoidal comparison voltage; the resistance method is preferred because its reactance is of less concern than the resistance of a mutual inductance and also it serves admirably as a terminal impedance for a constant impedance attenuation network. Shielding is easier with resistance coupling.

For frequencies higher than 1000 kc. the above method becomes unworkable and a double-detection type of receiver is used after calibration as a vacuum tube voltmeter: The received field strength is evaluated in terms of three measured attenuation factors, the received signal voltage, and the loop effective height. Static energy and static "noise value" are of interest; continuous static is readily measurable in terms of the telegraph signal strength masked by it. The enormous variability of usual static has prompted measuring it by noting the gain of the receiving set necessary to maintain constant static output. A non-restoring type of deflection instrument comparable to a fluxmeter has

merit in summing the received energy over a definite interval. (See paper No. 5.)

The problems of measurement of the common electrical properties of the individual elements and of circuit units of radio receiving sets having been dealt with, there are remaining those factors of set performance which differentiate sets with respect to their selectivity, sensitivity, fidelity of reproduction, and reradiation. Each of these attributes of a completed set have been reduced to a quantitative definition and measuring method which evaluates them in terms of output voltage obtained on response to the input from a controlled signal generator. Thus sensitivity is determined as the ratio of output voltage to input field strength at various output voltages and input frequencies. Dimensional analysis of the expressed ratio results in reduction to length units; therefore, sensitivities are expressed in meters. Selectivity is determined in terms of the input field strength required to maintain a constant minimum value of output voltage for the requisite range of frequencies. Quality performance is expressed as the ratio of output voltage at the various modulation frequencies, the antenna voltage and degree of modulation being maintained constant. Radiation is expressed in meter-amperes, the meters being the antenna height and the amperes that value of current required to establish various output voltages in a detector of known sensitivity when the latter is supplied with the radiation output of the receiving set. (See paper No. 6.)

Telephone Carrier-Frequency Measurements

In the field of telephone carrier frequencies, the line characteristics of chief interest are attenuation, impedance, and cross-talk for frequencies up to about 50,000 cycles. Apparatus for field and laboratory measurement of these quantities has been developed and standardized on a unit basis. The units consist of oscillator, detector-amplifier, impedance-bridge, thermomilliammeter, variable attenuator, cross-talk set, and frequency meter. The oscillator is a vacuum-tube and tuning circuit giving 0.4 to 0.7 watts maximum at frequencies from 100 to 50,000 cycles and above 3000 cycles has no harmonics of more than 10 per cent of the fundamental amplitude. The detector-amplifier is adapted to both aural and visual balancing or indication. The impedance bridge is of the balancing or differential coil type. The thermomilliameter carries its own d-c. calibrating circuit and provides for the use of three thermocouples of a range of characteristics to cover a current range from 0.2 to 50 milliamperes. The attenuator is a network of known loss and terminal impedance and the cross-talk-set is a similar attenuator adapted to cross-talk measurements of the order of 10^{-6} times the transmitted currents. The frequency meter is a resonance bridge. Attenuation measurements made on the current-transmitted versus current-received method are possible for energy ratios up to 30×10^6 to an accuracy of about 3 per cent. Impedance measurements are of importance in connection with non-homogeneous lines and these are generally made on the line after terminating it in its characteristic impedance, usually a resistance of about 600 ohms; the results indicate the efficacy of loading to meet carrier-current operation. Avoidance of cross-talk with carrier-frequency operation presents many difficulties and necessitates a highly refined system of transpositions; the cross-talk measurements made to determine the effectiveness of the transpositions are a specialized form of attenuation measurements, *i. e.*, attenuation to cross-talk must be high and to line transmission, low.

It is by such a system of measurement that a telephone circuit is tested for its quality after the necessary modifications have been made in preparation for carrier-current operation. (See paper No. 7.)

A substantial part of the increased attenuation at carrier frequencies is due to skin effect of the conductors, and the leakage conductance of the insulators is found to increase rapidly with the frequency; radiation is a negligible factor. It is permissible to attribute to leakage conductance all losses except those of an $I^2 R$ nature in the metallic conductors; the leakage conductance, G, may of course, be derived from measurements of the attenuation but the line would have to be at least 100 mi. in length. A direct measurement of G on a line short enough (250 ft.) to avoid propagation effects and a phase shift of more than five degrees has been made on an experimental line with sufficient comparability to represent the shunt losses in long lines; the line contained 25 poles spaced 7 ft. apart and with 6-in. spacing of the insulators on the crossarms. A certain amount of transposition was resorted to, but the important precautions pertained to the manner of leading the conductors into the test station.

Each circuit is in effect a conductance shunted by a capacitance and thus the equivalent of the leaky condenser; the bridge for the conductance measurements is similar to those employed for the determination of the loss angle or power factor of dielectrics and condensers. The high resistance of a few insulators in parallel would appear to require a correspondingly high value of resistance in the standard side of the bridge but this is avoided by placing a condenser in series with a lesser value of resistance. A method of obtaining continuous record of d-c. leakage has been developed; a similar continuous record of the high-frequency leakage is greatly to be desired but as yet awaits solution. (See paper No. 8.)

The performance of communication apparatus depends principally upon its impedance and in the precision and routine measurement of resistance, inductance, and capacitance, standards of primary and secondary nature are necessary. The prime standards may well be resistance and frequency and the derived standards those of inductance and capacitance. Self-

driven forks (calibrated by phonic wheel for 24-hr. period against Arlington time) can be maintained within 0.001 per cent of 100 cycles. Other frequencies can be compared with the standard by means of the cathode ray oscillograph. Resistance standards must have minimum and constant phase angle; 1000-ohm standards have been constructed with effective inductance not exceeding five microhenrys up to 100 kc.

Secondary standards of capacitance are made with mica dielectric impregnated with paraffin; such condensers can be obtained with temperature coefficient below 0.005 per cent per deg. cent. and with less than 0.1 per cent capacitance variation from 500 cycles to 100 kc. and phase angles less than one minute. Air condensers are feasible for the smaller capacitances. Secondary standards of inductance must be constant and preferably with small external field. Air-cored standards of large inductance involve considerable distributed capacitance; on this account cores of permalloy have been used with considerable success. Secondary standards of resistance in dial form inevitably involve more distributed capacitance than single primary standard resistances.

In the comparison of secondary standards against primary standards, methods which determinate the unknown in terms of circuit constants are preferable to those requiring the measurement of current and voltage. The bridges used must be carefully shielded and the equal ratio arm bridge is to be preferred wherever possible. The bridge circuits in use provide for impedance determinations when direct current is superposed on the high-frequency alternating current; these bridge methods also provide means of measuring flutter (telegraph impulse affecting the telephone frequency inductance of apparatus in the common circuit), transformer ratios, capacitance unbalance, attenuation and gain, and cross-talk. (See paper No. 9.)

The harmonic components of non-sinusoidal quantities create difficulties in the measurement of impedance of circuit-elements of a non-linear nature, where the ratio of instantaneous currents and potentials is not constant throughout the cycle. Vacuum tubes are non-linear as to resistance and iron-cored coils at high flux densities are non-linear as to reactance. In a-c. bridge measurements of such quantities it is found that the measured impedance depends on harmonic factors introduced from the source of supply, the magnitude of the resistance in the bridge ratio arms, the impedances of the detector and of the source of supply to the fundamental frequency and to the possible harmonic frequencies, and also upon the method used in attaining bridge balance. As for the last item, the measured non-linear impedance may well be different if balanced, in one case, against standards of resistance and inductance and, in the other case, balanced against a non-inductive resistance after establishing resonance with a standard capacity.

It is thus often essential to arrange the measuring circuit so that the impedance or other quantity measured shall be characteristic of the non-linear device and not of the bridge and supply network. The complicating effect introduced by a non-sinsuoidal impressed potential wave is readily removed by the use of a frequency-selective circuit between the source and the measuring network. The complicating effect of harmonics arising out of the non-linear reaction of the element under measurement may be suppressed in two ways, one, a modification of the usual bridge method and the other, an a-c. potentiometer method.

In the modified bridge method, two balanced high-inductance coils with high-coupling are inserted in the 1:1 ratio bridge arms. The fundamental fluxes neutralize but the harmonic components of current encounter the series-aiding impedance and are effectually suppressed. In the a-c. potentiometer method the harmonics are suppressed by a filter of low impedance to the fundamental and high impedance to the harmonics developed in the non-linear element. Further modifications make possible the determination of the non-linear characteristics of the element without suppressing the harmonic current flow. (See paper No. 10.)

In the transmission of speech it is not only essential that the circuit possess prescribed reactions to steady state conditions but also that it fulfill certain other limitations upon transient conditions. The oscillograph is inadequate to the analysis of the couples waves encountered in, for example, the multi-channel repeater employed in carrier telephone systems and other means of analysis had to be devised. Any distortion by amplifiers or circuit elements results in the development of new frequencies that are multiples of the components of the impressed wave or are algebraic combinations of those components; these extraneous components may call for detection and measurement when their amplitude is even as low as 0.1 per cent or less of the true signal components. The heterodyne beat method is found useful in such detection and measurement; by a d-c. indicator in the plate circuit of a biased grid tube the amplitude of the d-c. component is directly determined. The same indicator will by relatively slow periodic change in deflection show by a beat method the presence of a minute component of a particular difference-frequency when the oscillator frequency is brought close to the frequency of the component. The method does not lend itself readily to a quantitative determination however.

Practically all analyzers for waves of small amplitude are modifications of the elementary form in which a selective circuit couples a vacuum tube amplifier to the circuit under investigation. Whether the voltage drop across L or C be chosen for application to the grid of the detector depends upon the frequency of the components sought; L for low, and C for high frequencies. The procedure is tedious and long if a wide range of frequencies is sought and there has been developed a

device for automatically tuning over the desired range and automatically recording the amplitudes of discovered components. Means are also available for examining the variation of a single component of a complex wave as conditions affecting it are varied; the required selectivity is attained by employing several analyzers in tandem.

For more exacting requirements even the above method is inadequate and for such cases a heterodyne analyzer has been developed; thereby the frequency range to be examined is translated to a lower position of the frequency scale with the advantage of greater fractional separation between components. (See paper No. 11.)

INSTRUMENTS FOR MODERATELY HIGH FREQUENCIES

A vacuum tube voltmeter has been developed in which the plate impedance forms one arm of a Wheatstone bridge. With zero voltage impressed upon the grid-filament circuit of the tube the bridge is initially balanced by means of an adjustable resistance, the bridge indicator then reading zero. When an unknown voltage either alternating or direct is then impressed upon the grid-filament the plate-impedance changes, and the bridge balance is disturbed; the resulting deflection of the bridge indicator is a direct indication, after appropriate calibration, of the voltage impressed on the grid filament. (See paper No. 12.)

Professor Bedell describes a method for producing stationary curves on the screen of a cathode ray oscillograph and establishing a linear time axis which involves the use of an auxiliary circuit consisting of a source of constant voltage, a neon gas-filled lamp and an electron-tube arranged in the general form of a bridge. The voltage across a portion of this circuit, which varies directly with time, is connected across one pair of deflecting plates of the oscillograph tube and in this way establishes a linear time axis. By means of a motor-driven distributor, the other pair of deflecting plates is connected first to one part of a circuit and then to another, thus making it possible to study several phenomena simultaneously. (See paper No. 13.)

The employment of very low frequencies (say three or four cycles per second) involves in some respects as much difficulty as the higher frequencies. The problem of locating opens in telephone cable conductors involves the determination of impedances; a study has been made of the degree of accuracy and sensitivity obtainable in impedance measurement with different frequencies of supply voltage. For long cables the input impedance is a hyperbolic rather than linear function of the characteristic impedance; the error in impedance measurement arising from this functional departure proves to be least for the lower frequencies. On the other hand, the bridge sensitivity is improved by somewhat higher frequencies. A thorough mathematical and experimental analysis of the sensitivity of impedance measurement of cable fault locations up to 70 mi., by means of a de Sauty bridge, indicates the desirability of using frequencies of the order of four cycles. The sensitivity is further increased by controlling the phase of the field excitation of the bridge galvanometer. Use of such low frequencies as four cycles per second is not common and the generating apparatus, bridge, detector, and graphical treatment of errors and sensitivity of measurement of impedances at this frequency are of interest in a report on measurements under other than power frequencies. (See paper No. 14.)

The telephone receiver, due to its simplicity, sensitivity and convenience, has been widely used for determining a-c. bridge balance and under favorable conditions is quite satisfactory. The aural method, however, involving as it does the receiver associated with the ear, has two serious limitations; first, it can be used only where there is very little extraneous noise and second, the frequency range for best operation is restricted to a band of, say, from 200 to 2000 cycles unless a heterodyne scheme is adopted.

A visual method has been devised using a d-c. microammeter in the plate circuit of an electron tube rectifier, associated with one or more stages of amplification, which gives maximum reading for a state of balance, thereby permitting the use of a sensitive meter and at the same time making it fool proof. A large bridge unbalance reduces the deflection to nearly zero and as balance is approached it increases. No change in reading on short-circuiting the indicator terminals of the bridge, which would correspond to zero voltage, shows definitely a perfect balance. This method not only completely overcomes the limitations of the aural method, but also renders a quantitative determination of the degree of unbalance. (See paper No. 15.)

ELECTRICAL MEASUREMENT OF PHYSICAL VALUES

By PERRY A. BORDEN

(Supplementary Bibliography)

The following bibliography, prepared at the instance of the Committee on Instruments and Measurements, is supplementary to that accompanying the writer's paper on the above subject published in the TRANSACTIONS of the A. I. E. E. Vol. XLIV (1925) p. 238. While most of the articles referred to have appeared in the technical press during the current year, some are of earlier dates, and a few references are made to standard works on electrical measurement. The arrangement of headings has been retained as in the original paper, but the references are not numbered.

Electrical Communication

Annual Report of Committee on Communication*

To the Board of Directors:

During the past Institute year, notable progress has been made in many branches of the art of electrical communication. The committee has selected for its report the items which were considered to be of most general interest and these are described under the various subheadings below.

Telegraphy

In the field of printing telegraphy, there has been a considerable extension during the year in the use of the simplified tape printers on branch office circuits and in private offices of business houses.

Additional installations have been made of the automatic tape transmission system for telegraphic tickers mentioned in the 1926 report, and direct service and full market quotations have been extended through the southwest.

For trans-ocean traffic, a notable example among the permalloy-loaded cables laid during the year is the New York Bay Roberts Penzance cable. Multi-channel operation for direct traffic between New York and London is now in effect on this cable.

In the larger telegraph central offices, a system for automatically dispatching carriers in pneumatic tube lines is displacing manual dispatching. Space at the routing center is conserved, efficiency of operation is improved, and savings are effected in operating costs. In this system, a tube clerk drops a carrier containing telegrams for transmission to a branch office into the proper one of a group of open-end gravity tubes located in front of the working position. The gravity tubes lead to the floor below where the automatic sending inlets are located. The inlet contains a rotor which oscillates on a horizontal axis through an arc of about 70 deg. at the rate of about six times a min. The carrier enters a pocket in the rotor when it is in alinement with the gravity tube at one end of the rotor's travel. At the other end of the arc, the pocket containing the carrier is in alinement with the end of the outgoing tube. The rotors of a group of sending inlets are driven by one motor through reducing gears and crank mechanisms. Interlocking devices feed one carrier at a time into each rotor and a visible signal is provided to indicate failure of any inlet to perform its function. Automatic sending inlets act as spacing devices in the transmission of carriers and eliminate trouble from overloading which occurs with manual sending on busy tubes. The average transit time from the main to the branch office is therefore generally decreased.

The great development of message telegraph systems involves interesting traffic problems, including layout of wires, traffic routing, office layout, operator assignment, etc. These problems were discussed in an interesting paper entitled, *Telegraph Traffic Engineering*, by Messrs. H. Mason and C. J. Walbran, which was presented at the Winter Convention.

Another very important telegraph subject which was discussed at the Winter Convention is the measurement of telegraph transmission (*Measurement of Telegraph Transmission*, by Messrs. H. Nyquist, R. B. Shanck, and S. I. Cory.) This subject has been of growing importance for a number of years, partly because of the advent of telegraph circuits having a large number of sections and partly on account of the increasing importance of accurately determining the effect on telegraph transmission of various amounts of interfering currents and of changes in individual circuit elements.

Dial Telephony

The rapid application of dial telephone systems has continued. During the year about 500,000 dial telephone stations were installed, bringing the total in service in this country, as of the first of January 1927, to approximately 2,400,000.

A means has been developed for remotely operating small magneto telephone plants where this is desirable. The name applied to this means is the semi-automatic magneto exchange. In a system of this type the subscribers' stations are equipped with magneto telephones. Connections are switched remotely by means of automatic telephone apparatus under the control of an operator, who employs a dial trunk from a control center into the exchange area. Any number of such exchanges may be controlled from the operating center.

Toll Telephone Service

Further progress has been made in the development and application of methods for increasing the speed of toll telephone service. The plan, the so called A-B method, of handling the large volume of messages between nearby points in a manner quite similar to that used in handling local traffic, has been considerably extended. The improvement of service has progressed to a point where even at the longer hauls it is now possible in many cases to complete a toll call while the

*Committee on Communication:

L. F. Fuller,		C. A. Wright.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

calling subscriber remains at the telephone. An important factor in this improvement is the development of a method of operation combining the work of the line and recording operators so that if the number of the called telephone is given the recording operator, she can proceed at once with the handling of the call.

A new type of toll switchboard has been made available for toll centers having sufficient traffic to require separate toll and local switchboards. The signaling equipment which was previously located in the cord circuits has been transferred to the line and trunk circuits and use has been made to a considerable extent of common positional equipment.

Telephone Toll Cables

The year witnessed the opening on December 15, 1926, of a new long distance cable link between Chicago and St. Louis, insuring for the future the best possible storm protection for communication through from New York to St. Louis as well as between intermediate points. This cable forms a part of the network of cables connecting Chicago, Detroit, Toledo, Cleveland, Pittsburgh, and other cities with the cities on the Atlantic seaboard, and contains circuits for both very long-haul and short-haul telephone business. The longest circuits of the network are about 1500 mi. in length, but even this does not represent the maximum distance over which circuits of this type can be operated. Telephone repeaters on these circuits are spaced at intervals of approximately 50 mi. Echo suppressors are used to permit operating with volume efficiencies comparable with other long distance telephone circuits. Automatic regulators are employed to compensate for the effect of temperature in changing the attenuation of the cable conductors by suitable changes in the amplification of repeaters in the circuit.

The new link is 344 mi. in length. It provides more than 250 telephone circuits, and over 500 telegraph messages can also be sent simultaneously, making it the equivalent of 10 heavy pole lines of open wire.

The increasing development of toll cable networks is of extreme importance in the protection of telephone service from interruptions due to sleet storms. During the year 1926, about 2000 mi. of such cables were put in service in various parts of the country, adding more than 400,000 mi. to the telephone circuits of the nation.

Carrier-Current Systems

An interesting example of the rapidity with which new developments are finding their way into practical use is to be found in the extensive application of carrier-current telephony and telegraphy to the long distance open wire telephone circuits of the country. There are now of the order of 100,000 mi. of long distance telephone facilities provided by carrier methods and some 250,000 mi. of telegraph facilities so provided.

The recent growth in carrier-current circuits results from the progress which has been made in perfecting the performance of the apparatus itself and in the development and standardization of methods for coordinating a large number of carrier systems upon the wires of a pole line.

During 1926, an interesting application of carrier telephony was made on one of the two Catalina Island telephone cables. Because of the relatively short length of these cables and of their transmission stability, it has been possible to obtain in this way as many as six additional two-way circuits, making a total of seven telephone channels and one telegraph channel on a single-conductor cable. The apparatus employed in this system is similar to that used on open wire lines. By an arrangement of this character, the loss of one of the cables would temporarily reduce the number of telephone circuits only from eight to seven. This system was described in a paper by Mr. H. W. Hitchcock which was presented at the Pacific Coast Convention in September.

The use of carrier-current telephony for communication on power transmission lines has increased appreciably. The power circuits involved vary from those of 22 kv. to 220 kv. and the distances communicated over vary from a few miles to those in the order of 300 mi.

The coupling to the transmission lines which in the earlier stages of the art was effected in some cases by means of parallel wires is now being accomplished very largely by coupling condensers or capacitors which are now available in several types for voltages up to and including 220 kv. Considerable progress has been made in the development of by-pass apparatus, repeater stations, portable equipment, and various other supplementary pieces of apparatus. With the increased application of this form of communication, the demand is rapidly increasing for multiple communication channels, particularly in connection with the more extensive individual power systems where load dispatching is divided into districts and in the case of the rapidly growing number of transmission line interconnections between the large power systems.

Transcontinental Telephony

An important event during the year was the completion of a new transcontinental telephone and and telegraph route. The new route connects Chicago with Seattle by way of Minneapolis, Bismarck, Billings, Helena, and Spokane. The through circuits comprise at the present time three telephone circuits and 14 superposed telegraph channels. The repeaters in use on these circuits represent the very latest development in this field.

There are now three transcontinental telephone routes in service, the others being routed, one through Omaha, Denver, Salt Lake City, and Sacramento, and one via St. Louis, Dallas, El Paso, Phoenix, and Los Angeles. A discussion of some of the more interesting transmission problems and other considerations which

are important factors in determining the design of these facilities was presented at the Pacific Coast Convention at Salt Lake City last September in a paper by Messrs. H. H. Nance and O. B. Jacobs entitled *Transmission Features of Transcontinental Telephony*.

Loading of Telephone Circuits

An outstanding development in loading coil design which has been put into commercial use in the past year is the use of permalloy in compressed powdered form in the cores of some types of these coils. The application of this desirable magnetic material has resulted in material reductions in both the size and cost of loading coils. The lower cost of loading resulting from this and the other improvements in loading coils referred to in last year's report is, together with the large installations of toll cable in this country, bringing about a very large increase in the use of loading coils.

Electrical Amplification

In the development and application of amplifiers, there is sometimes occasion for amplifying extremely weak signals. Considerable interest attaches to the question of what limitation, if any, is imposed on the strength of the signals that can be amplified. Recent researches have shown that the limit of amplification may be set not by noises coming from the vacuum tubes or the batteries supplying them, but instead from the internal characteristics of the electrical conductors comprising the circuit whose minute currents are to be amplified. In any electrical conductor, minute electromotive forces are continuously produced by the thermal agitation of the electrons and atoms. This is true whether or not external electromotive forces are connected to the conductor. When an electrical conductor is connected to the input of a carefully built amplifier of sufficiently high amplification, readily audible sound may be heard in a telephone receiver connected to the output of the amplifier. The fact that the noise does not come from the amplifier can readily be proved by cooling the conductor by means of liquid air, when the noise heard in the receiver immediately diminishes in intensity, the reduction in noise being due to the reduced thermal agitation in the conductor. The laws underlying this phenomenon were determined experimentally by Mr. J. B. Johnson and presented in a paper at the December 1926 meeting of the American Physical Society at Philadelphia. These laws were later deduced from thermodynamical considerations and presented by Mr. H. Nyquist at the February 1927 meeting of the American Physical Society at New York.

Characteristics of Speech

The continued researches in the characteristics of speech and hearing and the nature of vocal and musical transmission have continued to give results of great importance for the improvement of telephone service, and have also led to many noteworthy developments in allied fields. A very important development based on these researches is the combination of improved phonographic recording devices and high quality reproduction synchronized with motion pictures.

A paper by C. F. Sacia and C. J. Beck entitled "The Power of Fundamental Speech Sounds" published in *The Bell System Technical Journal* of July 1926 describes the continuing work in the study of speech power by means of the oscillograph. Sounds are considered individually on the basis of instantaneous and mean power. In earlier analyses, the principal emphasis was placed upon the power in speech as a whole.

Radio Telegraphy

Long distance radio telegraph communication is rapidly changing from long waves or low frequencies generated by alternators or Poulsen arcs to short waves or high frequencies generated by thermionic tubes. Within the last 18 months, transmitters up to 40-kw. capacity operating on frequencies of 10,000 to 20,000 kc., 30 to 15 meters, have been produced and put into service. These are replacing arc generators up to 500-kw. and alternators of 200-kw. capacity. Reliable continuous daylight communication has been obtained by using wave lengths around 15 meters, notably between New York and Buenos Aires. During hours of darkness, wavelengths from 25 to 75 meters have been in use in both transatlantic and transpacific services. The greater reliability of the short waves is the result of almost complete immunity to summer static, and the new system is much more economical because of the low power consumption compared to that used for long wave transmission.

The scope of international radio service was further extended during the year by the opening of direct radio circuits for duplex operation between the United States and Brazil.

An analytical study entitled *Behavior of Radio Receiving Systems to Signals and to Interference*, made by Professor L. J. Peters, was reported by him at a Regional Meeting of the Institute at Madison, Wisconsin, in May 1926. This paper discusses methods for studying transient effects of current in radio systems, the degree to which interference can be mitigated by frequency selection methods, and the factors determining the interference caused by transmitting stations of various types and by static.

Transatlantic Radio Telephony

An event of outstanding importance in the progress of international electrical communications occurred early in the present year with the opening of transatlantic telephone service between the United States and England. This first telephonic bond between America and Europe was opened to the public on January 7, 1927, following an exchange of brief greetings

between Mr. W. S. Gifford, President of the American Telephone and Telegraph Company, and Sir Evelyn Murray, Secretary of the General Post Office of Great Britain.

Although the service was at first limited to the metropolitan areas of New York and London, during the months following, service was extended successively to greater areas until it has included most of the British Isles on the European end and the United States and Cuba on the American end. No attempt has been made to give 24-hr. service, but service has been available daily for the period which includes the overlapping portions of the business day at the two ends, and is being extended.

The principal features of the system added since the description given in last year's report of this committee are that arrangements were perfected whereby both the east-bound channel and the west-bound channel are transmitted in the same frequency band. Thus, the entire two-way system occupies only 3 kc. (58.5 to 61.5 kc.). One thing which contributed materially to this accomplishment is the employment at both terminals of voice-current operated switching devices which function to cut the transmission path to and fro from west-bound to east-bound automatically in accordance with the flow of conversation between the two speakers.

Radio Broadcasting

The results of investigations carried out during the last few years in ascertaining the service area for which broadcast transmitting stations are effective were summarized in a paper entitled *Radiobroadcast Coverage of City Areas* presented at the New York Regional Meeting last November by Mr. Lloyd Espenschied and printed in the January issue of the Journal. This is a subject that is receiving considerable attention. These investigations raise questions regarding the desirable power levels to be used for radio broadcasting.

Electrical Transmission of Pictures

During the year the scope of the commercial telephotograph service which has been given for two years between New York, Chicago, and San Francisco was materially enlarged by the extension of the network to Boston, Cleveland, St. Louis, Los Angeles, and Atlanta. Several important developments have taken place during the year, notably the arrangement of the circuits for two-way operation, the installation of phase-correctors on the New York-Boston and Chicago-St. Louis telephone cables to make these circuits suitable for picture transmission, and the fitting of the southern transcontinental route to make it available for service to Los Angeles and San Francisco.

Television

On April 7, 1927, a successful demonstration was given of electrical television by wire circuit between Washington, D. C., and New York, and by radio from an experimental station at Whippany, N. J., to New York.

Television employs many of the principles and some of the apparatus of telephony. The object of television is to reproduce a scene with action, and to do this a series of essentially instantaneous views must be transmitted and reproduced at a rate, 15 or more per second, such that an observer will detect no discontinuity of action. In its present form, the sending apparatus is adapted to obtaining for one participant in a telephone conversation a continuous view of the face of the other participant. The receiving apparatus recreates this view on a picture plane about two by two and one-half in.; or, with a alternative form of apparatus, on a plane about two ft. sq. for observation by more than a single person.

At the sending end a narrow beam of light, or rather a rapid succession of beams scan the subject to be transmitted, illuminating at one time an area about a quarter of an inch square and sweeping over the entire scene in less than one-fifteenth of a sec. This scanning process is repeated continuously. A group of large photoelectric cells responds to each change in the reflected light.

At the receiving station, a glass tube filled with rarified neon gas and provided with electrodes responds with a brilliancy corresponding to the current received from the photoelectric cell. The high potential requisite to the operation of the neon tube is obtained by the use of vacuum tube amplifiers in the connecting circuit. All parts of the neon tube have the same brilliancy at any instant but the observer views only a small portion at a time, which is uncovered by the synchronizing apparatus provided to insure that the light shall appear to the observer at each instant in the same position on a picture plane as that occupied by the beam-illuminated spot of the distant scene.

In the production of the larger image, a very long neon tube is folded back and forth to form a grid. This tube is provided with 2500 electrodes along its length. Each electrode corresponds to a single elemental area of the picture plane which is scanned by the light beam of the transmitting apparatus. As the current corresponding to each area reaches the receiving station, it is distributed through contacts to the appropriate electrode and so causes a flash of light similar in location and intensity. The speed of operation causes the observer to see not a series of flashes but a picture as a whole.

New Rectifiers

A new type of rectifier suitable, among other uses, for charging batteries used in communication circuits was described in a paper by Messrs. L. O. Grondahl and P. H. Geiger presented at the Winter Convention. The rectifier consists of partially oxidized disks of copper. The rectification appears to take place at the

junction between the copper and the oxide without observable physical or chemical change, and is similar in character to rectification by the hot cathode type of rectifiers.

Manufacture of Copper Wire

The developments of the past few years have led to great improvements in the methods of drawing copper wire, particularly in the speed of the process. Some of the outstanding features in these developments, together with a description of a copper rod and wire mill designed to meet the new requirements and a brief survey of the copper rolling and wire drawing art, are included in the paper entitled *Developments in the Manufacture of Copper Wire*, by J. R. Shea and Samuel McMullan which was presented at the Winter Convention of the Institute.

Wood Preservation

During the past year, a large amount of research work has been continued in improvements in methods of preserving wood poles, crossarms, and other timber. As a result of studies which have been made by the Western Union Telegraph Company, they are placing in service a treatment by which a solution of zinc and arsenic is forced into the poles. Their investigations indicate that on exposure of the treated wood to the atmosphere, chemical changes take place which deposit in the wood zinc arsenite, a toxic material which is practically insoluble and permanent, and that this will constitute a very effective method of preservation against decay.

Fire-Alarm and Police Signal Systems

The past year has seen some further refinements in alarm signaling devices. These were chiefly along the lines of simplification and increased reliability of recording devices, improved insulation for street fire-alarm boxes, and improved protective devices for circuits entering buildings. The early fire-alarm devices were insulated against other signaling circuits only; circuits entering buildings had only the comparatively simple lightning arresters then known to the electrical telegraph art. Now, with fire-alarm circuits on the same pole lines with 2300- and 4300-volt circuits, a high grade of insulation of the associated apparatus has become necessary. Recent improvements in boxes have been made to provide this necessary protection.

There has been a considerable increase in the use of electric sirens as fire-alarms in smaller communities where the expense of maintaining normally closed telegraph circuits for this purpose would be felt as a burden. The sirens are generally operated on normally open circuits actuated from the public power supply.

In April, the seventy-fifth anniversary of the opening of the first electrical fire-alarm system in the United States and the first successful one anywhere was celebrated. An exhibition was held at the new fire-alarm office in the Fenway, Boston.

There has been a general tendency toward the adoption of the red-amber-green cycle of signals for the regulation of traffic; red to stop, amber to warn of change and permit clearing of intersections, and green to go. This three-light cycle gives opportunity for control or stopping of all wheeled traffic in congested sections while foot traffic is permitted to proceed, and for stopping all traffic during the passage of fire apparatus, police cars, ambulances, etc. There has also been a widespread tendency toward synchronizing signals along a street or throughout a district. In the town or small city, the business district is frequently concentrated along a main street. Hence it becomes comparatively easy to synchronize signals along this street so that traffic may move fairly continuously for certain intervals, during the long intervals along the main street, during shorter intervals across the main street, with still shorter intervals between these while the light shows amber to clear the traffic from intersections. In some places this control obtains only during the period of heavy traffic; at other times only flasher or caution lights are shown at certain intersections. In the larger cities, this synchronizing may cover a large congested section so that by due attention to the time intervals between signals points, traffic moving at an average rate may proceed with little or no stopping. The possible saving in traffic police and in consequent expense due to carefully planned signals of this type is evident.

H. P. Charlesworth, *Chairman.*

Production and Application of Light

Report of Committee on Production and Application of Light*

To the Board of Directors:

In accordance with requirements of the by-laws, there is submitted herewith a review of the development during the past year of the art of lighting with electricity. This review constitutes the annual report of your Committee on Production and Application of Light. It has been prepared through the cooperation of members of the Committee.

The personnel of this Committee has been chosen with a view to insuring comprehensive consideration of the subjects lying within the purview of the Committee. Its members concur in the view expressed by the Committee to Review Technical Activities in a report dated June 26th, 1924, to the effect that this Committee should function in an "initiatory and determinative" capacity in matters pertaining to the production of light and in a "joint or reportorial" capacity in matters pertaining to the application of light. Accordingly, the Committee endeavors to maintain close touch with developments in the production of light by electricity and looks to organizations more specifically concerned in the application of light for information as to developments therein.

Production of Light

No developments in the production of light from electricity which are new in principle or which constitute a radical improvement in the art have come to the Committee's attention during the past year. Progress in the development of illuminants described in earlier reports is reviewed briefly in the following paragraphs.

Incandescent Filament Lamps. In the following paragraphs there is presented a brief review of significant changes in manufacture and utilization of incandescent electric lamps.

The past year has witnessed the general introduction of incandescent lamps with bulbs frosted on the inner surface, announced in the report of this Committee last year. Eighty per cent of the demand for replaceable types is now being supplied by lamps of the new type.

Among tungsten filament incandescent lamps the gas-filled principle has been extended to lower wattages than heretofore employed in this type for general lighting purposes in this country, though not to such small wattages as those in which it has been sometimes employed in Europe. In the 50-watt 115-volt size the principle has been applied to what appears to be the minimum size for which its use is justifiable in the present state of the art.

Limited ability to withstand rough usage and vibration has always been a handicap of the tungsten filament lamp. Despite notable improvements by American lamp manufacturers, which have increased greatly the sturdiness of the filament, it remains true that after some hours of burning, the filament crystallizes and becomes less sturdy than the filament of a new lamp, and too fragile for some forms of service.

In an effort to meet requirements for rough service (for example, in garages, where lamps are used on portable cords), manufacturers have recently developed a "rough service" lamp. This lamp is available in the 50-watt, 115-volt range. It is of the vacuum type and has a bulb of the same size as the usual 25-watt lamp.

Where continuous, high-frequency vibration is encountered (as that due to high-speed machinery), the lamp manufacturers recommend, if small lamps must be used, the 50-watt coil filament vacuum lamp in the P-19 bulb. It is preferable, however, to use larger, more sturdy lamps, and if necessary, to employ vibration reducing devices.

Two lamps for decorative service have been made available during the year in new forms of flame-shaped bulbs. One is of 15 watts with a candelabra screw base. A similar lamp had previously been supplied in a bulb having spiral fluting. The other is a 25-watt lamp with a medium screw base. These lamps are regularly supplied with a flame tint coating to add to the effect suggested by their flame shape.

According to a recent report issued by the Lamp Committee of the National Electric Light Association, carbon lamps are being used to a surprisingly large extent in ordinary lighting service. Because of their relatively low efficiency, the cost of producing light with these lamps usually is greatly in excess of that applying in the case of tungsten filament lamps.

The trend of operating practise appears to favor 115 and 120 volts. The demand for 110-volt lamps is steadily decreasing and is now only 12 per cent of the total in the 100-130-volt range; 115 volts accounts for 48 per cent and 120 volts for 35 per cent, leaving only 5 per cent for all other voltages in this range. The total number of lamps supplied from 200 to 260 volts is now but 3 per cent of the number supplied in the 115-volt range and this percentage is gradually diminishing. The concentration of lamp demand upon the fewest practicable number of voltages is desirable as a means of eliminating needless and expensive complications in manufacture and distribution.

The 23- and 36-watt lamps for street railway headlight service are now made in the "A" shape bulb of clear glass. The change from the round bulb

*Committee on Production and Application of Light:

	George S. Merrill,	

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

(G-18½) in which they were formerly supplied, enables one standard light center length of 2 3/16 inches to replace 2 1/16 inches, 2 3/16 inches and 2¼ inches light center lengths in the old bulbs. This can be done because the shape of the A bulb permits a wider range of adjustment of lamp position in the headlight.

A special lamp has been developed for use in traffic signals. It is a 60-watt gas-filled tungsten filament lamp in a clear bulb of the shape and size used for the regular 40-watt lamp in the inside-frosted line. The filament is semi-concentrated to permit of more accurate light control by the signal lenses. The lamp has a light center length of 2 7/16 inches. It is designed for burning in either a horizontal or base down position.

To premote simplification in the line of lamps for series burning, it has been recommended that street lighting circuits now operating at 4, 5.5 and 7.5 amperes be changed over to 6.6 amperes, for which there is by far the greatest demand. The progress of standardization in this respect is slow.

There is still a demand for series burning lamps of 600 and 800 lumens (approximately 43 and 55 watts respectively) which, it is generally believed, could be replaced advantageously with lamps of at least 1000 lumens (approximately 65 watts).

Series Lamps Unsatisfactory on Multiple Circuits. Some use has been made of series lamps operated with auto transformers from multiple circuits. Investigation of this form of operation has shown that multiple lamps operated on multiple circuits are more economical and give more satisfactory performance than any of the series lamp auto transformer combinations. The series lamp is designed to burn at a constant current which means that the filament cross sectional area is very accurately determined while variations in manufacture are noted by changes in filament length. This manufacturing variation is particularly noticeable when a series lamp is burned on a constant voltage circuit. Furthermore, in the larger size series lamps, a large amount of filament material during the normal life of the lamp is evaporated and deposited on the bulb. This blackening causes a decrease in lamp candle power. When the series lamp is operated on a constant current circuit the decrease in filament area results in an increase of brightness which partially offsets the blackening of the bulb. A lamp burned at constant voltage however, suffers because of diminution of current as the lamp ages due to increased filament resistance. It is seen, therefore, that all the factors present in both multiple and series lamps which make for decrease in lamp output are combined when a series lamp is operated on a constant voltage circuit.

The lamp manufacturers recommend that multiple lamps be burned on multiple circuits and that series lamps be burned only on series circuits.

Luminous Arc Lamps. It is understood that there have been no material changes in the design of construction of the luminous arc lamp during the past year. The modern lamp, with its shorter casings and larger globes, as constructed for service in Washington and elsewhere, represents the latest development in this type of lamp which, as shown elsewhere, is employed rather extensively in street lighting service.

Ultra-Violet Radiation. Efficient production of ultra-violet radiation is accomplished by electric discharge through vapors, usually of a metallic nature. The conditions of use impose the further limitation that the source, particularly one of the arc type, be completely enclosed to prevent the egress of undesirable vapors in therapeutic work, or the ingress of inflammable vapors in chemical work. The mercury arc in quartz, being inherently an enclosed arc, is uniquely adapted to use as a source of ultra-violet radiation. Units of 450 and 900 watts capacity for operation on 110 and 220 volts respectively have met with increasing use during the past five years. The former are used largely in therapeutic work for the direct irradiation of patients in the treatment of rickets, bone tuberculosis, skin diseases, superficial infections, etc., while the latter are used for water sterilization, the testing of materials, irradiation of foodstuffs to produce antirachitic properties, the treating of leather, varnishes, etc.

The use of rare gases as an aid in the starting of discharge has recently permitted the design of a practical induction lamp having unique properties when made of quartz. It permits greater control of the relative ultra-violet energy distribution than before was possible and it is especially well adapted to the solution of many of the mechanical problems limiting the usefulness in photochemical processes of the older mercury arcs.

It is said to be possible to duplicate economically by means of these artificial ultra-violet sources practically any photochemical effects now secured through exposures to direct sunlight. This is important for sunlight, though inexpensive, is offset by the fact that it is of value only during the middle five hours of the day, if available at all.

As an example of a highly developed ultra-violet application, mention may be made of a recently designed apparatus in which, by means of a quartz mercury arc and filters, tests may be made of the light fastness of dyed textiles, inked papers, or painted woods in a much shorter time than ever has been possible by sunlight and with a quality of fading action directly comparable with that of sunlight.

Application of Light

In contrast with the relatively meager developments in the production of light, the past year witnessed a wealth of development in the application of light. Artificial light is now available at such a low cost that improvement in its utilization can be undertaken with greater freedom. In consequence the lighting art is advancing rapidly.

Residence Lighting Equipment. The past year has seen an expanding interest on the part of central station

companies in residence lighting equipment. Several companies have conducted re-fixturing campaigns with marked success and many are planning such activities for the current year.

Interest in this project is evidenced by the preparation, beginning in the autumn of 1925, of tentative specifications for residence luminaires, prepared under the supervision of a committee of the Association of Edison Illuminating Companies, with which the Illuminating Engineering Society has cooperated. These specifications promote consideration of a luminaire from three principal standpoints:

1. Illuminating qualities
2. Mechanical and electrical construction
3. Aesthetic values

The application of these specifications results in a final figure of percentage which represents the over-all quality rating for each luminaire considered. Part of the determination of necessity must be arrived at by personal judgment and part by laboratory measurements. Very consistent results have been obtained by using averages of the personal judgments of several competent persons. An interesting by-product of this activity is the production of a practicable glare-gaging device, in the form used in the measurement of glare in residence luminaires.

The Home Lighting Committee of the National Electric Light Association has already prepared outlines of typical plans for such re-fixturing campaigns. Other information and material is being prepared and will be disseminated by that Committee throughout the year. The month of October has been chosen as the period of specialized activity in promoting improved residence lighting.

There is a noticeable trend in manufacturers' lines toward luminaires embodying provisions for the shading of lamps, although the development is far too slow to be considered as satisfactory. Several inexpensive devices are on the market to enable the use of shades on modern types of lamps.

Street Lighting. The attitude of the electrical industry toward street lighting seems to be undergoing a wholesome alteration. Street lighting is coming to be regarded as a phase of utility operation which is capable of becoming remunerative both to the community and to the utility. Accordingly, both the engineering and commercial aspects of street lighting are being given more intensive and forward-looking consideration than in the past. It is coming to be recognized that through comprehensive planning, coupled with general plans for city improvements and growth, economies may be had through standardization, reduced obsolescence, efficient energy distribution, and control.

It is generally recognized that street lighting deserves the accurate methods of the engineer since nationally we are confronted with the need for many extensive improvements. There is dawning a new era in street lighting, trailing the new era in vehicular traffic. Street lighting systems for the main streets of large cities, and some already in use, have been designed to deliver 50,000 to 150,000 lumens (2- to 6-kw. demand) per standard instead of 10,000 to 15,000 lumens (0.5- to 0.75-kw. demand) which was considered adequate in the past.

Progress has been made in the manufacture of equipment for remote control over existing commercial networks to widely scattered relays actuating switches to supply the street lights from existing distribution systems. Several new remote control switches, both solenoid and motor operated, have been developed to be controlled from a pilot wire.

These new equipments are suitable to supply the power for either series or multiple lamps and may be selectively arranged to disconnect alternate units during the late hours of the night when there is little traffic. These various control equipments are receiving more attention with the trend toward increased load density.

There has been considerable activity in the further development of enclosing glassware for street lamps. The tendency seems to be in the direction of a compromise between directional control and diffusion, the one intended to place the light where it is wanted, and the other to avoid excessive glare.

In overhead lighting equipments the trend is definitely toward the use of dust-proof units, to obtain a higher average efficiency between cleaning periods by avoiding the absorption of light otherwise due to the collection of dirt on the lamp bulb, and on enclosing accessories.

The Illuminating Engineering Society's Committee on Street Lighting is making progress in developing a method of appraising the qualities of street lighting to determine the relative illuminating merits of various street lighting installations.

The Street and Highway Lighting Committee, National Electric Light Association, has outlined a three-year program to cover thoroughly the sales and financing aspects of street lighting systems. It purposes issuing a manual on street lighting.

The lighting of interurban highways is slowly progressing with promise of greatly accelerated growth in the near future. Rural electrification is an interlinking factor, and nation-wide legislation providing enabling acts is the primary desideratum. There are many indications that as legal obstructions are removed, large growth in highway lighting will follow. The problem in its present status is one of legislation rather than of engineering. However, more engineering analysis and evaluation of the social economic aspects of highway lighting will hasten the required legislation.

Table I presents a partial list of intensive street lighting systems in the United States as of March 1st, 1927. Additional intensive installations are being made or are planned in several other cities. From this list it is evident that existing high intensity installations

are divided between luminous arc and tungsten lamps, although present indications point to a trend toward tungsten installations in the immediate future.

*As an index of grade of lighting "lumens per linear foot" is evidently inexact. No better basis of terse statement is, however, available for these installations.

Signal Lights for Traffic Control. The need of standardization of electric traffic signals is apparent. In some cities one may make a right or left turn on a red signal while in others such a movement is prohibited. There seems to be a divergence of opinion as to whether there should be three colors or two. A committee appointed by the governor of an eastern state has recently gone on record as approving a two-color system, while a similar committee in a neighboring state has also gone definitely on record as favoring a three-color system. Tourists traversing these two states are likely to encounter trouble.

There also seems to be a wide difference of opinion as to the proper location of signals. Some city officials prefer the pedestal type mounted in the roadway; others prefer the bracket type of suspension from messenger wire across the street. It is not unusual to hear of controversies between officials of the State Highway Department and of municipalities as to the type of signal. Most of the State Highway Departments will not permit the use of pedestal type signals on the roadway owing to the fact that if they fail to light they become a hazard.

The lack of standardization in the use of the colored lights in connection with the control of traffic has made it difficult for the police to enforce the regulations. It is needless to dwell further upon the chaotic conditions which exist at the present time. The traffic problem requires the cooperation of the architect, civil engineer, police officials, electrical engineer, illuminating engineer, transportation engineer, etc., in order that all the various phases of the problem may receive due consideration. All of these are concerning themselves with it, but often independently and without coordination.

In a recent number of the *Architectural Forum* there is an article by a nationally known architect which deals with the relation of the height of buildings and the density of pedestrian traffic upon the streets.

Out of this maelstrom of independent activity comes the announcement of the organization of a committee of the American Engineering Council, under the chairmanship of Dean Dexter S. Kimball, of Cornell University, which shall study the problem and prepare a standard code, so that when the automobilists from New York are driving in San Francisco, or vice versa, the signals will carry the same message. Such standardization now exists in the railroad industry where red to the railroad man means only one thing—danger. Yet the general public has been educated to regard the use of red light in a building as a safety exit in case of fire, or, on a street, a safety aisle. In navigation the use of red for port and green for starboard is standard the world over. Possibly after the standardized code for the control of traffic is available, action can be taken to replace the red lights in the interior of buildings as an indication of safe exits in case of fire.

Automobile Headlighting. The art of automobile headlighting is receiving a great deal more attention than many people, perhaps, know. While it cannot be said that any great developments have been recently consummated, it is still a fact that efforts by many agencies, along different lines, but all directed toward the same object, have considerably advanced the general knowledge of the subject and have brought an ultimate satisfactory situation just so much closer. Among such activities now in progress, are: recognition of the Uniform Vehicle Code, enforcement of headlight laws, activities productive of a better understanding of the nature and prevention of glare, the relation of automobile headlighting to street lighting, mechanical requirements for headlights, and recognition of the shortcomings of present equipment.

The most notable development in automobile lighting practise during the past year has been the very general adoption by manufacturers of the better grades of cars, of a changeable beam headlighting system. This has been approved by all the states as legal. A brief review of the history of this development may not be out of place here.

A number of years ago, the Illuminating Engineering Society and the Society of Automotive Engineers,

working together, endeavored to improve the unsatisfactory condition of automobile headlighting by adopting a set of minimum and maximum limits covering a light distribution that would yield a maximum of good driving light and a minimum of objectionable glare. These limits were based on permanent and fixed adjustment and pointing of the headlights. In the nature of things, these limits were a compromise, but were so well worked out as to produce a marked improvement in road driving conditions after dark.

Since these limits were adopted, however, there has been a considerable change in many of the elements of the problem. The average height of the eyes of drivers above the road surface is considerably less than it was five years ago, due to the constant lowering of cars. Vehicle springs are now being made softer than they used to be. Cars therefore pitch through greater angles due to road inequalities. Furthermore, because the passenger load comes very largely on the rear springs, there is a big change in car angle under varying conditions of load. Having these changed conditions in mind, committees of the Society of Automotive Engineers and of the Illuminating Engineering Society jointly undertook to devise specifications covering the use of an alternative distribution of the headlight beam for use in passing another car. The driver is then expected to change from one type of distribution to the other as conditions demand. Experience has shown that drivers can be trusted to do this if they are provided with a reasonably good passing light.

By the use of the alternative system of distribution of the beam, two things are accomplished: first, a great amelioration of the glare difficulty is obtained by the use of the changed beam, and second, since the beam can be removed from other drivers' eyes, the adjustment of the headlamps may be such that the top of the beam is higher than with the fixed beam equipment, thus providing a better driving light where the absence of oncoming cars renders it practicable to keep the beam in its normal position.

At the present time, a joint committee, composed of members of the two societies, is conducting research to determine the proper limits to govern the new types of light distribution. Without waiting for the final results of this committee's work, many motor car companies are adopting systems in which the regular driving beam is lowered through an angle of two or three degrees in passing another car. A number of simple and economical ways are now available for accomplishing this result and the public approval of the change has been very marked

The old system of reducing the candle power by dimming is condemned by everyone and it is hoped that it will become obsolete in the near future.

Lighting of Exteriors. The advantages of flood lighting have been amply demonstrated, not only by the number of large installations during the past year, but by the diversified character of the installations. Illumination intensities have in general been higher, and larger numbers of projectors have been used on individual installations than have ever been used before.

Two state capitols, those of New Jersey and Texas, were added to the list of half a dozen or more that have been flood-lighted previously. Two large office buildings in Detroit were lighted; in one case over three hundred and the other over one hundred projectors were used. In Brooklyn over one hundred projectors were used on an office building, and in New York nearly five hundred projectors are employed to light the upper portion of a new theater. Kansas City has lighted its huge war memorial by means of searchlights; steam emerging from the top is illuminated by colored light from projectors concealed in the top.

Great interest is developing in lighting recreational areas. In order that children may be kept from the streets, school and public playgrounds have been lighted. Colleges in increasing numbers are lighting their stadiums for night football. Considerable impetus was given this movement by the success of the lighting of the stadium at the Philadelphia Sesqui-Centennial grounds.

Electric Signs for Daylight Use. Electric lighting display, having been highly developed in this country for night use, is being extended into the daylight hours.

Tubes of neon and other gases or vapors offering striking color contrast with daylight are entering into service in some sections of the country quite extensively. This follows a like development in Europe.

The diameter of the neon tubes which are ordinarily employed for signs varies from 7 to 32 millimeters (usually 11 to 15 millimeters). The characteristic orange-red color of neon predominates in displays erected to date but other colors are to be seen. These are derived from the admixture of helium, argon, etc. The characteristic radiation of mercury vapor is likewise to be seen in some signs.

The tubes vary in length from 10 to 40 feet. Starting voltages are approximately 200 volts per foot of the tube; alternating current 25 to 60 cycles is employed, rotary converters being used where the supply is direct current.

For typical tubes of 20-foot length and 15-millimeter diameter, the manufacturers state that the consumption is about 200 watts. This increases rapidly if the diameter of the tube is increased. The power factor of such a sign is stated to be approximately 50 per cent.

The usual filament-lamp electric signs are being adapted in some cases to daytime use. For this purpose an area of brightness is built up optically so that the entire surface of a letter is given the brightness of the filament itself when viewed from certain directions.

In obtaining a large area brightness, the light has been concentrated into a relatively narrow angle; hence, within this angle only is its effectiveness at a maximum. Such a sign is of greatest value when the traffic is massed within a relatively narrow viewing angle, and where

people approach the sign nearly "head on" for a considerable distance. There are many such locations—atop the marquise projecting over the sidewalk; at a dead-end street; on a highway curve;—where the new type of sign may be effective.

Illuminated Bulletin Boards. The use of illuminated poster and bulletin boards is rapidly increasing and it is noted that more consideration is being given architectural features as well as the use of novel lighting, and mechanical effects.

The appearance of animation or action is sometimes accomplished through color by the absorption method. The advertisement is painted on the bulletin board with carefully selected oil colors. There are two lighting equipments, one for example, for red lighting and the other for blue-green lighting. Supply circuits are controlled by a two-circuit flasher so that by the alternate flashing of the red and blue-green lights, the fading out of certain words or images on the bulletin is accomplished. For example, the red light will apparently "absorb" the red painted images or words on the sign leaving visible only the darker colors which do not contain red. Equivalent effects are had with the blue-green.

A rather interesting mechanical bulletin board has made its appearance in the Middle West. The face of this board consists of a series of equilateral triangular members each of which operates on an axis so that the entire face of the sign revolves simultaneously. In this manner three separate advertisements can be painted on the respective faces of the triangles. An electric motor operates the mechanism so that the sign may be changed four times a minute. These displays are illuminated for night operation.

A rather effective plan has been worked out whereby the use of a modern show-window is combined with a billboard. The show-window is built flush with the face of the bulletin. The bulletin bears the usual advertising, while behind the plate glass of the show-window is arranged a display of merchandise. The face of the bulletin is lighted by means of angle reflectors in the usual method and the interior of the show-window is illuminated with show-window reflectors.

It is interesting to note that the electrical advertising industry has taken action to improve the appearance of bulletin boards and also to restrain members of their industry from installing posters and bulletin boards in places where they impair the beauty of the scenery. The unrestrained activity on the part of various poster advertising companies in locating their stands in places where they detract from the natural beauty of the landscape has caused very unfavorable public comment and it is logical that the industry should take action to remove the cause of the criticism.

Lighting for Aviation. The rapid advance of aviation, especially in the United States Air Mail Service, has given rise to demand for lighted air-ways. It is reported that 3700 miles of transcontinental route are now lighted and appropriations have been passed for lighting the following routes for 1927:

New York to Boston
St. Louis to Chicago
Dallas to Chicago
Salt Lake City to Los Angeles
Pasco to Elko
Chicago to Twin Cities
Cheyenne to Pueblo

Under the auspices of the Department of Commerce there has been developed a lighting system, employing usually 24-inch revolving beacons, equipped with 900 or 1000-watt tungsten lamps located at average intervals of ten miles along the air routes. Intermediate landing fields are located every 25 miles along the routes, each equipped with a beacon and 20 boundary lights. A green approach light and red lights on top of obstructions near the fields are used.

A typical airport has approximately 30 kw. of lighting load, involving from $5000 to $12,000 worth of lighting equipment. It comprehends:

1. Revolving beacon to guide the aviator to the airport.
2. Boundary lights (60-c. p. series) all around the field to show the limitation of the boundary area.
3. Red lamps on all obstructions near the field, such as radio towers, telegraph poles, etc.
4. An illuminated wind indicator to show the strength and direction of the wind.
5. A ceiling light (1000-watt, 18-inch searchlight) to show the height of the bottom of the clouds.
6. Flood lights on the roofs and sides of the hangars (200-watt lamps).
7. A high-intensity arc searchlight, or a couple of 10-kw. tungsten lamps to floodlight the landing field itself.

There are already nineteen lighted fields in the United States and forty others from which regular flying is being done on such schedules that lighting is required. Many cities are alive to the coming air commerce, and are appropriating funds to prepare lighted ports. It is a movement which is spreading very fast. Estimates indicate that by the end of next year there will be 2000 lighted fields in the country.

In 1926 the Post Office Department used on their fields in the Air Mail Service, 3710, 900- and 1000-watt lamps; 1920 200-watt lamps and 1440 600-lumen series lamps. The 1927 plans are for over three times as much air mail service as in 1926, with a corresponding increase in lighting.

Subterranean Lighting. The new vehicular tunnel from New York to Jersey City offers the outstanding installation of this class of electric lighting. It will probably be the most heavily traveled long tunnel in the world.

Although the main travel will be in one direction in each of the two tubes, the use of unidirectional lighting was impracticable because of the possibility of only one

tube being used for travel in both directions when repairs are being made. The lighting is accomplished by incandescent lamps behind windows set at the joints between the side walls and ceiling, and arranged so that the units on one side illuminate the opposite half of the tunnel, and avoid glare in the eyes of drivers. About two foot-candles are provided, with an overlapping distribution to minimize shadows from high vehicles.

At each end additional light is provided for daytime use, to lessen the contrast with daylight.

Railway Lighting. Developments in lighting in the steam railroad field during the past year or so have largely kept pace with the general development in other fields of lighting. As a whole, railroads are appreciating the benefits of higher intensities of illumination, particularly in shops and offices where artificial illumination may be required a large percentage of the time, with the consequence that the average levels of illumination intensities for interior lighting throughout the railroad field are being considerably raised.

Considerable attention is being given to providing better illumination in passenger carrying cars. In the matter of intensities the best practise of today represents from 75 to 100 per cent higher average illumination intensities than the practises of eight or ten years ago. This has been made possible by the improvements in the efficiencies of train lighting lamps and the successful development of lamps of higher wattages, also the development of economical car lighting axle generator equipment and batteries of larger capacity.

The past year has seen very rapid growth in the general interest in the subject of flood lighting as applied to railroad yards, as well as the application of this system at a rapidly increasing rate. The proper and economical lighting of large railroad yards presents many problems, in which connection, until recently there has been available but comparatively little engineering data that would aid in laying out such lighting systems. There is also still considerable difference of opinion among railway engineers as to the system of flood lighting that will produce the most effective results. This subject is being actively studied by the Committee on Illumination of the Association of Railway Electrical Engineers and it is expected that by another year illuminating engineering practise in the application of flood lighting in this field will gradually crystallize along definite lines of procedure.

In view of the number of lighting problems that are more or less peculiar to the lighting field the Association of Railway Electrical Engineers has also prepared, with the assistance of the illuminating engineering staffs of the incandescent lamp manufacturers a "Manual of Lighting Practises for Railroads" which serves as a general code of lighting practise as applying to this field.

Illumination of Outdoor Substations. The illumination of outdoor substations is primarily intended to facilitate operation, but it has been found, in many cases, to have an advertising value as well. One installation recently described in the technical press emphasized the advertising value by employing a hot galvanized finish on all structural steel and two coats of aluminum paint on transformer cases, switch housings, and other exposed metal surfaces.

Lighted Ornaments. Artificial light has been employed thus far primarily for utilitarian purposes. Only occasionally, and to a very slight extent, has it been employed in residences for the illumination of ornaments. Evidently the potentialities of such employment of artificial light are very great. There are some indications that these potentialities are beginning to be realized, and in the not very distant future the employment of lighted objects of decoration solely for the purpose of ornament may assume considerable proportions.

Related Topics

Photometry. Progress in photometry during the past year has been principally in the application and use of the photoelectric cell in conjunction with suitable light filters. At the present time photoelectric photometers are largely used for routine measurements of incandescent lamps; this includes street series lamps, miniature lamps, colored bulb lamps, etc. The photoelectric cell equipment has also been adapted to distribution photometers, the spectro-photometer, and color temperature determinations.

The extreme sensitivity of the photoelectric cell equipment has permitted the establishment of light values to a much higher degree of accuracy than obtains with visual methods.

Effect of Illumination on Industrial Production. The Committee on Industrial Lighting of the Division of Engineering Research of the National Research Council has completed a three year study of the effect of illumination upon industrial conditions. A report covering this investigation will be published in the near future and will contain many points of interest to illuminating engineers and factory managers alike.

Lighting Service Manual. A manual for Lighting Service Departments, under preparation by a committee of the National Electric Light Association, is approaching completion. Part 1, which deals with the lighting field, organization activities, etc., has been finished. It will provide an excellent guide for central station lighting activities.

Schools of Lighting. Evidence of the increasing interest in illumination is shown by the demand for local lighting schools. These have become more numerous during the past year. As a rule they are promoted by individual central stations for the benefit of their employees engaged in lighting. In several instances they have included local electrical contractors and dealers and when this has been the case, the schools have been held under the auspices of a local electrical league or some similar body. The instruction in

these schools has been conducted mainly by the incandescent lamp manufacturers.

Illumination Items in the Journal. In view of the fact that lighting programs are included in Institute meetings only occasionally, this Committee has found it expedient to endeavor to keep Institute members advised of lighting developments through the medium of brief articles which appeared from time to time in the columns of the JOURNAL. List of titles of articles which have appeared during the past year is as follows:

A Daylight Electric Sign.
Lighting Totaling 25,000,000 Candle Power Burned Nightly in Broadway Signs.
Europe Organizes Its Lighting Activities.
Inside Frosted Lamps.
Trend of Electric Lighting.
Must the Traveler Read Slowly?
Practical Color Photometry.
Industrial Lighting Activity of N. E. L. A.
Meet the Well Lighted Car.
European Lighting Progress Discussed at Rome.
Illuminating Engineering in Germany.
Home Lighting Contest in France.
British Lighting Contest begins with a Burst of Enthusiasm.
A Recent Lighting Demonstration in Holland.
Incandescent Lamp Ratings in France.
Artificial Lighting in Foundries.
British Investigate Light and Industrial Efficiency.
Carbon Lamps.

CONCLUSION

The Committee on Production and Application of Light, notes with satisfaction advances which are being made in the application of electricity in the field of illumination, and is gratified to observe a tendency of the related industries to organize for more effective achievement along these lines. The potentialities in this field the Committee believes to be great, both in prospective engineering achievement and in benefit for the public.

P. S. MILLAR, *Chairman.*

Discussion

E. A. Williford: (communicated after adjournment) I should like to augment the information given in this report on the production and application of ultra violet light for medicinal and industrial purposes.

The chief natural source of ultra violet light is the sun. There are, however, many artificial sources of ultra violet light, among them being the various forms of carbon arcs, the mercury vapor arc in quartz, and other metal arcs.

The emanations from the mercury arc are confined to certain bands of wavelengths, especially in the shorter wavelengths in the region of 2200 to 3200 Angstrom units, with very little continuity of the spectrum. Every different metal gives its own characteristic quality of radiation when its vapors are introduced into the arc stream. It is possible, therefore, to control the quality of the radiation by modifying the chemical composition of the electrodes; or, in the case of the carbon electrodes, the composition of the core. The following are typical instances:

Arcs between pure carbon electrodes give ultra violet light chiefly of wavelengths from 3600 to 4000 Angstrom units.

If the electrodes are of nickel or if carbon electrodes are impregnated with nickel, a large proportion of the ultra violet is in a band from 3400 to 3600 Angstrom units.

Similarly, aluminum gives much radiation in the region of 2950 to 3300 Angstrom units, while cobalt gives an arc rich in the very short wavelengths from 2200 to 2500 Angstrom units and again from 3300 to 3500 Angstrom units.

Iron gives a large amount of radiation through the entire ultra violet spectrum. Cerium and the other rare earths give ultra violet from 2900 Angstrom units to the visible spectrum, quantitatively and qualitatively very similar to the spectrum of sunlight. For this reason, carbon electrodes impregnated with these rare earths have been found by the Bureau of Standards to be the nearest in quality to natural sunlight of any known artificial light source.

The materials referred to above are not toxic. They can, therefore, be used as arc electrodes without enclosing globes and without danger of toxic poisoning. If required for special applications, the arcs can be isolated from the surrounding atmosphere by suitably ventilated housings constructed partly of quartz or some of the newer ultra violet transmitting quartz substitutes.

These metals, if used as pure electrodes, give satisfactory arcs on two or three amperes of direct current. If the metals are used to impregnate carbon electrodes, so as to make the so-called impregnated or flaming arcs, they can be operated satisfactorily on either alternating or direct current at amperages from 2 to 150. Because of this wide range of energy consumption possible, any desired quantity of the particular type of radiation required can be obtained with these arcs.

The known applications of these different types of radiation are as varied as the qualities of the arcs themselves. For instance, those arcs giving long-wave ultra violet light are especially valuable in the photographic, photo-engraving, and blue-printing industries.

The arcs which give light similar to sunlight are essential in dye-fading and paint-testing work where such materials are ordinarily to be used in sunlight itself. Artificial sunlight from these arcs also is utilized by physicians to augment natural sunlight or to substitute for it when natural sunlight is not available in the treatment of tuberculosis and rickets.

Other electrodes containing metal are used when it is not necessary to attempt to duplicate sunlight. Such cases are those where it is sought only to produce a tan or artificial sunburn. Those arcs giving very short-wave ultra violet radiation give large amounts of light having a powerful sterilizing or germicidal action.

From the foregoing, it is apparent that it is possible to make a selection of an artificial source of ultra violet light that will best accomplish almost any work which requires the use of ultra violet radiation.

Electrical Machinery

Annual Report of the Committee on Electrical Machinery*

To the Board of Directors:

This committee has carried on its work during the past year according to the general plan of organization which has been in force for the past three years. The membership of the committee has been materially increased over the number of last year in an endeavor to be prepared to handle the increasing amount of work naturally resulting from the rapid growth in quantity, size, variety, and quality of electrical machinery. Experience has shown that the work of a committee can be effectively carried on only when the members are able to get together and carry on a discussion across a table, following, perhaps, a preliminary exchange of views by letter. For this reason, the membership of the committee has been restricted to those living within a day's journey of New York or in the territory east of the Mississippi River. This territory embraces practically all of the manufacturers of electrical machinery, a large number of universities, and large users of machinery for power generation and distribution. It is not intended, however, to exclude any members who are in a position to, or willing to, assist in any way whatsoever. In this connection, your attention is directed to the general call for volunteers which appeared on page 1 of the Journal of January, 1927, over the name of the chairman of this committee.

The committee has held two general meetings, one in October and one in February at the time of the Winter Convention. In addition to these, the various subcommittees have held meetings in connection with the work that has been assigned to them. In general, the subcommittees have reported progress of their work and presented opportunities for general discussion at the meetings of the whole committee.

The organization of this committee comprises subcommittees on (1) Standards, (2) Papers, (3) Research, and (4) Education. It is probably not necessary to review here the functions of these subcommittees. Mr. E. C. Stone is chairman of the Standard Subcommittee, Prof. V. Karapetoff is chairman of the Research Subcommittee, Prof. C. A. Adams is chairman of the Education Subcommittee, while Mr. H. M. Hobart with the whole committee has acted as clearing house for receiving suggestions, obtaining and reviewing papers dealing with electrical machinery.

During the year, 15 papers have been presented under the auspices of this committee at the general meetings of the Institute. Turning to the developments in research as affecting the design of electrical machinery, probably the most important theoretical contributions have been in connection with the subject of the synchronizing power and stability characteristics of synchronous machines and the determination of the flux distribution in magnetic fields. In the field of design and manufacture, advances have been made in capacities of turbo generators, transformers, waterwheel-driven generators, and synchronous condensers, there have been improvements in construction looking toward reductions of losses, the knowledge of the cooling and ventilation of machinery has been increased and definite steps have been taken to raise the operating characteristics of a-c. fractional horsepower motors to a higher level. In standardization, this committee has taken up a larger volume of work than ever before in the revision of existing A. I. E. E. Standards and the preparation of new Standards to keep pace with the continual development of improvements and new types of machinery and the necessity of changes arising from a better knowledge and understanding of the art. All of these additions to our knowledge and the improvements in design are chapters in the great story of the engineer's untiring efforts for the betterment of our social and economic status.

The following review has been prepared with the assistance and collaboration of the members of the committee and an attempt has been made to include the more important articles that have appeared in domestic and foreign journals in the several bibliographies. Undoubtedly, articles of real merit have been overlooked and the committee will welcome having such omissions brought to their attention.

Research

Undoubtedly the most important phase of this committee's work is that which has to deal with the advancement of the art of design and manufacture of electrical machinery, through research. Without research, progress would be very slow. It is with a considerable degree of satisfaction that important contributions have been made during the year, both theoretical and experimental.

Effect of Altitude on the Dielectric Strength of Insulations. The committee has carried out some experiments to determine the relative puncture strengths of standard insulation at different atmospheric pressures. The results of these tests indicate that the reduction in the value of the voltage causing pucnture with decreased

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

atmospheric pressure is so small that no change in the A. I. E. E. Standards is considered desirable so far as insulated windings are concerned. When air is depended upon for insulation, however, a correction should be made for that part of the insulation which consists of air in series with solid insulation.

Surge Tests of Insulation. Work that has already been done indicates that the breakdown strength of solid insulation depends upon the kind and mode of test voltage and it does not seem feasible to specify for general use a test that will truly duplicate service conditions. A conventional test of the simplest kind will be just as satisfactory, provided the magnitude of the voltage is sufficiently high to provide a reasonable margin for the most unfavorable transient voltage liable to occur under actual service conditions. For example, if high-frequency oscillations are liable to take place and experimental data should show an ultimate strength of only 50 per cent as compared with 60-cycle voltage, then the magnitude of a 60-cycle test must be at least twice that of the maximum high-frequency oscillation to which the machine may be occasionally subjected in operation. In large machines designed to meet definite service conditions where the most unfavorable overvoltages are reasonably well known, the factor of safety may be chosen accordingly, but competitive considerations will largely govern the choice of insulation and its test for machines made in quantities for the general market.

It is recommended that designers study such data as are now available on this subject and that experimental assembled machines be tested by the different kinds of voltages for the purpose of obtaining data upon which may be based ratios for use in design and in specifications and guarantees.

Hot Spots in Cores of Turbo Alternators. Tests made by three manufacturers of typical American machines show that the temperature at the bottom of the slots at ends of the core is less than that between coil sides at the middle of the core and it is concluded that no change is needed in the present A. I. E. E. Standards as regards the location of temperature detectors.

Evaluation of Conventional Losses. Some work is being done to determine the feasibility of determining the stray load losses of alternators, synchronous motors, and condensers by a more convenient means than those described in the Standards.

Calorimetric Method of Determining Losses in Alternators. Apparently this method requires such close supervision of detail and conditions that it may be considered more of a laboratory method than one which can be used for general commercial purposes. It is recognized, however, that this method has inherent possibilities for experimental work and is worthy of continued investigation. A paper giving results of extensive tests has been presented to the Institute during the year.

Stability of Alternators. A paper, *Stability Characteristics of Alternators,* has been presented by Mr. O. E. Shirley which showed the relation between stability and the short-circuit ratio and the subject has been referred to the Standards Subcommittee for the consideration of the establishment of a standard.

Some years ago it was the practise to design synchronous machinery with good inherent voltage regulation. With the advent of the vibrating voltage regulator, this practise changed since it was more economical to design machines with lower inherent voltage regulation and to depend on the voltage regulator to maintain voltage. This principle formed the basis of machine design until, in recent years, the work done on system stability indicated that for machines which were to be used on those systems where stability is an important consideration, a reversion to the former practise of designing for good inherent voltage regulation was desirable.

Recently, in the engineering of certain large power projects and extensions to existing systems, it has been decided to employ machines having lower leakage reactance and higher short-circuit ratio than machines of normal design for the same rating would have. The purpose of this is to increase the stability of the system upon which they are to be used and, in particular, to reduce the probability of system disturbances causing loss of synchronism of the terminal apparatus with consequent interruption to service.

For system stability it is desirable that reactance be kept low, whether it be that of transmission lines, transformers, or generators. It is not feasible to reduce the reactance of the transmission lines appreciably except by building additional lines in parallel. Transformer reactance is a relatively minor part of the total and can be reduced below the normal values only at considerable cost. On this account, attention must be focused on the generators where it is economical to increase the cost to reduce the reactance below normal since such a reduction increases the capacity of the relatively much more expensive lines to carry load with less probability of service interruption due to system disturbances.

Another important consideration in maintaining synchronism is that of sustaining voltage throughout the system during a disturbance. This may be partially accomplished by the use of machines having high short-circuit ratio. Higher values than those corresponding to normal design have been decided upon for certain projects for the purpose of increasing system stability. Beyond a certain degree, it is more economical to employ quick response excitation systems which serve to accomplish the same object as increasing the short-circuit ratio, namely, that of sustaining the voltage during a disturbance.

Within the past year, the construction of machines embodying these special features for improving system stability has been undertaken for certain high head developments in California where the length of the transmission lines and the amounts of power involved are such as to cause the stability to be an important problem. Machines of special characteristics are also under construction for certain low head hydroelectric devel-

opments in the East and the South where the reactance of the slow-speed machines is of necessity relatively high and where the amounts of power to be transmitted are very large.

Relation between Dielectric Tests on New and Used Machines. This subject has been referred to the Standards Subcommittee and it is intended that a paper should be prepared for the purpose of setting forth the principal considerations and a suggested standard.

Characteristics of Synchronous Machines. Supplementing a study of the characteristics of synchronous machines by an extension of Blondel's theory of two reactions as mentioned in the report of last year, the second part of the series of papers by Doherty and Nickle should also have been mentioned, which treated the steady-state, power-angle characteristics. A further study has now been presented by these authors on the torque-angle characteristics under transient conditions and a further study of torque characteristics under short-circuit and transient conditions has been promised. Another contribution to this subject has been made by Mr. H. V. Putman in a paper presented to the Institute. Results of experimental studies of the transverse armature reaction in synchronous machines have been presented in a paper to the Institute by Prof. J. F. H. Douglas to show that the effect of transverse reaction can be most accurately estimated by the use of a m. m. f. diagram.

Stray Load Losses. Sources of stray losses and means of their reduction and elimination present a field of study which is of considerable importance in the never-ending endeavor to improve the efficiency of electrical machines. Papers have been presented to the Institute dealing with several phases of this subject. An analysis of the m. m. f. waves of polyphase windings of the fractional slot or irregular types shows the possibility of the existence of sub-synchronous harmonics having wave-lengths greater than two-pole pitches which may induce currents in the damper windings of synchronous machines. Connection arrangements of this type of windings have been investigated for the purpose of preventing these losses. The existence of eddy current losses in the copper of armature windings has been a fertile field of investigation both as to a means of determining their magnitude and their reduction. Recent studies have resulted in simple conductor transpositions and arrangements that have been effective in almost entirely eliminating these losses. Investigations made by the calorimetric method in connection with several turbo generators gave results that appear to confirm the correctness of assuming the stray load losses being equal to the additional losses under sustained short-circuit conditions.

One of the colleges has undertaken a series of experiments on methods of determining load losses of synchronous machines which, it is said, gives promise of adding materially to the knowledge of this subject. It is hoped that the results of these experiments will be presented to the Institute during the coming year.

Synchronous Converters. A treatment of the theory of the converter has been presented that is based on the method of "harmonic analysis" by which any regularly repeating function may be represented, and presenting a conception of the internal voltages, currents, heating, and armature reactions as related to the physical structure of the simple converter and as related to the passage of time which may be called space and time relations.

Synchronous Motors. A theory for the calculation of the complete starting performance of synchronous motors has been presented which utilizes a system of negatively rotating vectors to take care of the unbalance in the damper winding which is not continuous.

Reactances for Direct Current. A direct method of design for the predetermination of the correct air-gap in reactances and transformers which are to be used with direct current has been offered. This subject is of particular importance in building rectifier filters for radio telephone work.

Magnetic Fields. The distribution of magnetic flux is a very important factor in the design of electrical apparatus and there is need of methods for determining the magnetic fields with a reasonable degree of accuracy. A rather complete treatment of this subject has been presented to the Institute in a group of papers covering the graphical method from the standpoint of the theoretical considerations, comparison between calculations and tests and the practical application to a particular type of machine.

Dielectric Tests on Windings of Large Alternators. The attention of the Subcommittee on Research has been called to the question of whether or not there should be a difference in the value of voltage applied in making dielectric tests on one phase to other phases connected to ground and from all phases connected together to ground. Information on this subject is desired.

Effect of Damper Windings in Alternators upon Single-Phase Short Circuits. It is customary in Europe to add dampers to the field structures of alternators to enable them to more effectively carry unbalanced loads and reduce peak voltages when single-phase short circuits occur. This subject is included in a research report by the Department of Electrical Engineering of the M. I. T. of June 1926, and information is desired as to whether it is advisable to follow this practise in America.

Evaluation of Conventional Losses. A discussion of the paragraph under this heading in this committee's report of last year has suggested that suitable commercial test methods of determining the internal voltage drop of an alternator winding which is due to leakage reactance should be devised so that the real core loss under load conditions could be taken into account in figuring the efficiency instead of using the no-load value of core loss which may be considerably lower. If such tests could be made, the value of the conventional efficiency would

more nearly approach the real efficiency. The value of this drop in field ampere-turns might be taken from the test short-circuit impedance curve if the armature reaction in ampere-turns were known. This latter term can be quite accurately calculated from the armature winding data but the test codes of the A. I. E. E. Standards are based upon the principle that the characteristics must be determined from only those quantities which can be directly measured by test. Some reasonably accurate method of measuring the leakage reactance would be a valuable addition to the present standards.

Alternator Short Circuits. The work done previously on this subject has been to determine the amount of current that will flow for various conditions of short circuit. The torque produced during a short circuit is also of importance and an instrument has been developed which will give a record of the instantaneous values of torque during a short circuit or similar transient condition. It is also possible with this instrument to investigate the synchronizing power of a machine and tests are being made at the present time to study this synchronizing power as well as the short-circuit torque of a number of machines.

Within the past few years, the methods of calculating phase-to-ground and phase-to-phase short-circuit values as well as the currents flowing for any abnormally unbalanced operating condition have been greatly simplified by the use of the system of symmetrical coordinates developed by Mr. C. L. Fortescue. In order to apply this method of symmetrical coordinates, it is necessary to have a knowledge of the impedance of the rotating machines to zero and negative phase sequence voltages. A great deal of experimental work has been done to determine the proper method of determining these impedances. A series of rather simple shop tests has been devised to obtain the desired information and during the past year a number of machines has been tested to find the values of their impedance to zero and negative phase sequence voltages.

Standards

The following report has been made by Mr. E. C. Stone, Chairman of the Subcommittee on Standards.

General. Following the policy laid down by the Chairman of the Committee on Electrical Machinery, the Committee on Standards has kept in close touch with developments in the manufacturing and operating fields, and has attempted to sense the needs, as they have arisen, for modification or further development of the present standards and for the setting up of new standards.

By consistently following the policy of having subcommittees continuously at work on the revision and further development of standards for electrical machinery, it is hoped that the Institute standards in this field may be kept fully abreast of the times and adequate to meet the changing conditions under which electrical machinery is called upon to operate.

The various subcommittees have been actively at work during the past year, have initiated a number of proposals for modification of old and creation of new standards and have carefully worked up a number of definite recommendations which has been formally proposed to the Standards Committee of the Institute.

The preparation of standards covering two types of apparatus, mercury arc rectifiers and constant current transformers, not covered by present standards, has been started and definite recommendations may be expected within another year.

A number of changes in, and additions to, present standards on synchronous machines and on transformers, A. I. E. E. Standards Nos. 7 and 13, has been recommended. Additions of importance include the following:

Method for the calculation of natural frequency for synchronous motors driving reciprocating machinery.

Definitions for short-circuit ratio, per cent synchronous impedance and per cent transient reactance.

Definition for and method of rating grounding transformers.

Ability of transformers and reactors to withstand short-circuit current.

Method of measuring losses in transformers.

The operation of electrical machinery on a total temperature basis rather than on a temperature rise basis was actively discussed by the committee. The increasing demand under economic pressure for operation of electrical machinery in such manner as to get out of it the greatest possible capacity under all conditions, and of taking advantage of the greater capacity inherently present when a machine is operated in a temperature below that for which it was designed, was recognized, and it was agreed that the committee should give active attention to the subject. In this work the committee was instructed to cooperate with Working Committee No. 38 of the Standards Committee, Mr. Hobart, Chairman, whose function is "to revise the general principles upon which the rating of electrical machinery is based, with a view of presenting at a later date a document that will explain the connection and distinction between test specifications for rating and *operation under service conditions*, the purpose being to place before the various working committees a working basis on which service may be established for each line of apparatus."

The subject of standards for dielectric tests immediately after putting in service and periodically while in operation, was taken up actively. The investigations have shown that the problems involved are not well understood and that there is a wide variation both in opinion and practise with respect to them. Accordingly, Messrs. Gilt and Barns have promised to prepare a paper on the general subject of dielectric tests on equipment after installation, in which the principles, problems, and practises will be crystalized and an attempt made to develop a definite method of arriving at a satisfactory solution to meet the various conditions that are encountered.

In the field of fractional horsepower motors, little could be done because of the unsettled status of the negotiations now under way between the N. E. M. A., A. E. I. C., and N. E. L. A. with regard to the performance characteristics of this class of motor.

There is a growing tendency among power companies to place restrictions on the permissible efficiency power factor, and starting current of fractional horsepower motors. These characteristics are particularly important in the ¼-hp. motors used for domestic refrigerating and oil burning equipments, which at present have very poor characteristics in these respects. One company has already put out a rule requiring that all such motors connected to its lines must have an apparent efficiency of not less than 42 per cent and a starting current of not more than 15 amperes at 115 volts.

The negotiations referred to above have been carefully followed by the subcommittee. It appears that definite progress has been made towards reaching an agreement at which the performance of fractional horsepower motors will be substantially improved, with a result that the over-all cost to the operator on such motors, giving consideration both to the cost of the motor and of the power to operate it, will be reduced.

The following is a brief résumé of the activities of the various subcommittees.

Standards for Alternators, Synchronous Motors, and Synchronous Machines in General. W. J. Foster, Chairman. Revisions of the following paragraphs have been suggested:

Paragraph
Number
7-66 Definition of Open Machine.
7-67 Definition of Protected Machine.
7-457 (b) Ventilating Blower Losses.
7-457 (c) Other Auxiliary Apparatus Losses.
7-465 Determination of Losses (to include 7-472).
7-467 (b) Friction and Windage Losses of Engine Type Alternators (to include Synchronous Motors).
7-470 Stray Load Losses.
7-551 Insulation Resistance—Minimum Values.

Additions to this pamphlet have been recommended to cover the following:

Method of Calculation of Natural Frequency of Synchronous Motors Driving Reciprocating Machinery.

Definition, Short-Circuit Ratio.

Definition, Per Cent Synchronous Impedance.

Definition, Per Cent Transient Reactance.

Standards for Transformers, Induction Regulators and Reactors. G. Faccioli, Chairman. The following new paragraphs have been recommended:

13-161 Grounding Transformers—Definition and Rating.
13-254 Grounding Transformers—Momentary Load Limitations.

Revisions of the following paragraphs have been recommended:

13-250 Short-Circuit Current of Transformers—Momentary Load Limitations.
13-252 Current Limiting Reactors—Momentary Load Limitations.
13-306 Measurement of Losses in Transformers.

The following subjects are suggested for attention during the next year:

Guaranteed Secondary Voltage of Step-Up Transformers under No-Load Conditions.

Cooling of Air-Blast Transformer Windings after Shut-Down.

Self-Protection of Transformers against Impulse Transient Voltages.

Operation of Transformers by Temperature.

Standards for Synchronous Converters. C. H. Sanderson, Chairman. The further study of the following subjects for the revision of Standards No. 8 is recommended:

Normal Rating.

Measurement of Cooling Air.

Quantity of Air Required for Cooling.

Short-Circuit Protection.

Standards for Mercury Arc Rectifiers. B. G. Jamieson, Chairman. This subcommittee was created through the request of the Standards Committee of the Institute at the January 1927 meeting. It is intended that it will develop as rapidly as possible definite standards for mercury arc rectifiers.

Standards for Constant Current Regulating Transformers. H. C. Louis, Chairman. This subcommittee was organized at the time of the Winter Convention and it is expected to develop definite standards for constant current regulating transformers.

Standards for Fractional Horsepower Motors. E. C. Stone, Chairman. On account of the unsettled status of fractional horsepower motors due to the negotiations now under way between the N. E. M. A., A. E. I. C., and the N. E. L. A., it has been impossible to formulate any definite recommendations on this subject.

It is recommended that this subcommittee be continued next year and that the A. I. E. E. Standard No. 10 covering this subject be reviewed and such revisions recommended as may be necessary to fit in with the revised practise set up.

Ventilation

The ventilation of machinery is a very important consideration not only in regard to the cooling of the machine itself and the supply of an adequate amount of clean, cool air but also as a means of deadening noises inherent in the operation of large and high speed machines. In the endeavor to realize every possible economy for obtaining high efficiencies, attention is being paid to relatively small features of construction to obtain small resistances to the passage of cooling air, and much attention has been paid to forms of fans. The importance of paying attention to small details in improving efficiencies of turbo alternators has led to investigations in the laboratory by the use of a model in which changes in fingers, slot wedges and dimensions of slots can be readily made and the effects determined. Tests are also being made to study the flow of air through rotors.

The report of this committee for last year mentioned that closed ventilation systems had been adopted for hydroelectric plants. The question may well be asked as to what consideration would make it advisable or desirable to use a closed system in a water power plant. The many illustrations of water power plants which are published in the current literature show locations remote from sources of smoke and dust which are not associated in our minds with broad expanses of water and wilderness. There are often conditions surrounding the location of power houses that make it advisable to provide a closed system. Hydroelectric plants located on rivers in the midst of manufacturing plants where much coal is burned have as much need of this type of ventilation as the turbo generators in steam plants in the same locality. There are also conditions in some remote locations which make closed systems advisable, such as severe dust storms in barren districts. It often happens that the initial installation in a hydroelectric development is only a small part of the final capacity and there may be construction work going on over a long period after the first few units have been put into operation with considerable dust from masonry work in the air. In an instance of this kind, it was found that the generators had become sufficiently clogged with dust to raise

their temperature 10 deg. One installation of eight 12,550-kv-a., 100-rev. per min. waterwheel-driven generators includes closed ventilation systems. Probably the largest waterwheel-driven generator to be provided with this system is a 30,000-kv-a., 300-rev. per min. vertical unit. In these installations, the air coolers are located in enclosures immediately behind the stator frames, and after passing through them, enter ducts leading to the pit underneath the generators. In the case of the 30,000-kv-a. generator, the air is returned to the space above the rotor also. The coolers are arranged so that they can be lifted vertically out of their pockets for repair or replacement without disturbing any part of the generator themselves.

Another unusual application of the closed system of ventilation is in connection with a German Diesel-engine-driven 13,000-kv-a., 94 rev. per min. alternator.

Much valuable data for future design work regarding hydrogen cooling have been obtained from thorough tests on a 6250-kv-a., 3600-rev. per min., 13,200-volt turbo generator. These tests were highly gratifying and indicated that practically the same benefits may be obtained as may be expected from theoretical considerations. There are indications that hydrogen cooling may eventually be used for large synchronous condensers and frequency converters. It has been suggested that helium could be used with advantage in the place of hydrogen and this possibility is being investigated. A seal has been developed to prevent the loss of hydrogen or the admission of air at the section where the shaft of the machine enters the end bell. Tests made over long periods of time on this type of seal have proved very satisfactory. Tests have also been made on heat-flow across laminations when surrounded by hydrogen.

The necessity of minimizing the noises given out by rotating machinery in substations located in business and residential areas has presented some difficult problems, especially in connection with d-c. machinery. It is a comparatively simple matter to enclose a synchronous motor so that the noises are quite effectively deadened but in the case of a d-c. generator or a rotary converter, the necessity of providing ready access to the commutator brushes presents serious difficulties and the accumulation of metallic and carbon dust becomes a serious contributing factor toward insulation failures.

An early attempt to enclose a rotary converter consisted of a housing in the form of a wired glass and steel framework closely shrouding the commutator and mounted directly on the arms of the brush spider. A metal housing covered the collector rings and pedestal with sufficient room to allow an operator to enter the housing and inspect the rings and brushes. Test showed, however, that this arrangement hindered the free ventilation of the commutator and from an operating point of view the commutator was too inaccessible. A later attempt which has proved successful has taken the form of a large semi-cylindrical steel housing of about the same size as the over-all projected dimensions of the converter and of slightly greater height. Doors are provided at each end while steps on the bearing pedestals with suitable screens, guard rails, and adequate lighting make the rings and commutator safely and easily accessible. Air is introduced through the pit at the d-c. end, a small part being admitted under the collector rings and passing axially through the machine; it is discharged into the exhaust ducts from the top of the collector end of the enclosure. This scheme has been successfully applied to 4200-kw., 12-phase converters having their two transformers mounted on the base plate. Blowers located in the basement beneath the converters are used to force the air through the housings. Some 2100-kw., six-phase converters have been similarly equipped.

During the past year extensive experimental tests have been made to determine the surface heat transfers in electrical machinery with air flowing at various velocities through radial and axial ducts. Investigations have been made to determine the influence of shape, size, cross-section, condition of the surface, mean temperature, and several other factors.

The most important fact brought out in these tests is that the rate of heat transfer is not constant along the path of air-flow but varies in value from point to point along the path. This variation in the rate of heat liberation for a constant air velocity in a given duct is caused by the changes in the turbulency of the air-flow along the duct. As a result of this change of turbulency, it is found that the rate of heat transfer near the entrance of a duct is about twice that at a point further along where stable flow conditions are found. This explains why electrical machines with short duct length have a capacity in proportion to their surface greater than those with similar ducts but with longer air flow paths. This also explains why the surface heat transfer coefficient of a duct, averaged over its total length, will be an inverse function of the length. It also explains why results as given by experiments on ducts of various length should vary.

WATER-WHEEL GENERATORS

Probably the most notable water-wheel-driven generators of the past year are the seven machines now under construction for the Conowingo Development. These

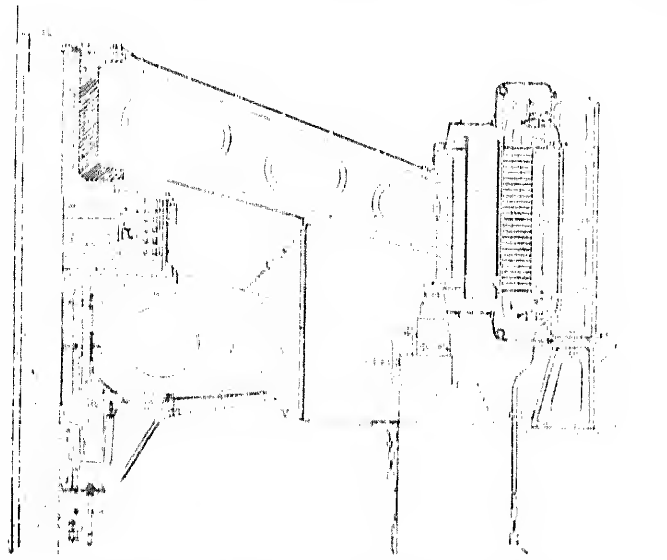

FIG. 1—SECTION OF 27,500-KV-A., 90-REV. PER MIN. VERTICAL-SHAFT ALTERNATOR WITH OVERHUNG ROTOR

alternators are notable not only because of their size but also because of the fact that they are to supply power for the first 220-kv. transmission line in the eastern part of the United States. They are rated 40,000-kv-a., 90 per cent power factor, 81.8 rev. per min., 60 cycles, 13,800 volts, and are the largest in physical dimensions of any electrical machines that have ever been built. They are being built by two manufacturers, and by a large degree of cooperation between them, it has been possible to obtain similarity in characteristics and appearance and interchangeability of some important mechanical parts. The outside diameter of the stator frame is 38 ft. One manufacturer has made use of steel plate construction almost exclusively for the mechanical parts of the stator frame and the rotor. The rotor rim will consist of heavy rolled plates in several layers overlapped so as to give the greater strength for the amount of material used and fastened together with bolts and dowels. The pole pieces will be fastened with bolts through the rim. The stator frame is of the welded steel plate construction and greater uniformity in shape has been obtained than is possible with castings. The largest capacity thrust bearings ever built will be required for these generators. Their capacity will be a total load of 750 tons.

On account of the stability characteristics desirable for operation with the 220-kv. transmission line, the generators described above have a short-circuit ratio of 1.25 which is somewhat higher than has been found satisfactory for nearly all other hydroelectric developments. As a further aid in securing continuous parallel operation without hunting or dropping out of step during disturbances on the system, a scheme of high-speed excitation is being used. As in the case of the large generators at Niagara Falls, each main generator has direct-connected to its shaft a service generator which supplies power to a high-speed motor-generator set for providing excitation for the main generator. The service generator is provided with its own direct-connected exciter. The generator of the main exciter set will be separately excited by a suitable direct-connected exciter. To take full advantage of the high-speed excitation provided by this scheme, special voltage regulators are being used to control the main generator excitation through the control of the field current of the exciter generator. The fields of the exciter generator will be connected in two parallel circuits in order to obtain an effect equivalent to that of using double potential on the whole field connected in series. Generators having the same scheme of excitation have been installed in power houses on the Gatineau River in Quebec for supplying power to the 260-mile transmission from Ottawa to Toronto. One of these generators is rated 32,000 kv-a., 90 per cent power factor, 100 rev. per min., 6600 volts, 25 cycles, and the other is rated 22,500 kv-a., 88.3 rev. per min.

The largest vertical shaft water-wheel-driven alternators yet built in Europe are now under construction. They are rated 35,000 kv-a. at 337 rev. per min. and 375 rev. per min., 10,000 volts, 40 cycles. These machines are equipped with direct-connected main and auxiliary

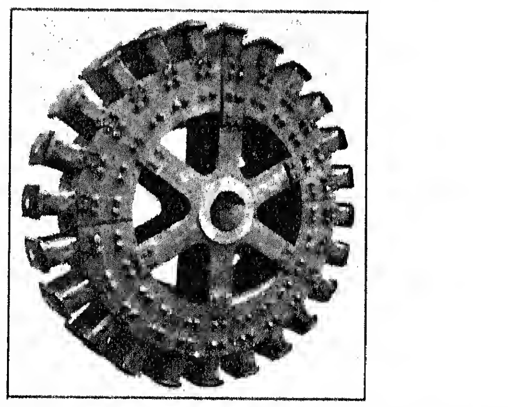

FIG. 2—ROTOR OF A LARGE WATERWHEEL-DRIVEN ALTERNATOR OF RECENT DESIGN USING STEEL PLATE CONSTRUCTION

exciters. The rotors are made up of two wheels, each consisting of five cast steel disks bolted together. The pole pieces are dovetailed to the rotor spider.

There are under construction three of the largest vertical shaft water-wheel generators of the "umbrella" type yet built. Two of them are rated 27,500 kv-a., 80 per cent power factor, 90 rev. per min., 13,800 volts and the other is rated 22,500 kv-a., 75 rev. per min., 60 cycles. With this construction, a common shaft is used for generator and water-wheel and the thrust and guide

bearings are located beneath the rotor. There is no guide bearing above the rotor. The ventilation arrangement is noteworthy in that no air is taken from the wheel pit and no air currents pass over the bearing oil pans to draw oil vapour into the generator. A number of smaller generators of this type has now been put into operation and their operation has proved satisfactory.

European manufacturers of water-wheel equipment are apparently finding it more economical to offer geared units for low head installations. An installation on the Trent River in Ontario consists of a 1400-hp., 120-rev. per min. vertical shaft turbine geared to a 600-rev. per min. horizontal shaft alternator through a set of helical bevel gears which are claimed to have an efficiency of 98 per cent. Some recent German plants contain vertical shaft turbines driving vertical shaft alternators through double spiral gears.

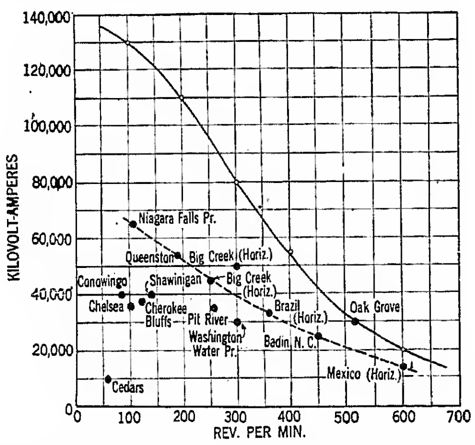

FIG. 3—COMPARISON OF RATINGS OF EXISTING SALIENT POLE ALTERNATORS WITH RATINGS WHICH MANUFACTURERS ARE PREPARED TO BUILD

The full line curve shows ratings which manufacturers are prepared to build as mentioned in the June 1926 report of this committee

During the year a very large automatic hydroelectric station has been put into operation. It consists of a 17,500-hp. vertical turbine driving a 13,333 kv-a., 6600-volt, 225-rev. per min. generator and is controlled from a station seven miles distant. Another large generator rated 9000 kv-a. arranged for full automatic control has been put into operation.

In the report of this committee last year, there was given a list of large ratings at different speeds which manufacturers were prepared to build. No doubt, if the necessity should arise, greater ratings could be constructed. A reader who was interested in knowing how close the ratings of machines already built came to these limits has plotted the list of maximum ratings and speeds in the form of a curve and added the more outstanding ratings that have been built. The curve and plot is reproduced to show what appears to be the limit line of hydroelectric unit capacities that have been considered economical up to the present time. It will be noticed that the highest ratings at different speeds of machines built or under construction fall on a well defined curve with the exception of two machines that are above the curve.

Recent developments in the design of Pelton wheel water turbines promise that larger horizontal shaft generators than heretofore built are possible requirements of the future. The standard arrangement of units with this type of turbine is to mount a runner on each end of the generator shaft. Units of this type have been built for capacities of 40,000 hp. and 56,000 hp. and studies have been made of still greater capacity wheels which may be built when the proper economic conditions are presented. There are now being built two of the largest capacity alternators for this arrangement that have been produced. One of these is rated 50,000 kv-a., 60 cycles, at 300 rev. per min. and the other is rated 45,000 kv-a., 50 cycles at 250 rev. per min.

TURBO ALTERNATORS

The trend of development during the past year has been toward larger units. In connection with the manufacture, shipment, and installation of the large alternators now being produced, there has been an extension of the use of the skeleton frame construction for stators, and also in speeds of 1500 and 1800 rev. per min.

The old type of construction made a final unit which was necessarily heavy and usually too large for shipment on the railways. With the skeleton frame construction, the frame is strong enough to support itself during machining and assembly. Special bolted-on plates and trunnions for each frame facilitate handling during assembly at the works, loading and unloading during shipment, and final erection at the destination. The over-all dimensions of the frame, assembled for shipment, allow the completely assembled unit to be shipped direct to its destination. The ventilation requirements are cared for by an external superstructure of sheet metal applied at the destination. With this construction, 1800-rev. per min. turbine generators up to 75,000 kv-a. can be built and wound at the works and shipped complete. As a result of this, large turbine generators can be tested at the works, the freight charges are reduced, handling during assembly, shipment and erection is made easier, closer inspection is made possi-

ble during manufacture, and there is less confusion to the purchaser when shipment is made.

There has been considerable activity in developing new types of stator windings, involving transposition of strands in each conductor, and transpositions at the heads of the machine, or in the connections. The use of half-coils is becoming more common practise among the different manufacturers. It has been found that the use of continuous coils and the control of the eddy current loss factor by transposing the strands of each conductor at one end of the machine is satisfactory up to about 50,000 kv-a. In larger capacity machines, coil length and weight are so great that it is difficult to handle the coils during manufacture and assembly. This has favored the use of half-coils, especially in view of the facility with which damaged coils can be replaced in the machine.

To make the eddy current loss in half-coils as low as in continuous coils, either elaborate transposition of the strands at each end of the machine or transposition of the strands inside the armature core is necessary. Complete external transposition of half-coils is undesirable because of the large number of complicated connectors and the large space required for connection. For these reasons, types of half-coil construction are being used in which the strands of each conductor are transposed in the slot portion. One construction provides a complete transposition in the slot of all the strands in the conductor as one group while in another construction the strands are arranged in small groups and the strands of each group are transposed internally while the groups are transposed at the ends. These constructions permit the use of coils which are relatively easy to handle and assemble and yet make the eddy current losses as low as possible.

The past year has seen the realization of the predicted possibilities in large high-speed turbo generators which were mentioned in the report of this committee last year. There are under construction generators of the following ratings:

Single-Shaft Units.

100,000 kv-a., 90 per cent power factor, 1500 rev. per min.

75,000 kv-a., 80 per cent power factor, 1800 rev. per min.

Triple-Shaft Units.

Two—64,706 kv-a., 85 per cent power factor, 1800 rev. per min. and one 57,647 kv-a., 85 per cent power factor, 1800 rev. per min. with two 4286-kv-a. house service generators to form a 165,000-kw. unit.

Two—72,941 kv-a., 85 per cent power factor, 1800 rev. per min. and one 89,412 kv-a. 85 per cent power factor, 1800 rev. per min. with two 5333-kv-a. house service generators to form a 208,000 kw. unit.

The present tendency to very large generating units and ever increasing station capacities has made the switching problem, on account of the enormous currents involved, a serious one. This situation is being met in some instances by connecting step-up transformers directly to the generator terminals and doing all the switching on the high-tension side of the transformers. In other cases, the generators are being built to operate at voltages considerably higher than those previously employed. As examples of the latter practise, the two 100,000-kv-a. units mentioned above are being constructed for 16,500-volt operation; the main generators of the 208,000-kw. triple shaft unit above referred to will operate at 22,000 volts, and there is also under construction a single-shaft generator of 61,675-kv-a. capacity which will operate at 22,000 volts. All of these will have dielectric tests in accordance with the A. I. E. E. Standard, i. e., twice normal voltage plus 1000 volts.

During the year some large two-shaft units have been put into operation. One of these consists of two 40,000-kw. generators. The turbine and generators are operated as a unit, the two generators being solidly tied to each other and to an auto-transformer stepping up to 27,600 volts with switching on the high-tension side only. The neutral points of both generators and auto-

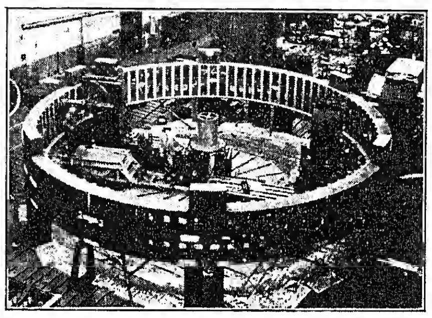

Fig. 4—Shop View of Stator Frame for 40,000-Kv-a. Vertical Shaft Alternator

For Conowingo Development

transformers are solidly grounded. The unit is started with field on both generators, the low-pressure element starting as a motor. The two generators are identical and are each rated at 40,000 kw., 1800 rev. per min., 13,800 volts, 90 per cent power factor. The generators also have a one-hour overload rating of 80,000 kw. at 80 per cent power factor. A 250-volt exciter is direct-connected to the generator of the high-pressure element. Each generator has its own field rheostat but the two face plates are coupled together and operated as a unit by a single pilot motor. A closed cooling system is used for each generator.

Another unit comprises a 64,700-kv-a., 85 per cent power factor, 1200-rev. per min. generator, a 38,825-kv-a., 85 per cent power factor, 1800-rev. per min. generator, and a 4666-kv-a., 75 per cent power factor, 1800-rev. per min. house service generator making a combined capacity of 91,500 kw.

Still another two-shaft unit which is under construction consists of an 88,200-kv-a., 85 per cent power factor, 1800-rev. per min. generator and a 100,000-kv-a.,

95 per cent power factor, 1200-rev. per min. generator. Both generators are wound for 13,800 volts.

Two 62,500-kv-a., 1800-rev. per min. generators which have been put into service show by performance that the rating can be increased to 70,600 kv-a. without exceeding the original temperature guarantees and without change. They have a test efficiency of 98 per cent. Another manufacturer has completed a 59,000-kv-a., 12,000-volt, 1800-rev. per min. turbo generator which

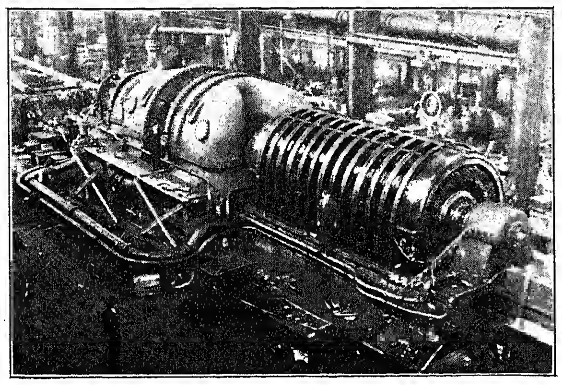

Fig. 5—Shop View of 59,000-Kv-a., 1800-Rev. per min. Steam Turbine-Alternator Unit showing Skeleton Frame Construction

will soon go into operation. This single-shaft set is to be ventilated by two external blowers and the armature winding has transposed conductors.

During the year, several of the European manufacturers have built 50-cycle turbo generators at 3000 rev. per min., in sizes from 30,000 kv-a. to 37,500 kv-a., but the experience of some of these companies in testing the generators before shipment has not been reassuring. In consequence, at least one of the principal manufacturers

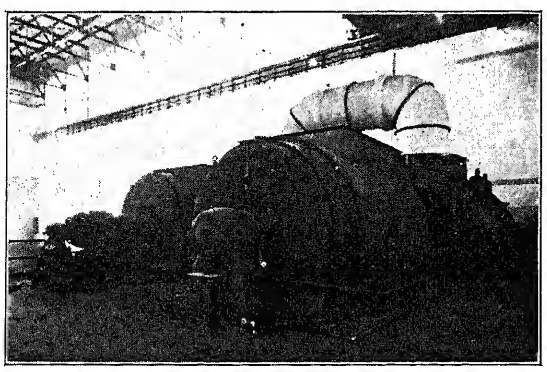

Fig. 6—80,000-Kw. Cross-Compound Turbo Alternator Set

has decided to build 30,000 kv-a. hereafter, at 1500 rev. per min., instead of 3000.

In England there has been built a 31,250-kv-a., 80 per cent power factor generator which is remarkable for its voltage. It is wound for a terminal voltage of 33,000 volts and in order to avoid increasing the dimensions of the machine unduly, due to the thickness of the insulation, a special arrangement has been used to keep the voltage at a low value between adjacent conductors and ground. This high voltage would appear to be an innovation but it should be recalled that a 500-kv-a., 30,000-volt water-wheel-driven generator which was built for the city of Rome about 20 years ago, is reported to have operated all that time without breakdown.

Tests made to determine the additional losses in turbo alternators due to stray field have shown that the short-circuit losses can be reduced if non-magnetic rotor retaining end rings are used. Laminated stator end flanges and laminated magnetic shields attached to the stator flanges have been proved advantageous and a number of machines has been built with these features.

Transformers

The design of a transformer is often influenced by space limitations. To meet special limitations, individual radiators may be removed from the sides of the transformer tank and mounted in a single group. This arrangement has been used on an 89,000-kv-a. bank of self-cooled auto-transformers. The single-phase units which comprise this tank are the largest transformers on which radiators have been mounted apart from the transformer.

The development of the load ratio transformers which was reported last year has justified the claims for its growing importance. There has been a continual growth in the use of transformers arranged for load ratio for tying-in two operating systems for properly distributing the load over different portions of the same system, and for electrolytic and metallurgic processes in industrial service.

The voltage range for which these equipments were designed varied within wide limits, the maximum to

date being 120 per cent range in voltage in 18 ratios, and the minimum 10 per cent voltage variation in nine ratios. The largest banks so operated are as follows:

Three-phase, water-cooled, 60-cycle regulating auto-transformer capable of handling 60,000 kv-a. for use with three single-phase, 20,000-kv-a. units rated 132,000 grounded Y, 36,000 grounded Y, 12,000 volts.

Automatic control by means of a contact making voltmeter was provided for two three-phase, self-cooled, radiator type transformers of 10,000-kv-a., 60-cycle out-

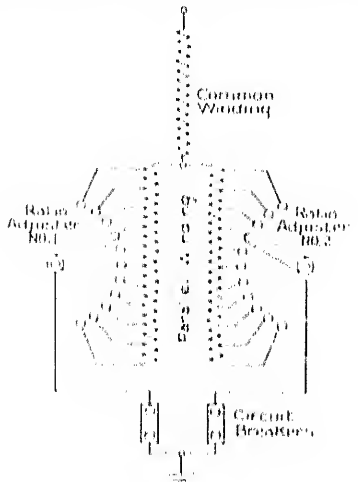

Fig. 7—Diagram of Typical Circuit Arrangement for Automatic Load Ratio Control of a Power Transformer with the Two-Winding Arrangement

put. These machines transformed 11,000 volts to feed a grounded Y, 41,400-volt system. To adjust the line voltage in accordance with the changing load, the high-voltage windings have 11 taps of 2½ per cent each. To permit a change of taps without interrupting the load, a part of the 41,400-volt winding is made in two sections, operating normally in parallel and dividing the load equally. Each of these winding halves is connected to an 11-point ratio adjuster and the resulting circuits brought out of the transformer tank and led to two three-phase circuit breakers.

It is thus possible during the tap-changing period to open-circuit one section in each phase, and change the voltage tap in this open-circuited section while the other section temporarily carries the entire load of the transformer. Copper of ample cross-section and the very short transition period make this possible. The same change is then made in the second half. The entire change from one voltage tap to the next requires only eight sec. For a brief period, less than 1½ sec., when both breakers are closed but the two ratio adjusters are one tap apart, an internal circulating current exists, which, however, is kept within predetermined limits by sufficient inherent reactance in the transformer windings.

A motor-operated mechanism mounted on the transformer truck insures a properly timed operation of the internal ratio adjusters and the external circuit breakers. For the proper execution of the tap-changing cycle, it is essential that the three corresponding ratio adjusters of the three phases move simultaneously from one tap to the next; therefore these ratio adjusters are mounted together on the same shaft with full phase insulation between them. The resulting two stacks of adjusters are arranged in a vertical position along the coil stacks of the transformer, and their two main shafts connect on top to a special internal intermittent gear. Turning the driving shaft of this gear train one complete revolution will first change one set of the three adjusters one step, then lock this set, and then turn the second set one step.

Contact making voltmeters relieve the operator of any manual starting of the mechanism. If the line voltage deviates from a set value for a period longer than a predetermined time value, the tap-changing mechanism is automatically put in motion in one direction or the other to bring the voltage back to normal. A positive but adjustable time delay is insured by a relay, driven by a small induction motor. Between the motor shaft and the contact making element, a train of gears with a gear shift mechanism is introduced, allowing adjustment from one sec. to 30 min.

Two contact making voltmeters are used on each of the two transformers, one adjusted to respond to a narrow range of voltage variations, while the other one is set for much wider differences in voltage. If the line voltage rises or drops only slightly, and if this condition persists long enough to bridge the introduced time delay, the transformer will shift to the next proper tap. If, on the other hand, a considerable rise or drop occurs, the second contact making voltmeter will respond and

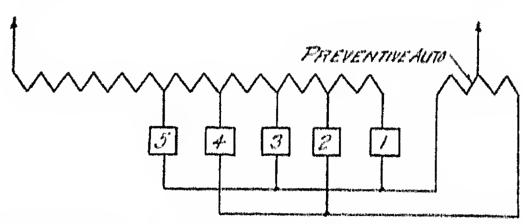

Fig. 8—Diagram of Typical Circuit Arrangement for Load Ratio Control of a Power Transformer with the Self Protecting Auto-Transformer and Single-Winding Arrangement

will cause immediate adjustment without any time delay. The necessary instruments, relays, timing devices, etc., are arranged on two switch panels.

A large number of transformers has been built during the past year with external auxiliary equipment for changing taps under load. A simplification of the problem of taps changing under load is claimed for a new development of the single-winding scheme. By use of a self-protecting preventive auto-transformer, only one switch operation is required to change the voltage ratio of the transformer under load and protective equipment is not required for the transformer windings as no winding is overloaded during the change in taps. This method of tap changing under load permits mounting all the

switches external to the transformer tanks and requires a minimum number of switches.

The following is a description of the operation of the single-winding arrangement shown on the schematic diagram Fig. 8. On position No. 1 with switch No. 1 closed, one-half of the preventive auto-transformer carries the load current of the main transformer. The change from voltage position No. 1 to voltage position No. 2 is made by the single operation of closing switch No. 2. In this second position, each half of the preventive auto-transformer winding carries half of the load current of the main transformer and the voltage obtained is equivalent to a voltage midway between taps. The resultant current in the two halves of the auto-transformer will be the vector sum of the exciting current of the auto-transformer and one-half of the load current. The switching cycle as given above is repeated throughout the entire range of taps. As a switch is opened only upon each alternate voltage position, two voltage positions are obtained for each switching cycle, which is relatively light duty cycle for tap changing service. A slight inequality in voltage steps is found in changing from one voltage position to the next, due to the change in reactance on alternate positions. The reactance difference during this cycle is an invert function of the circulating current which is present when the auto-transformer is connected across adjacent taps and is controlled by the use of suitable air-gaps in the core of the auto-transformer. By this means, the reactance variation may be reduced to a minimum so the voltage difference is small and not objectionable.

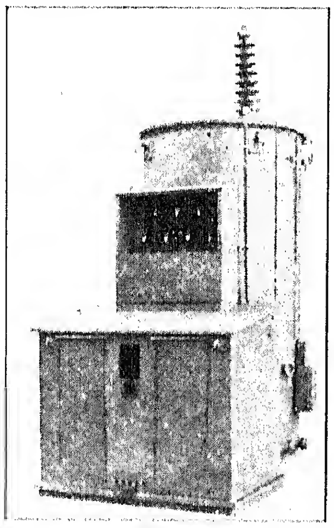

Fig. 9—20,000 Kv-a., 60-Cycle, Single-Phase, 13,200/12,000-Volt Power Transformer with Load Ratio Changer Placed in Grounded End of High Voltage Side

Two 36,000-kv-a. transformer banks have been installed using the transformer under load. The nominal voltage of the transformer banks is 132,000 to 11,500 volts with plus or minus 10 per cent voltage variation under load on the low-voltage side. The tap changing equipment used in this installation is the first equipment built with complete automatic control. As the low voltage raises and lowers with load variation, the tap changing mechanism automatically changes taps to compensate for the variation. If desired, the tap changer may also be operated by a remote control switch, or, in case of emergency, manual operation may be used.

During the last year, the largest artificially-cooled unit built was a 66,667-kv-a., 25-cycle auto-transformer. It is the largest transformer so far constructed in the United States, not only in rating, but in physical dimensions. For instance, it required 36 tons of steel and 17 tons of copper for the windings. The total weight including oil exceeded 120 tons. This transformer is utilized to step up the voltage of a turbine-generator line from 12,000 to 24,500 volts and its equivalent rating as a transformer is 34,000 kv-a.

Four single-phase auto-transformers of record size were also built for air cooling. They are rated 30,000 kv-a., 220,000 Y, 125,000 Y, 10,640 volts. These transformers have a larger capacity and exceed in physical dimensions any transformer of this type so far constructed. The conservator which contains 1300 gallons of oil is in itself equivalent in dimensions to the tank required for a 2500-kv-a., 60,000-volt transformer. The weight of the conservator is approximately five tons and the total weight of the transformer exceeds 130 tons.

In connection with the transmission of power from the Conowingo development, there will be required 580,000 kv-a. in 220-kv. transformers. The step-up service at the generating station will require 13 water-

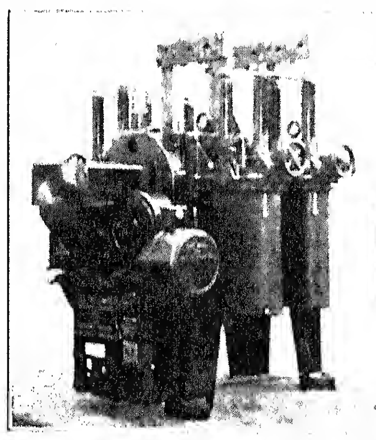

Fig. 10—Circuit Breakers and Operating Mechanism for Load Ratio Changer of 20,000-Kv-a. Transformer and Arranged for Motor or Hand Operation

cooled transformers rated 26,667 kv-a., 220 kv. These will be connected in banks of 80,000 kv-a. In the step-down substation, there will be seven 33,333-kv. a., 220-kv. straight self-cooled, three-winding transformers to step the voltage down to 66 kv. These will be connected in banks of 100,000 kv-a. and will be arranged for ratio changing under load. These will be more than 50 per cent greater in rating than the largest self-cooled, single-phase transformers reported last year.

The largest artificially cooled single-phase transformers were completed this year. They are rated at 31,400 kv-a., 60 cycles, 12,000 to 132,000 Y volts and are water-cooled. These transformers, while of greater rating, do not exceed in physical size the 28,000-kv-a., three-winding transformers shipped two years ago to Japan. These three-winding units, of American manufacture, have not been exceeded in physical size by any other water-cooled transformer. The present maximum capacity for two-winding transformers will be exceeded upon the completion of some 33,333-kv-a., two-winding transformers now under construction. The 33,333-kv-a. units are for 220,000-volt service, for which a great number of units has been constructed during the year. They are cooled by radiators with forced air cooling and are the largest size to which this method of cooling has been applied.

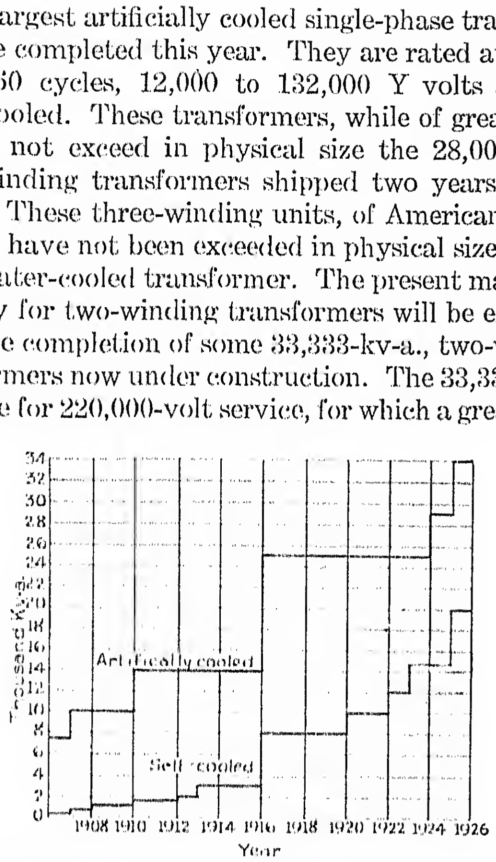

Fig. 11—Growth of Unit Capacity of Self-Cooled and Artificially-Cooled Transformers

The largest totally self-cooled transformers were recently put in operation. They are rated at 25,000 kv-a., three-phase, 60 cycles, stepping-up from 13,000 to 120,000 volts. The windings are equipped with tap changers designed for future tap changing under load. An overload capacity giving 35,000 kv-a. is obtained by means of forced oil circulation through the cooler.

The development of means to increase the rating of self-cooled transformers by the method of blowing air on the cooling surface, which originated about five years ago, has been applied to a number of large installations during the past year. It has been found that in some cases where transformer efficiency is not of prime importance, the saving effected in the transformer itself is sufficient to offset the cost of the blower and air duct equipment.

For use in underground distribution systems, a new subway transformer tank has been developed which is suitable for larger capacities, higher voltages, and heavier currents. The junction boxes form an integral part of the tank and provide adequate high- and low-voltage terminal facilities.

Peculiar conditions in connection with the marketing of both 25-cycle and 60-cycle power from the new hydroelectric developments on the Gatineau River in Quebec have called for the use of some 14,000-kv-a. water-cooled transformers suitable for use on either 25 cycles or 60 cycles without any change whatever in the windings.

The outcome of the recent attempt to formulate standard voltages will have far-reaching effects upon the transformer industry. Standard voltages and capacities will result in economies both in manufacture and use.

Recognition of the advantages of a means of changing ratios under load has resulted in a large demand for this type of transformer in Europe, as well as in America.

In the report for last year, mention was made of some large single-phase transformers for 16 2/3-cycle railway work and arranged for three voltages. The claim is made that these are the largest transformers in the world. If a 50-cycle transformer were built with the same material, its rating would be 100,000 kv-a. The design of these transformers is of particular interest because it was necessary to divide the 15,000-volt winding between the 66,000- and 132,000-volt sides to secure the necessary mechanical strength for short circuits. To meet the various magnetic conditions for the different methods of operation, it was necessary to provide a special by-pass core for the magnetic leakage fluxes.

Among the large transformers built in Europe, it is of interest to mention six 3-phase, 5-leg, 44,000-kv-a., 50-cycle units for the Rummelsburg power station.

An interesting European development along the lines of high-voltage testing transformers are some 750,000-volt units which are constructed on an entirely new principle. It has been the practise to immerse the whole active parts of such a transformer in an oil tank but in this design only the windings are oil-immersed. This is accomplished by arranging the inner and outer insulating cylinders concentrically in such a way that they form a container for the oil. This allows dispensing with expensive insulating bushings. The following advantages are claimed for this construction:

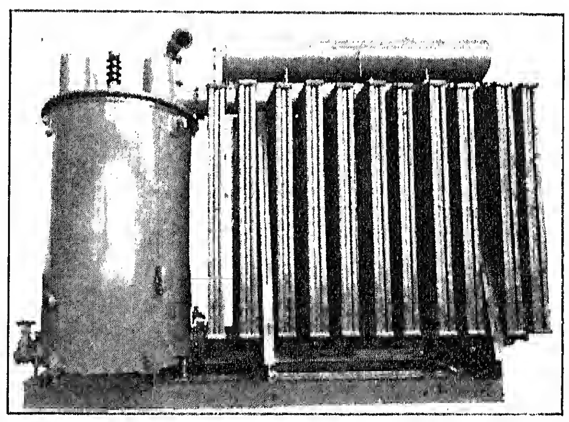

Fig. 13—29,667-Kv-a. Transformer with Radiators Mounted Apart from the Tank

1. Low manufacturing cost, owing to the absence of bushings and tanks and less oil.

2. Small floor space as compared with testing plants using multiple stage cascade connections.
3. Increased reliability, owing to independence from atmospheric influences.
4. Ability to withstand heavy loads owing to the comparatively small leakage voltage.

Tests at 1,500,000 volts have been made with two of these transformers connected in series.

What are probably the highest capacity testing transformers were constructed during the year for use in cable testing. They are rated 400 kv-a., 2300/200,000 volts, 60 cycles, single-phase.

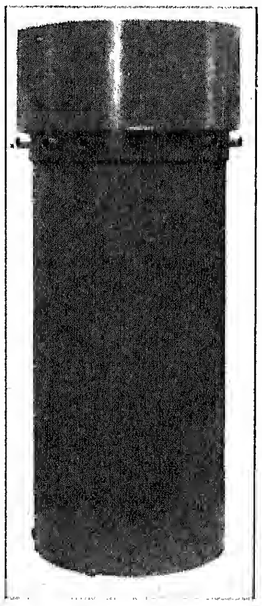

FIG. 14—UNDERGROUND TRANSFORMER

This type of transformer may be buried in the ground

The highest voltage instrument potential transformers that have been considered for commercial use have recently been designed and will be built and installed during the coming year. These will be suitable for 220 kv.

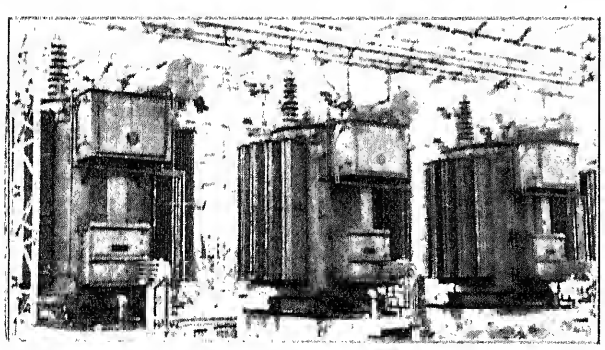

FIG. 15—36,000-KV-A. BANK OF TRANSFORMERS WITH COMPLETE AUTOMATIC CONTROL OF RATIO CHANGER UNDER LOAD

Probably the largest electric furnace transformer ever built is now under construction in a Canadian factory for an aluminum plant. It is rated 15,000 kv-a., three phases, 60 cycles, 13,200-250 volts with taps on the high-tension winding to give full capacity in the low-tension winding over a range from 225 volts to 275 volts. The high current of 38,500 amperes at the 225-volt rating involves some very unusual problems in the arrangement of windings and terminals.

A year or two ago, the Power Commission of the city of Toronto was presented with the problem of dealing with objections raised by property owners in some of the better residence sections against mounting distribution transformers on poles. Arrangements were made with a manufacturer to build a few transformers that could be buried in the ground as an experiment. It was found that the ground is as effective in cooling as the air and practically the same heating was obtained from a given core and coil when buried in an underground tank as when hung on a pole in the ordinary out-door tank. The results are so satisfactory that other transformers have been ordered for regular service. These units are contained in welded tanks with an extension to the top to which is fitted a suitable man-hole cover. The whole may be buried in a lawn so that the man-hole cover is even with the surface of the ground and the primary and secondary leads carried underground to the nearest distribution pole. When it is desired to examine the transformer, the man-hole is removed to give access to the cover of the transformer tank proper. Later designs of these transformers have an arrangement whereby the taps may be changed by means of a key without removing the transformer cover. A surprising feature of the tests on the trial transformers was the fact that the snow did not melt appreciably more in the immediate vicinity of the transformer than in other parts of the lawn.

INDUCTION MOTORS

The demand for squirrel-cage motors, suitable for starting at full voltage without compensator or other starting device, has very greatly increased during the past year. Where the service does not require very heavy starting torque, such as centrifugal pumps, blowers, motor-generator sets, etc., the starting current can be reduced sufficiently without reducing the starting torque beyond the requirements by simply increasing the reactance of the squirrel-cage winding. For other classes of service where a normal or even a high starting torque is required, the situation is met by adding a second higher resistance squirrel-cage to the regular working winding which still has high reactance. The high-resistance winding having a low reactance, this type of machine is commonly called a double squirrel-cage. Standard lines of motors up to 50 hp. of these types have been brought out by several different motor manufacturers. In general the characteristics of this type of machine are such that up to and including 30 hp., they are successfully made so that the static current is within the N. E. L. A. requirements, and the static and pull-in torque are substantially better than is possible with a single squirrel-cage winding. Generally the efficiency is practically the same as for the single squirrel-cage and the power factor is practically the same as for two-and four-pole machines but there is a reduction of a few points in the power factor of the six-pole machines and a correspondingly lower power factor as the number of poles increase.

The use of ball and roller bearings seems to be growing in favour for the number of motors with this type of bearings forms a greater part of the total sales each year. An advantage which is claimed is that motors may be shipped with the necessary lubrication ready to be put into operation and shields do not need to be changed to ceiling or wall mounting. Grease lubrication has been found satisfactory for motors up to two hp. at 8000 rev. per min.

The principle of directing jets of air on the surface of self-cooled transformers to accelerate the convection of heat has been applied to totally enclosed induction motors by equipping them with fans arranged to blow air over the outside surface. By this arrangement it is possible to build totally enclosed motors of somewhat larger capacity and especially in the larger sizes they are less costly than the straight enclosed motors without ventilation.

The growing tendency for system interconnection is resulting in the gradual elimination of odd frequencies so that the demand for motors is very largely for the standard 60-cycle frequency. It is probable that within a short time there will be no demand for 40-cycle motors because many of the 40-cycle systems are being changed over to 60-cycle.

For many years, 220 volts has been a standard voltage for small general purpose motors and power companies have provided suitable service for this voltage. Re-

cently, due to the apparent economies of four-wire distribution for power and light services, an active demand has grown up for 200-volt motors, and it is probable that stocks of motors for this voltage will soon be regularly carried.

A very interesting development in single-phase, induction motor design was brought out by a German firm. The motor has no commutator, but is able to develop sufficient torque to make the motor suitable for railway work. This motor has two rotors on the same axis. The first rotor is synchronous and excited from a direct current source but does not transmit any torque to the shaft. The second one rotates inside the first driving the shaft and is an ordinary slip-ring motor. The synchronous rotor supplies the magnetization and it is possible to obtain unity power factor at different loads. It is also possible by increasing the excitation to compensate for the effect of voltage drop on the maximum running torque. A motor, rated 225 hp., 50 cycles, has been built.

An induction motor with Ward-Leonard control capable of carrying peak loads of 18,000 hp. deserves to be mentioned among large machines. This motor was recently built in Europe and was furnished for rolling mill drive.

The rapidly increasing use of fractional horsepower motors for domestic and other purposes has caused the power companies to become concerned about poor power factor conditions because there is no restriction about the performance characteristics of motors sold to the householder. The power companies have been seeking relief from this situation and recently an association of motor manufacturers, appliance manufacturers and power companies has been formed to study the situation. It has been agreed that motors for refrigerators and oil burners must have an apparent efficiency of 42 per cent and it is urged that improvements in design be made as rapidly as possible with the aim to obtain an apparent efficiency of 45½ per cent. It is possible that a single motor design will not be applicable to all domestic apparatus because of the wide range in duty.

A special application of a small motor to feeding the electrodes of an arc welding machine where it is required to operate close to the arc has led to the development of a water cooled motor. The motor has copper water tubes cast in the aluminum frame.

The desirability of domestic appliance motors being capable of operating without noise has lead to the provision of a spring support for some special application motors to eliminate the noise that is inherent in single-phase machines.

A new type of repulsion motor with a squirrel-cage in addition to the commutated winding has been developed in England for which advantages are claimed over the ordinary type.

The synchronous induction motor of the type using separate direct current excitation continues in favor in Europe. However, European literature indicates that the possibility of designing new types of self-excited machines is being actively investigated. Although the separately-excited type of motor was used commercially in America as long ago as 1911, it has not been so vigorously exploited as it has been in Europe. This year, however, a larger manufacturer has built motors of this type for driving tube mills where heavy starting torques are met and long periods of operation at full load make high power-factor motors highly desirable. This motor is the same in general construction as a wound rotor induction motor and has the same starting operation. It is provided with five collector rings for the rotor winding instead of the customary three rings. The exciter is wound for a low voltage and is connected permanently in the rotor circuit so that the starting operation is as simple as that of a wound rotor induction motor and requires no extra switching operation for the exciter. In order to limit the amount of excitation required these motors have deeper slots and considerable more copper for the rotor winding than the corresponding induction motor would have. Two motors of this type rated 900 hp., 180 rev. per min. have been put into operation this year and a 1500 hp. motor is being built.

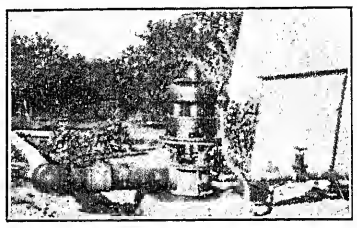

FIG. 17—VERTICAL INDUCTION MOTOR FOR PUMP DRIVE

Arranged with hollow shaft through which the pump shaft extends to clutch at the top.

A brush shifting, a-c., adjustable speed commutator type of motor is now available for operation with a continuous rating at low speed as well as at high speed.

The largest adjustable speed induction motor with Scherbius control to be built in America has been installed for driving a bar mill. It is rated 6700/5000/3320 hp. at 500/375/250 rev. per min.

During the past year, special induction motors have been designed and built for vertical irrigation pumps of the turbine or centrifugal type. These motors have hollow shafts through which the pump shafts project. The motor and pump shafts are connected by a clutch at the top of the motor. Important advantages are easy adjustment and alinement of the pump impeller, elimination of whipping action at the upper end of the pump shaft, or damage due to the momentary reversal of the motors during a power failure. Special windings obtain a low starting current when the motors are started at full line voltage. Relatively high starting and pull-out torques are obtained, with an efficiency and a power factor, at full load, approximately the same as those obtained with standard motors.

SYNCHRONOUS MOTORS

In the report of last year, mention was made of the use of single-phase, synchronous motors as parts of motor-generator sets to be installed on railway locomotives for supplying d-c. power to the main traction motors. These sets have been made in three sizes,—400 kw., 1000 kw. and 2500 kw.,—the ratings of the synchronous motor being 500 kv-a., 1200 kv-a., and 3100 kv-a., respectively,—25 cycles, 2300 volts, 750 rev. per min. These sets are equipped with direct-connected exciters and single-phase commutator motors, which are used not only for starting up the sets but also for furnishing excitation to the main traction motors for regenerative braking. For the purpose of maintaining uniform voltage at the terminals of the synchronous motors, the single-phase transformers for stepping the voltage down from 11000 to 2300 volts are provided with automatic tap changers. The two smaller sets are constructed with two bearings in the end shields while the large set has four bearings with the synchronous motor at one end and driving the two 1250 kw. d-c. generators in tandem.

A new type of self-starting synchronous motor has been developed for use in time switches, traffic signals.

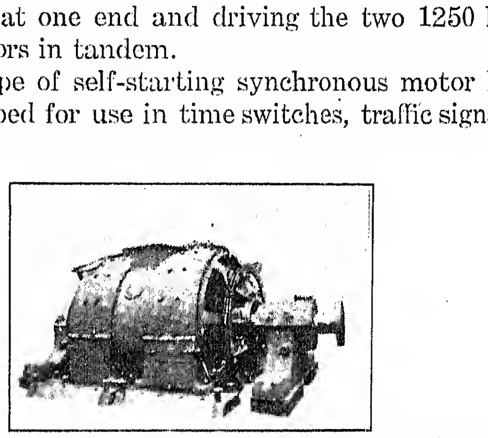

FIG. 18—DOUBLE PROPELLING MOTOR FOR DIESEL-ELECTRIC TUG BOAT

and other small devices requiring very small amounts of power. It is similar to the ordinary induction disk motor which has a disk type rotor revolving between the poles of a stationary electromagnet. The synchronous characteristic is obtained by means of a series of small iron inserts pressed into the disk near the periphery, which locks into synchronism with the alternating flux. A motor of this type which is probably the smallest electric motor that was ever made for actual commercial use has been built. It is two inches high and weighs four ounces and its output is less than one-millionth hp.

As has been mentioned in the 1925 report of this committee, two types of synchronous motor construction, particularly suitable for starting heavy loads, have been developed. One makes use of a built-in magnetic clutch which allows the rotor to come up to synchronous speed without load, the other is arranged so that the armature will be brought up to synchronous speed without load. For tube mills in cement manufacturing plants, there has been an active demand for motors of this type. The largest clutch-type motors have been

built during the year and are rated 900 hp., 1800 rev. per min., 100 per cent power factor. A new competitor in this field is the synchronous induction type, of which an important example is mentioned in the induction motor section of this report.

High-speed, synchronous motors of the turbo-alternator type have been successfully used for gas pressure boosters and blowers. Motors of 1800 rev. per min. and 3600 rev. per min. have been built for this service. The largest motor of this type that has been built was put into operation this year and is rated 2700 hp. at 180 rev. per min. It has successfully met the severe requirement of four starts in succession.

D-c. Machines

The application of Diesel electric power for the propulsion of boats, particularly tug boats and ferries which require a very flexible control for maneuvering, has swung strongly in favour of d-c. machines. For this purpose, some special types of propelling motors have been developed which are designed to fit the cramped space available for them. These motors are constructed with double armatures. Motors of this type rated 1250 hp. have been built for operation from a 1000-volt source. Normally the generating units are in pairs and their armatures are connected in series.

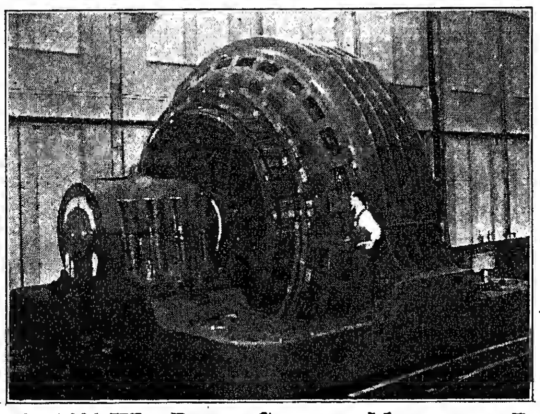

Fig. 19—8000-HP. Direct-Current Motor for Driving the Largest Blooming Mill in the World
This is the largest single armature direct current motor.

As in the case of induction motors a new line of totally enclosed fan-cooled, d-c. motors has been developed. These motors have fans, external to the parts that enclosed the windings and core, which draw air into the end shields and blow it over the surface. This arrangement makes it possible to obtain greater outputs from a given frame size than it is possible with the ordinary type of enclosure. For certain slow-speed ratings it is possible to increase the rating as much as 50 per cent.

Hydroelectric units with large size d-c., generators in vertical shaft settings are quite unusual, and for this reason, the installation in a European power house of four 4500-kw. machines should be noted. These will be capable of delivering 12,300 amperes at pressures ranging from 175 volts to 350 volts. The normal speed is 500 rev. per min.

Although synchronous and induction motor drives in steel mills have made great advances, d-c. motors are found to have indispensable characteristics for certain applications and there seems to be a decided tendency to go back to d-c. motors for drives where variable speed is required. During the year there has been built and put into operation; a blooming mill drive with Ilgner motor-generator set and reversing motor capable of handling peak loads of 15,000 hp. This apparatus embodies those features that have been found satisfactory in smaller units. During the past year work was completed on the 8000-hp. d-c. motor which is to drive the largest blooming mill in the world. This is the largest single armature d-c. motor ever built, both as to continuous horse-power and maximum torque. Other installations are a 3000-hp., 80/150-rev. per min., adjustable speed motor and a 7000-hp., 50/100-rev. per min., adjustable speed motor.

The first steel mill motor, using the series exciter scheme of connection for obtaining flat speed regulation, was put into service during the past year. This speed regulation is obtained by using two field windings on the mill motor. One of these fields is supplied from a constant potential source while the other has for its source a separate exciter, the field of which is in series with the armature of the main machine. The series field can therefore be made to compensate for the tendency of the motor to drop its speed with increase of load.

A recent contribution to the study of limits of large d-c. machines places the maximum commutator segment voltage at 30 volts and the maximum peripheral speed of the commutator at 360 ft. per sec., but at speeds above 100 ft. per sec., difficulties due to unreliable brush pressure are encountered.

Two 1400-kw., 125-volt, 11,200-ampere, 360-rev. per min. generators, built during the past year to electrolytic refining service are the largest 125-volt machines that have been built to date. These machines are notable for the extremely high current delivered at low voltage by a single commutator.

As mentioned in another part of this report, one of the means of increasing the transient stability of a transmission system is by increasing the speed of response of the exciter. This increase in the response of the d-c. machine can be accomplished by any or all of the following means:

1. Dividing the exciter field circuit into parallel paths.
2. Separately exciting the d-c. machines.
3. Increasing the rotational speed of the exciter by separate drive.

The advantages of this type of exciter in increasing system stability are now very generally recognized. Many large machines sold during the past year have been supplied with the quick response exciters.

Mercury Arc Rectifiers

There have been no radical developments in mercury arc rectifiers during the past year. It has been the first year in which rectifiers have been in service in the United States in considerable numbers, and the first time that they have been used in steam railroad electrifications in this country. For the first time, such a length of main line has been fed from rectifiers that service of the road has been dependent upon their continuous operation. That this device is a dependable piece of apparatus is indicated by the fact that a 1500-kw., 1500-volt rectifier has carried peak loads of 9000 kw. during an emergency extending over a period of several weeks.

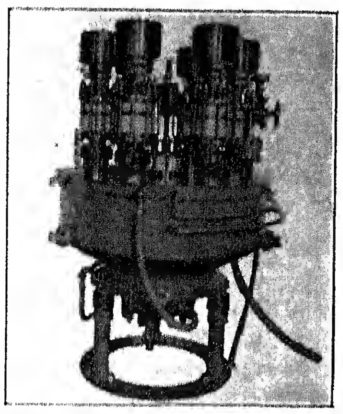

Fig. 20 Steel-Tank Mercury Arc Rectifier Rated 500 Kw., 600 Volts, or 750 Kw., 1500 Volts

It has been observed that inductive interference may be experienced in some cases of mercury arc rectifier operation but this problem has been met and methods have been worked out to bring the performance within communication standards.

A new type of rectifier has been placed on the market which has a higher current capacity than any built heretofore. This machine has twelve anodes and has a continuous rating of 2000 amperes at 600 volts. At higher voltages the current rating is a little less. Further progress has been made in the development of rectifiers for high voltages. Successful load tests have been made on steel cased units at 8000 volts. The application of power rectifiers of such high voltage is, at present, confined to certain chemical processes. Its overall efficiency is approximately 99 per cent. The voltage of rectifiers suitable for railway work is limited at present only by the design of the motor equipment. The total capacity of rectifiers installed by one large European manufacturer during the past year amounts to about 200,000 kw. and 90 per cent of them are for railway work.

Probably the most outstanding installation of rectifiers in the United States is that for the electrification of the Illinois Central Railroad terminal and suburban service at Chicago, where 9000 kw. in rectifier capacity is in use. An indication of the European confidence in rectifiers is made manifest in the placing of orders for a total of 95 units having a total capacity of 114,000 kw. by the Metropolitan railroads of Berlin.

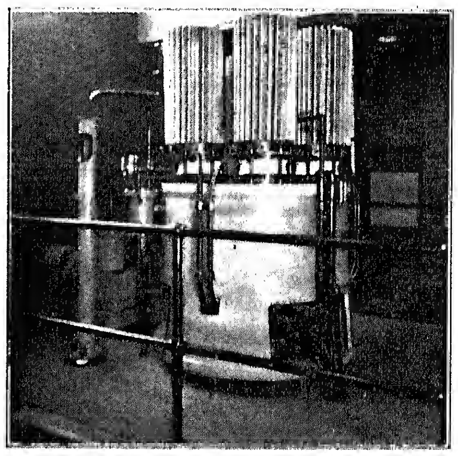

Fig. 21—View of Mercury Arc Rectifier of American Manufacture with Complete Equipment

During the past two years the total capacity of rectifiers manufactured and installed the world over has doubled each year.

In 1924 the total capacity was approximately 150,000 kw. In 1925 it increased to 310,000 kw., and in 1926 to 600,000 kw.

Diesel Engine Driven Alternators

During the year, the largest Diesel engine driven generator has been put into operation at Hamburg (Germany). The engine is rated at 15,000 hp. and is of the two-stroke cycle type with nine double acting cylinders. The direct-connected alternators are rated 13,000 kv-a., 94 rev. per min., 6000 volts, 50 cycles. The design of the shaft and coupling of a unit of this kind requires the consideration of torsional oscillations of the shaft.

Frequency Converters

Ties between power systems of the same frequency permitting control of the flow of power in either direction under conditions of varying voltage are made possible by the use of transformers having taps that may be changed under load and it is also possible to tie two systems of different frequency and control the flow of power under conditions of variations in frequencies by frequency converters of the induction type. This type of converter, consisting of a synchronous machine and an induction machine with Scherbius control, was mentioned in the report of this Committee in June 1925. A number of 5000-kw. sets of this description have been built. Another type of converter makes use of the cascade induction motor which depends upon a constant ratio of frequency. A number of 35,000- and 40,000-kw. sets of this type have been previously noted. During the past year there has been built a 15,000-kw. set of this description, and a 35,000-kw. synchronous frequency converter set has been arranged with suitable spring support for the generator stator so that it can be used for single-phase operation. This type of support minimizes the effect of the pulsating torque resulting from single-phase operation. The single-phase rating is 21,000 kv-a. The largest synchronous frequency converter set ever built has been put into operation. It is rated 50,000 kv-a., 300 rev. per min.

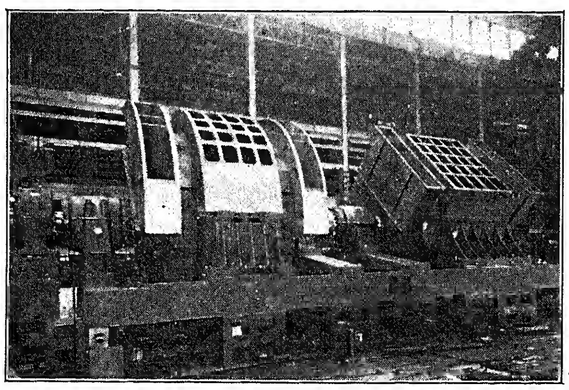

Fig. 22—Shop View of 30,000-Kv-a., 600-Rev. per min. Frequency Converter Set
Showing Arrangement of air intake and exhaust

Two sets with unusually high speed, have been built in the past year; one, a 30,000-kv-a. frequency changer at 600 rev. per min., and the other, a 17,777-kv-a. set at 720 rev. per min. The 30,000-kv-a. set is a 50-cycle—60-cycle set. The 50-cycle machine has been designed particularly for transmission line stability and incorporated in it the features described under the heading *Machine Characteristics for Stability*.

In Europe there has been an increased demand for synchronous frequency converters principally for railway work.

Bibliography.

"A 40,000-Kv.-a. Frequency Changer Set," R. A. McCarty, *Electric Journal*, July 1926, p. 339.

Synchronous Condensers

Because of the fact that synchronous condensers are in the class of non-revenue producing equipment, there has been a concerted effort to reduce costs and losses. This has been accomplished partly by designing for higher speeds. Sixty-cycle condensers have been constructed for operation at 900 rev. per min. up to a 10,000-kv-a. capacity and at 720 rev. per min. up to 20,000 kv-a. The largest condensers yet constructed are several that are for use for the regulation of the voltage at the receiving end of a 220-kv. transmission line in California. They are rated 50,000 kv-a., 600 rev. per min., 50 cycles, and the total calculated losses are only 1 2/3 per cent. They will be provided with a closed system of ventilation.

The largest condenser ever arranged for automatic control is under construction. It is rated 30,000 kv-a.

In Europe it is being found advantageous to employ as condensers asynchronous machines provided with phase advancers. A number of these have given complete success in service. They have been built in capacities up to 10,000 kv-a. Mention of these machines is made on p. 183 of the *Electrotechnische Zeitschrift* for February 10th, 1927.

"Determination of the Power of Synchronous Condensers Necessary for the Regulation of High Voltage Lines", H. Josse, Rev. Gén. Elec., Aug. 14, 1926, pp.. 243-250.

Sine-Wave Generators

The largest sine-wave testing generator has been completed during the year. It is rated 2000 kv-a., 2300 volts, 3-phase, 60 cycles, 1200 rev. per min., and is driven by a 600-kv-a., synchronous motor. This generator is capable of delivering 1200 kv-a., single-phase, and it is remarkable in that the voltage and current wave forms are sine-waves under all conditions of load. The characteristics are practically ideal. This set was built for use in testing high-voltage, underground cables.

High-Frequency Machines

During the past year a plan for the resonant control of street lights has been developed and this should give a new field for the application of high-frequency machines. This system of control requires a generating system which can supply both 440 and 660 cycles to the main lighting circuit. The entire system is described in the *Electric Journal* for February 1927.

"Type of High-Frequency Alternators," J. F. Calvert, *Electric Journal*, Jan. 1927, V. 24, pp. 36-39.

Induction Voltage Regulators

An improvement in the design of induction regulators for outdoor service has been made by bringing the driving spindle for the movable element out through one of the passages connecting the regulator tank and the expansion vessel, thus avoiding the use of all glands. An improvement in operation of induction voltage regulators as affecting vibration and noise has resulted from the use of roller bearings for the lower end of the shaft. A clearance in sleeve bearings will allow the movable element to vibrate and cause noise, yet tight bearings are liable to stick and interfere with the operation. Roller bearings can at once be made tight and free to turn. The use of all-welded, corrugated sheet-iron tanks has resulted in improved appearance, reduced weight, increased insurance against leakage, and greater ability to withstand shocks as compared with the corrugated cast-in construction.

Synchronous Converters

During the year, some synchronous converters have been built which have an unusually wide range of direct current voltage. They are rated at 1500 amperes over a range of 87 to 175 volts. The method of obtaining this variation in voltage is unique in that the a-c. voltage at the collector rings is varied by means of tap changing on the transformer. It is necessary, of course, to change the field excitation to correspond to the different transformer taps. Voltage variation between taps is obtained by field control.

The twelve phase synchronous converter which was mentioned in the report of last year has been put into operation and two more have been built. The various advantages which were mentioned have been fully realized in actual practise and it is not improbable that for future production the number of 12-phase converters will exceed that of six phase.

A recent English development in synchronous converters is the socalled binary converter, which in effect is a device consisting of an induction motor and a special direct current generator having a common magnetic circuit of sufficient size to take care of both rotating and stationary fluxes. This machine consists of a uniform magnetic circuit and a rotating armature. Two windings are located in the same slots of the stationary member, one for producing the stationary current flux and the other for producing a rotating flux. By a combination of a two-pole a-c. winding and a six-pole d-c. winding the six-pole d-c. winding on the rotating armature acts as a short circuit or squirrel cage winding for the bipolar a-c. winding. The usual commutator and brush gear is used with the armature winding.

Progress in Power Generation

Annual Report of Committee on Power Generation*

To the Board of Directors:

A meeting was held shortly after the appointment of the present chairman in February, to formulate plans for the committee's activities during the remainder of the administrative year.

The question of taking up certain subjects for special study and investigation was given particular consideration, but it was not thought advisable to attempt any work of this kind, because of the limited time available in which to prepare the annual report. There were presented at the meeting three subjects which the committee therefore recommends for investigation by its successors; *viz.,* Interconnection—its relation to station and unit capacity, reliability, and economy; Oil Circuit Breakers of Large Capacity—with particular reference to reliability, economy of space, and costs; and Comparison of American and European Power Station Practise.

At the invitation of the Standards Committee a "contact officer" was appointed for prompt cooperation with that committee on any matter of standardization in which the Committee on Power Generation may be concerned. In this connection the Standards Committee has been asked to cooperate with the A. S. M. E. in the preparation of a section on "Measuring the Output of a Generator" for inclusion in the A. S. M. E. Test Code for Steam Turbines. A subcommittee of your Committee on Power Generation has been appointed to assist the Standards Committee in this work.

There have been secured by the committee for presentation at the Summer Convention in June, two papers dealing with the design and operation of Power Stations, one by F. A. Allner on *Holtwood Steam Plant, Design and Operation in Coordination with Water Power,* and one by J. W. Anderson and A. C. Monteith on *Auxiliary Power at Richmond Station.*

Many important developments in power generation during the past year have been extensively reviewed and the following résumé and bibliography are presented to show the progress made and the trend in the art.

Résumé of the Year's Progress in Power Generation

One of the outstanding features in power development is the tremendous increase in the so-called ultimate station capacity over that anticipated at the time of the initial installation. In some cases, the ultimate capacity will probably be more than double that originally expected. What has brought this about is the unprecedented increase in system loads and the introduction of units of much larger capacity than those first installed. In the eternal quest for greater and yet greater economies in power stations, notable technical achievements have been brought about in practically every line of the industry. Such developments during the past year have been so many and so varied that it is possible in a brief survey to touch on only a few of the most noticeable tendencies.

In this résumé, the committee does not attempt to predict the future of the art in power generation, but simply points out the trend as indicated by the important developments that have taken place or are now under construction.

Steam Turbine Generator Units

Capacity. Turbines and generators of unprecedented size have been designed and completed during the year and still larger ones are now under construction. Less than two years ago the largest turbine being built was under 100,000 kw. The largest turbine to date is the 208,000-kw. unit now under construction and one of the manufacturers has offered a machine in excess of 300,000 kw. The largest single-cylinder turbine yet built in this country is a 65,000-kw. normal pressure unit. Without extensive interconnection it would not be wise or economical to install such large generating units.

The motive for these huge machines is not so much better fuel economy as it is reduced plant investment and the desire to keep the total plant capacity in reasonably few units. Experience with large units has demonstrated that they can be operated almost as continuously and easily as smaller machines. We may expect therefore, that the construction of huge generating sets will continue, although to what final limit it is difficult to predict.

As an indication of the trend toward larger units, it has recently been decided that throughout Chicago and adjacent territory no turbine will be installed in the future of less than 50,000 kw. capacity.

Type. The combination of turbines and generators to make up a single generating unit is quite varied. Tandem compound and two- and three-element cross-compound formations offer numerous means of providing generating units in excess of 60,000 or 70,000 kw. capacity. The actual formation depends to a large extent on local conditions to be met and the ideas of the turbine manufacturer and the plant designer as to the best means of accomplishing the results desired. It is likely that turbines of the compound type will be

used for the very large capacities. There appears however, to be a marked tendency on the part of many engineers toward still larger turbines of the single-cylinder design.

There are now under construction four outstanding turbine units each of a different type and the largest of its kind on record. The sizes and types of these units are: 208,000-kw. cross compound, three elements; 160,000-kw. cross compound, two elements; 94,000-kw. tandem compound; and 65,000-kw. single-cylinder.

Speed. The trend toward higher speed is evidenced by the fact that there are now on order a number of large turbines which are to operate at 1800 rev. per min. The prevailing turbine generator speeds are 1500 rev. per min. for 25 and 50 cycles and 1800 rev. per min. for 60 cycles. Smaller units up to as high as 10,000-kw. capacity have been made for operation at 3600 rev. per min. The largest 1800-rev. per min. generator designed to date is the 89,412-kv-a. machine for the high-pressure element of a triple-shaft unit now under construction, and the largest 1500 rev. per min. generators on record have a capacity of 100,000 kv-a. An indication of the rapidity of the development of the art is furnished by the fact that a little more than a year ago a 60,000-kw. generator was regarded as a conservative maximum limit of capacity in 1800-rev. per min. units.

It has been suggested by eminent authority on turbine design that some economies might be effected by a system of standardization, which would limit the number of sizes of machines built. The greatest economy in first cost is obtained by using the highest possible rotative speed, and the most profitable machine for builder and user alike is that of the greatest capacity at the given speed. It would be an advantage from the standpoint of investment to concentrate upon a relatively few standard capacities of large machines for 1800-rev. per min., 60-cycle service, and 1500-rev. per min., 25- and 50-cycle service. A larger number of standard capacities would be required in 3600-rev. per min. turbines of capacities of 10,000 kw. and lower for manufacturing requirements. In a growing power system having a number of interconnected stations, a new unit of large capacity added to the system may be operated within quite a range of its capacity without greatly affecting the efficiency of operation of the system, and therefore it would seem desirable to choose the largest standard machine to secure the advantage of lowest investment per kilowatt.

Pressure. The desire to secure high efficiencies in steam power plants has resulted in rapid increase in pressure and temperature to a maximum of 1400 pounds and 750 deg. fahr. in this country. In the United States, the boiler pressures in large steam power plants have been confined to three classes of approximately 1400 pounds, 600 pounds, and 400 pounds, the steam pressure at the turbine throttle being about 1200 pounds, 550 pounds, and 350 pounds respectively. These pressures represent about the average conditions, some may be 5 per cent or 10 per cent above or below. There appear to have developed three schools of engineering for the above pressures and each is apparently convinced that the pressure which it has adopted is the most economical one. From the turbine designer's standpoint no insurmountable problems have been presented up to the highest pressures so far considered.

The 1400- and 1200-pound boilers and turbines have continued to operate satisfactorily and the results in at least one station have justified the installation of additional high pressure units. For large stations, 500 pounds to 600 pounds has become more or less standard pressure. Stations with these pressures have given satisfactory service with no unusual difficulties. In fact, many of the expected serious difficulties with pipe joints and other details have so far failed to materialize. It may therefore be said that the way is clear for a general increase in the steam pressures of all new plants.

An investigation of the properties of steam was started about five years ago and it is expected that this work will be completed in the near future. These data will be of great value in designing high-pressure stations and will help us to analyze the results obtained in actual operation. As to the most economical pressure, some engineers maintain the following: "From our present knowledge it is not likely that steam pressures will very much exceed 400 pounds for all the main units of stations with average load factors and 650 pounds for all the main units of stations carrying what is commonly known as base load." A 400-pound steam pressure plant is probably the most economical installation for a small load factor or low price fuel. Furthermore, this pressure is very well adapted to the superimposition of a high-pressure steam cycle or a mercury cycle at a later date when warranted by an increased load factor or price of fuel. The experience at the Edgar Station of the Edison Electric Illuminating Company of Boston and the Lakeside Station of the Milwaukee Electric Railway and Light Company indicates that a boiler pressure of 1400 lb. per sq. in. is economically justified. Care must be taken, however, not to draw general conclusions from any particular installation for the local conditions are a big factor in determining what pressure is the most economical one for any contemplated station. A careful study must be made before a decision can be reached as to the proper boiler pressure for any new station. We must keep constantly in mind that the base load station of today will be the peak load station of tomorrow, and this fact should not be overlooked when figuring the investment warranted.

Temperature. The total temperature of steam has, in the last few years, been limited to 750 deg. fahr. for all pressures, while most of the plants are operating at temperatures varying from 700 deg. fahr. to 725 deg.

fahr. There probably will be some endeavor to resort to higher steam temperatures in the future, but whether the increase in temperature will be in decided steps by using special alloy steels, or whether there will be a gradual increase in steam temperature from year to year, cannot be predicted at present. Much research has been and is being conducted on the physical characteristics of materials at high temperatures, a feature being the tests carried out under continued stress and temperature. The general results will give opportunities for securing greater reliability under the maximum temperatures which obtain today in power plant operation in this country. It is reported that there are plants in Europe operating on the straight steam cycle at temperatures higher than 750 deg. fahr. but the general adoption of higher temperatures for this cycle will depend upon the results of the research work now in progress.

Bleeding and Reheating. Stage bleeding for heating the boiler feed water and evaporating the make-up water has become almost standard practise and in most of the large plants constructed recently, the bleeding is done in three or four, and in some cases five, separate stages.

One method extensively used is bleeding in which the feed water heating is done entirely by steam extracted from the main units. Such a scheme, in which a four-stage extraction heating system contributes a final feed temperature of 383 deg. fahr., has been adopted for the 94,000-kw. turbine in Long Beach Power Station, and is shown in Fig. 1. The evaporator and its separate condenser are interposed between the 10th and 14th stage extractions, which is a thermally efficient disposal of this apparatus, by virtue of the fact that there is no external heat degradation from the 10th stage to the 14th stage. It is economically advisable in a set of this size to employ separate drip return pumps for the two low- heaters and for the evaporator condenser. It noted that the drains from the 5th stage he passed to the shell of the 10th stage heat which point the combined drains of these tw enter the flash tank, which cooperates with the tor condenser. This generating set will hav high use-factor so the heaters have been cho close terminal temperature differences. The tors and heaters are of Griscom-Russell des removable tube bundles.

Reheating of the steam after it has com portion of its expansion, has proved satisfact successful where applied. Reheating in th room however, requires large piping to and f reheating boiler and also involves some loss in which partially offsets the gains from reheatin year has brought out a new development overcoming these objections and it is now pro

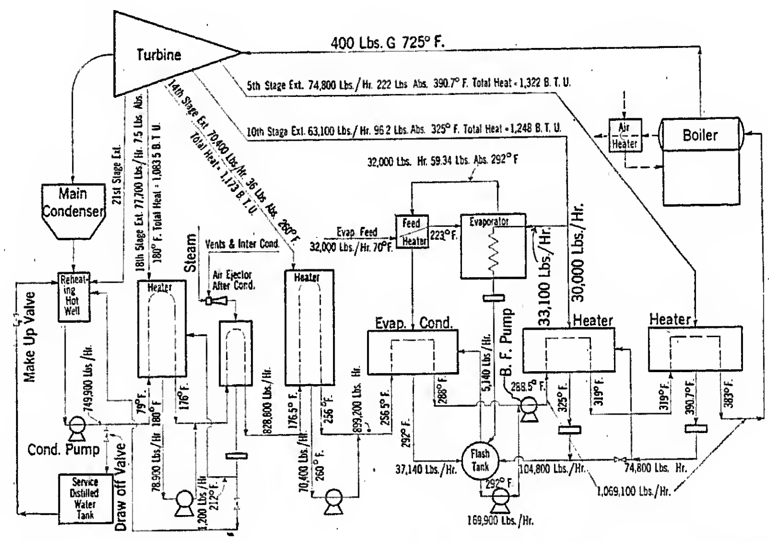

FIG. 1—APPROXIMATE HEAT DIAGRAM. SOUTHERN CALIFORNIA EDISON CO., LONG BEACH STEAM PLANT NO. 3—NO. 10 UNIT

reheat the steam at or near the turbine usi pressure live steam.

Voltage. With the increase in size of steam driven generators, which today have reached a r of 100,000 kv-a., an increase in the generator v desirable. It is well known that this higher will, by decreasing the current, affect a cons reduction in the cost of busses, switches, cabl and probably before very long many gener 50,000 kv-a. and upward will be wound fo voltages than have prevailed heretofore. illustration of this trend, there are now und struction a 100,000-kv-a. generator for 16, operation, the generators for a 208,000-kw compound three-element unit to be operated a volts, and also a single-shaft generator of 61,7 that will operate at 22,000 volts.

Generator Cooling and Fire Protection. It is

universal practise to employ the closed system of air circulation with surface air coolers for machines above 6000 kw. and quite common practise on smaller machines. The possibility of using an inert gas continuously has been suggested, but the predicted advantages have not been considered sufficient to warrant its introduction. The use of hydrogen, because of its lower density and higher specific heat promises many advantages, and provision is being made for its use at a later date in some machines now under construction.

The introduction of the enclosed machine has resulted in the installation of a number of CO_2 fire extinguishing systems. Where this protection is used on generators and similar rotating electrical machines the CO_2 is injected in the intake air duct and a predetermined concentration is maintained until the machine comes to a stand still. Leakage during deceleration is compensated for by introducing additional gas at necessary intervals. This application of course is particularly adapted to closed recirculating ventilating systems.

The following are some of the outstanding turbine and generator installations recently completed or now under construction:

Single Cylinder Turbine Units. The outstanding single cylinder turbine unit installations during 1926 were the 60,000-kw. General Electric units at the Charles R. Huntley (formerly River) Power Station of the Buffalo General Electric Company and at the East River Power Station of the New York Edison Company. The machine installed at Buffalo is supplied with steam at 250 lb. gage and 656 deg. fahr. The speed is 1500 rev. per min. and the generator is rated at 66,667 kv-a. At the East River Station the two 60,000-kw. 100 per cent power-factor units are also General Electric machines which are supplied with steam at 375 lb. gage and 700 deg. fahr. The turbines are twenty-stage impulse type units operating at 1500 rev. per min. and are bled at three points for feed water heating.

The record size single cylinder installation of 1926, however, will be exceeded by the addition now being installed in the Edgar Station of the Edison Electric Illuminating Company of Boston. This installation will include a 65,000-kw. single-cylinder General Electric turbine, which will run at 1800 rev. per min. and drive a 75,000 kv-a. main generator and a 6250 kv-a. auxiliary generator. This turbine will operate on steam at 350 lb. gage and 725 deg. fahr. In addition to the 65,000-kw. normal pressure unit, a 10,000-kw. 1200-lb. unit will be installed which will exhaust through reheaters into the 350-lb. steam header. The feed water will be heated with steam bled from three points of the 65,000-kw. unit and also from the exhaust of the 10,000-kw. high-pressure unit.

Tandem-Compound Turbine Units. The largest tandem-compound (single-shaft) units in operation in 1926 are the two 50,000-kw., 20-stage, impulse type, General Electric units at the Richmond Station of the Philadelphia Electric Company, and the two 50,000-kw., reaction type, Westinghouse units at the Hudson Avenue Station of the Brooklyn Edison Company. The Richmond Station units operate at a steam pressure of 385 lb. and 675 deg. fahr. total temperature. The speed is 1800 rev. per min. and the generators are rated at 62,500 kv-a., furnishing power at 14,000 volts, 60 cycles. The generators are cooled by two motor-driven external fans, solidly connected to the generator leads through transformers. Recent tests indicate, however, that the Richmond Station units can be given a higher rating, which has been tentatively and probably will be finally fixed at 60,000 kw., 0.85 power factor, *i. e.*, 70,600 kv-a. The machines at the Hudson Avenue Station are supplied with steam at 265 lb. and 611 deg. fahr. total temperature. The speed is 1200 rev. per min. and the generator capacity is 62,500 kv-a.

The 50,000-kw., tandem-compound, Allis-Chalmers turbine generator unit recently placed in operation at the Waukegan Station of the Public Service Company of Northern Illinois is also a notable installation, in that the steam pressure will be 600 lb. gage and the total steam temperature 725 deg. fahr. The generator is rated at 58,800 kv-a., the speed being 1800 rev. per min. The exciter will be direct-connected to the shaft. The turbine will be provided with five extraction nozzles.

The Southern California Edison Company will install at its new Long Beach Power Station No. 3, a 94,000-kw., 1500-rev. per min. single-shaft, tandem-compound, turbine generator unit. This will be a 21-stage, impulse type, General Electric unit, and will be the largest single-shaft turbine on record. The turbine will have two cylinders with complete double flow of the steam in the low-pressure cylinder. The steam pressure at the turbine will be 400 lb. gage and 725 deg. fahr. total temperature, and there will be four extraction points for heating feed water to a total temperature of 383 deg. fahr. The turbine will be direct connected to a 100,000-kv-a., 16,500-volt, 50-cycle generator with a 5000-kv-a. auxiliary generator and 60-kw. exciter for the auxiliary generator on the same shaft.

Cross-Compound Turbine Units. The largest cross-compound turbine generator unit placed in operation in 1926 was the 80,000-kw. Westinghouse unit at the Hudson Avenue Station of the Brooklyn Edison Company. This consists of one high-pressure and one low-pressure cylinder operating at 1800 rev. per min., each driving a 45,000-kv-a. generator, with the exciter direct-connected to the high-pressure element. Steam is supplied at 375 lb. and 700 deg. fahr. total temperature. The high-pressure element is a combination impulse reaction turbine, while the low-pressure element is a double flow reaction turbine.

All previous records of turbine sizes will be exceeded by the remarkable cross-compound units now in course of construction—the 104,000-kw. Westinghouse unit for the Crawford Avenue Station of the Commonwealth Edison Company, the 108,700-kw. Westinghouse unit

for the Hudson Avenue Station of the Brooklyn Edison Company, the 160,000-kw. American Brown Boveri unit for the Hell Gate Power Station of the United Electric Light and Power Company, the 165,000-kw. General Electric unit for the Philo Power Station of the Ohio Power Company and the 208,000-kw. General Electric unit for the State Line Power Station of the Commonwealth Edison system.

The 104,000-kw. Westinghouse unit (Fig. 2), for the Crawford Avenue Station is unique in that it was designed as a base load unit. The leaving loss of this unit is reduced to a minimum and is approximately 1 per cent at the economical load and 1¾ per cent at the maximum load, in both cases when steam is being bled at four extraction points for heating its own feed water. To secure this low leaving loss, the triple-flow, low-pressure principle is employed. The steam is supplied to the high pressure element at 550 lb. gage and 725 deg. fahr. and expanded to about 40 lb. absolute. It is then reheated, by means of a live steam reheater to 500 deg. fahr. the steam then entering the double flow intermediate element. One-third passes in one direction and is completely expanded, while two-thirds of it passes in the opposite direction expanding to 8 lb. absolute. It is then passed to the double-flow, low-pressure element which is in the same line of shafting as the intermediate element. By this arrangement, steam is exhausted to the six vertical condensers at three points, two condensers being at one end of the intermediate element and two condensers at each of the two ends of the double-flow, low-pressure element. Any one of the six condensers can be opened at the water end while the unit is in service with no other effect than a reduction of the condensing surface. The speed of each of the two lines of shafting will be 1800 rev. per min. and there will be two main generators.

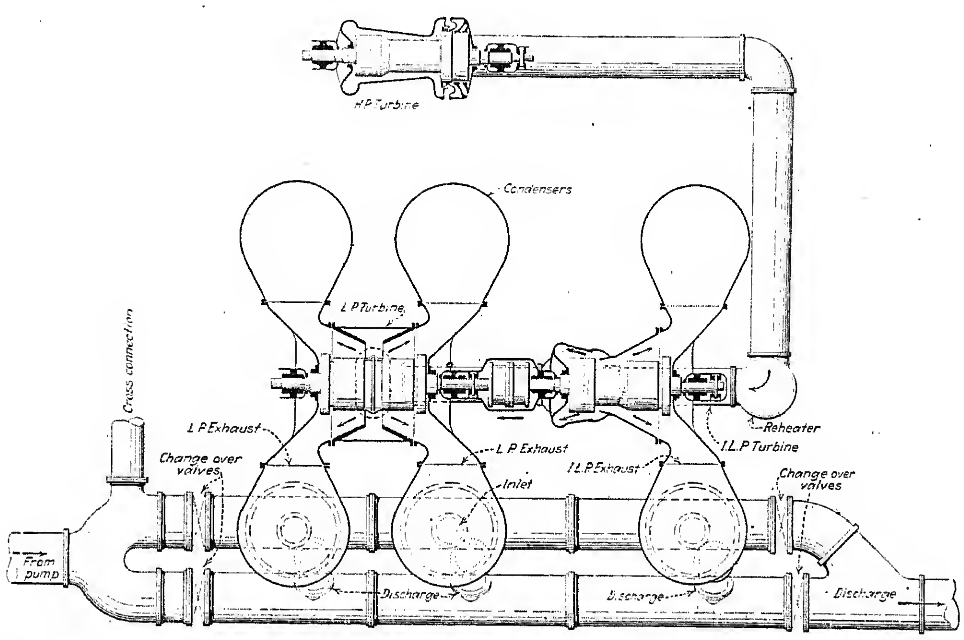

FIG. 2—ARRANGEMENT OF TURBINES FOR 104,000-KW. WESTINGHOUSE UNIT FOR CRAWFORD AVENUE STATION OF COMMONWEALTH EDISON COMPANY

The circulating-water piping shown for three of the condensers is duplicated for the other three.

The reheating of the exhaust steam from the high-pressure element by means of live steam from the high-pressure header is a new departure that is also being installed for the 91,500-kw. unit under construction for this station.

After the 104,000-kw. and 91,500-kw. units are installed, and including the 77,000-kw. unit recently placed in operation, the total installed generating capacity of the Crawford Avenue Station will be 432,500-kw.

The Brooklyn Edison Company has just closed an order for a Westinghouse 108,700-kw., 80 per cent power factor (136,000 kv-a.), 60-cycle, three-phase, 13,800-volt, cross-compound, two-element steam generating unit. The turbines are to be of the parallel-flow type and drive two 68000-kv-a., 1800-rev. per min. generators. The exciter is direct connected to the high pressure generator shaft. The machine will use a steam pressure at the throttle of 375 to 400 lb. per sq. in. at 700 deg. total temperature. It will heat the condensate in four stages of feed heating. Two interesting features of the design of the turbines are the five governor control valves in two steam chests and the stainless steel blading. The generators are arranged with internal fans, and generator air coolers are being supplied with the unit. The main generator fields will be alike so that they may be used on either stator, and the shaft ends will be alike for this purpose.

In deciding upon the size of the Hell Gate unit, the special problem arose of providing a turbine of the greatest possible output in the space available, which is

$25\frac{1}{2}$ ft. by 69 ft. Owing to the limited floor space, the turbine was designed as a two-cylinder machine with two lines of shafting (cross-compound) and it is a pure reaction turbine. The high-pressure element has a capacity of 75,000 kw. at 1800 rev. per min., and the low-pressure element can deliver 85,000 kw. at 1200 rev. per min. Steam will be supplied to the high-pressure element at 265 lb. and 600 deg. fahr. total temperature. There will be extraction at two stages for heating feed water, one at the low-pressure element inlet and one at about the middle of the low-pressure element. The alternators are built for a continuous output of 188,200 kv-a. at 13,800 volts and 60 cycles, the capacities of the generators driven by the high- and low-pressure turbines being 88,200 kv-a. and 100,000 kv-a., respectively. This unit will be required at present for a normal service of 50,000 to 100,000 kw., but in the event of one or more of the existing units failing, it must be able to take over 160,000 kw. continuously. In spite of the large overload, it was therefore necessary for the unit to have a high efficiency at a small load and it was designed with a flat efficiency curve.

The 165,000-kw. unit at the Philo Station will consist of one high-pressure and two low-pressure elements, each element having a speed of 1800 rev. per min. the high-pressure element having a capacity of 49,000 kw. and each low-pressure 55,000 kw. There will be in addition to the main generators, two 3000-kw. direct-connected auxiliary generators. Alternating current will be delivered at 11,000 volts, 60 cycles. The main generators will have a capacity of 57,647 kv-a. and 64,706 kv-a. each for the high- and low-pressure turbines respectively, and the auxiliary generators 4286 kv-a. each. Steam will be delivered to this machine at 600 lb. 725 deg. fahr. total temperature and there will be five extraction points for feed water heating, the highest point having a pressure of 360 lb. absolute, and the lowest 6.15 lb. absolute. The initial steam pressure for the low-pressure element will be 126 lb. absolute, 725 deg. fahr. total temperature after reheating.

The largest unit on record anywhere, is the 208,000-kw. three-element machine now under construction for the State Line Plant, a plan of which is shown in Fig. 3. It will consist of a 76,000-kw. high-pressure element and two 62,000-kw. low-pressure elements, all elements operating at 1800 rev. per min. Each of the two low-pressure turbines also operate a 4000-kw., direct-connected, auxiliary generator. The main generators will be wound for the remarkably high voltage of 22,000, the frequency being 60 cycles. The generator driven by the high-pressure turbine will have a capacity of 89,412 kv-a., the two generators driven by low-pressure turbines, 72,941 kv-a. each, and the auxiliary generators 5333 kv-a. each. The high pressure element will be supplied with steam at a pressure of 600 lb. and a total temperature of 730 deg. fahr., and the steam will be reheated between the high- and low-pressure elements to 500 deg. fahr., the pressure being 110 lb. absolute. The exhaust steam from the high-pressure element will be reheated with live steam from the high-pressure header. Eight Allis-Chalmers condensers having a surface of 22,000 sq. ft. each will be used with the 208,000-kw. unit. There will be five extraction points, including the cross-over, from a maximum of 380 lb. absolute to a minimum of 9.4 lb. absolute.

An interesting four-cylinder compound turbine generator unit has been reported in the technical press as being under construction by the Allgemeine Elektricitäts Gesellschaft for a new superpower station in the suburbs of Berlin. The unit will have a maximum rating of 85,000 kw. A high-pressure and an intermediate cylinder are arranged in tandem, driving a single generator and there are two low-pressure cylinders in tandem driving a second generator, the speed of both generators being 1500 rev. per min. The initial steam pressure and temperature are 500 lb. absolute and 750 deg. fahr., respectively. In the first stage a small Curtis wheel is installed and the remainder of the high

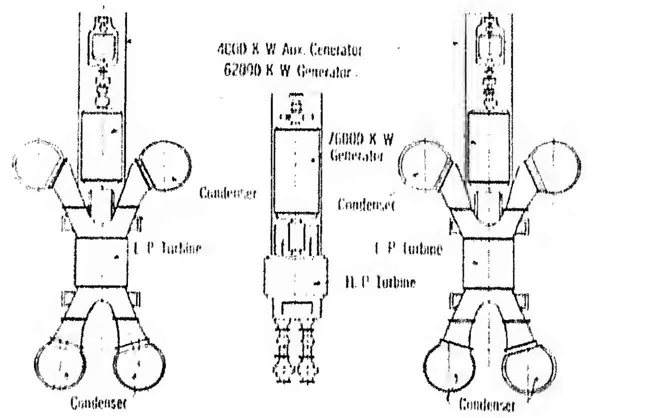

Fig. 3 Arrangement of 208,000-Kw. General Electric Turbine Generator Unit for the State Line Power Station of the Commonwealth Edison System

pressure and intermediate-pressure bladings consist of 30 stages of simple pressure compounded, impulse type. The two low-pressure turbines have 24 stages of reaction blading in each, and the steam flows through the two casings in opposite directions in order to eliminate the axial thrust.

Condensers

The factors governing the performance of a condenser are coming to be better understood. With increased knowledge of condenser performance and its relation to the cost of producing electrical energy, much attention has been paid in the last few years to increasing the efficiency of this apparatus. Condensers are now chosen on a capitalized basis, wherein initial cost, vacuum, power consumed by auxiliaries, and reliability are all given monetary value.

Condensers as measured by steam capacity have kept pace with the growth of turbine sizes. Although still larger units can be built, there is a tendency because of construction and installation difficulties, toward the

use of divided units for very large sizes. As an indication of this trend, the largest turbine on record to date will have eight condensers which will handle a total of 1,600,000 lb. of steam per hr.

There has been a marked reduction in the ratio of square feet of condenser surface to kw. capacity of the turbine. This has been brought about because of a more intelligent arrangement of tubes in providing lanes that give a proper direction of the steam flow, bleeding of turbines and improved turbine water rates. An investigation regarding condenser installations in modern power plants shows that, among forty of the most prominent power stations completed within the last two years, only two have a ratio of condenser surface to kilowatt of normal turbine capacity under 1.0. This ratio for the different stations varies considerably, one being as high as 2.75, and the average for all stations being 1.396. This year however, has seen a further reduction in the amount of condensing surface per kilowatt of normal turbine capacity. Considering the condensers of appreciable size now under construction, 50 per cent of them have a ratio of less than 1.0, the four largest ones averaging 0.86, the lowest one of the four being 0.77. The problem of selecting a condenser for a particular unit is essentially one of an economic nature, and the ratio recommended by the different manufacturers may vary considerably according to the condenser design of the individual manufacturer.

The single-pass condenser has been gaining in favor whereas up to within the last two years the two-pass condenser was almost universally used. There appears to be a decided tendency toward the use of both vertical and horizontal single-pass condensers. The first single-pass vertical condensers to be built are now under construction for the Long Beach Station and will be installed early in 1928. There are also under construction, vertical bottom inlet, single-pass condensers for the 104,000-kw. and the 208,000-kw. units to be installed in the Chicago district.

A recent unique development in tube sheet construction which is claimed to eliminate leakage, will be applied to several condensers now being built. These condensers will have a floating tube sheet at one end with a rubber expansion joint between the tube sheet and the condenser shell. With this arrangement the tubes are expanded into both tube plates rigidly, the movement of expansion and contraction being taken up in the floating tube head.

Tube cleaning still presents a considerable field for investigation. During the past year experiments were conducted on a large condenser in one of the plants in the Chicago district operating on very foul circulating water, to show the effect of velocities on keeping tubes clean and decreasing the rapidity of slime formation. The results of approximately a month's run showed that the higher the velocity, the cleaner the average condition of the tubes. Also that flushing these tubes periodically at relatively higher velocities for short periods tended to return the efficiency of the tubes to their original condition at the start of the run.

Condensers built with divided water boxes and provided with two circulating pumps are becoming increasingly popular, as it permits cleaning one-half while the other half is in service.

Improvements have been made in the construction of hot-wells, so as to cause violent ebullition of the condensate before discharging into the suction of the pump. In one form of construction the condensate is exposed to a lower absolute pressure before discharging to the pump and in another form the drips from the bleeder heaters are led into the comparatively cool condensate. The resulting ebullition in each case has been found to be particularly successful in affecting deaeration. This construction may eliminate the necessity for deaerators.

Motor-driven auxiliaries are in the majority and there is a tendency toward the use of duplicate units. The prevailing practise seems to limit the number of circulating pumps to two per condenser, providing for each an independent source of power supply.

In a number of cases, condensers and piping have been arranged in such a manner as to permit the reversal of flow of the circulating water through the condenser tubes. This arrangement makes it possible to wash the trash out from the tube ends and water boxes, and it is particularly justified economically in cases where the water carries a considerable amount of trash most of the time.

An interesting development which has recently been applied to large power stations is a vertical screw impeller type of circulating water pump having high efficiency at low heads which is so designed that the pump may be located in a pit below the intake water level. It is therefore always primed and presents the advantage of being able to deliver water to the condenser without the necessity of priming suction and discharge lines.

The following are some of the outstanding condensers now under construction or recently placed in operation:

The 208,000-kw. turbine unit for the State Line Station of the Commonwealth Edison system will have eight Allis-Chalmers condensers of 22,000 sq. ft. cooling surface each or a total of 176,000 sq. ft., two condensers serving each of the low-pressure ends of the two double-flow, low-pressure turbines. The condensers will be of the vertical, single-pass type, the circulating water entering the lower water box, passing upward through the tubes, and discharging downward through two over-flow pipes contained in the condenser shell. With a circulating water rate of 360,000 gal. per min., it is capable of condensing 1,600,000 lb. of steam per hr. There will be four vertical circulating pumps placed in a crib house outside the generating station.

At the Crawford Avenue Station of the Commonwealth Edison Company, the 104,000-kw. unit will be served by a total of 90,000 sq. ft. of condensing surface composed of six 15,000-sq. ft. vertical Westinghouse condensers of the single-pass, radial flow design, which will be capable of condensing a total of 730,000 lb. of steam per hr. Circulating water will be sent up through a center pipe and down through the tubes at a rate of 180,000 gal. per min., two vertical pumps being used.

In the condensers for the 94,000-kw. unit for the Long Beach Station of the Southern California Edison Company, provision will be made for reversing the flow of circulating water in order to clean the tubes. There will be four Ingersoll-Rand condensers for this unit and they will be of the vertical, single-pass type having 20,000 sq. ft. of cooling surface each, or 80,000 sq. ft. in all. Two motor-driven pumps will supply approximately 150,000 gal. of circulating water per min.

An instance of the trend toward a decreasing ratio of condensing surface to turbine capacity is the 25,000-sq. ft., single-pass, Wheeler condenser for the 31,500-kw. unit to be installed at the Cabin Creek, W. Va., Power Station of the Appalachian Power and Light Company. The ratio of condensing surface to turbine capacity will be 0.793 sq. ft. per kw. Provision will be made for reversing the flow of circulating water and an external 1500-sq. ft. air cooler will be used.

The 50,000-sq. ft., single-pass, Wheeler condenser for the 55,000-kw. unit being constructed for the Pekin Power Station of the Super Power Company of Illinois will also have provision for reversing the flow of circulating water. Specially built-in valves in the water chambers will be provided for this purpose, and there will be a 5000-sq. ft. external air cooler.

The unique development in design of using a "floating" tube sheet will be applied in the case of the 25,200-sq. ft. single-pass, Wheeler condenser for the 30,000-kw. unit for the Virginia Electric and Power Company at Norfolk, Va. A storage hotwell will also be provided for this condenser and there will be a 2000-sq. ft. external air cooler.

Another instance of the trend of decreasing ratio of condenser surface to turbine capacity is the two pass, vertical, twin-type Worthington condenser for the 91,500-kw. unit being constructed for the Crawford Avenue Station of the Commonwealth Edison Company. The total condensing surface will be 70,520 sq. ft., or 0.77 sq. ft. per kw.

One of the largest condensers being built is that for the 41,250-kw. turbine for the Colfax Station of the Duquesne Light Company. It is a Westinghouse radial flow, two pass type with divided water boxes, having a tube surface of 62,500 sq. ft. Steam will be condensed at the rate of 412,000 lb. per hour when using 72,500 gallons of circulating water per minute.

Boilers, Superheaters, and Economizers

Boiler development has been influenced by the trend toward larger units, higher pressures, higher operating ratings, new furnace designs exposing the maximum surface to the radiant heat of the fire, automatic combustion control, reduced plant investment, and operating cost.

The boiler will grow in size with the rest of the industry. One new station has been designed so that one boiler can readily generate all the steam needed to carry the main turbine, and a capacity of over 35,000 kw. has been developed with ease. It is reported that one boiler has already developed sufficient capacity to generate all the steam required for a 50,000-kw. unit. This has come about through operation at very high evaporative rates made possible by substituting water cooled walls for those refractory lined. The use of water-cooled furnace walls and bottoms, resulting in a large percentage of the heat absorption taking place in the furnace at heat transfer rates in the neighborhood of 60,000 B. t. u. per sq. ft. per hr., requires a readjustment of the boiler heating surface involving a reduction in that portion receiving heat solely by convection. This change caused higher boiler outlet gas temperatures which were reduced to very low values before entering the stack, by the extensive use of air preheaters and the adoption of water heating surface in the form of integral steaming economizers of relatively low cost as compared with water heating surface in the boiler proper. The use of economizers has been stimulated by the use of higher steam pressures permitting higher feed water temperatures so that in some cases both air heaters and economizers may prove economically justifiable.

That boiler designs are not only being modified and extended to huge proportions but also are being radically altered, is evidenced by the advent of the so-called Combustion Steam Generator. This equipment, utilizing pulverized fuel, is a recent product of the International Combustion Engineering Corporation and reflects the trend toward higher ratings, completely water-cooled furnaces, reduction of convection heating surface, and intense turbulence of the furnace gases. Twelve of these units have been contracted for, some of which are ready to go into service, and others are in course of erection. Considerable interest is being manifested in this development and the performance of the equipment will be closely watched.

The benefits of highly preheated air both for stokers and for powdered coal firing are becoming more generally realized. Developments in air preheaters have been rapid. It is probable that new stations will install air preheaters of such a capacity that the flue gases will be cooled to relatively low temperatures.

There have been no unusual developments in the design of superheaters during the past year except that manufacturers are ready to offer superheaters to furnish steam at a maximum of 900 deg. fahr. The preferential

location of the superheater for high temperature seems to be in the inter-deck position, although a few installations have been made of the combination convection-radiant type. A novel arrangement in the Fordson Plant consists of placing the superheater tubes in the side walls of the furnace and behind a protecting screen of water tubes.

Owing to the rapid development in the utilization of high-pressure and high-temperature steam, it has frequently been found advisable, when constructing additions to existing stations, to select a higher steam pressure and temperature for the new part, than is used in the old part of a station. The benefits secured, from the standpoint of economy, generally outweigh the complications introduced when operating sections of a station at different pressures and temperatures. This is one satisfactory answer to the question, "What is to be done with old steam generating stations?" The steam connection necessary between the two sections of a plant so operated must contain, of course, reducing valves and desuperheating equipment. Reliable and economical operation has been aided by adapting automatic control equipment to regulate the flow of steam through this apparatus.

An installation embodying a desuperheater and reducing valves, operated automatically by a system using compressed air, is that at the Hudson Avenue Station, between its high- and low-pressure sections. The regulating valve of the desuperheater is controlled primarily by the flow of superheated steam through the desuperheater and secondarily by the temperature of the outgoing steam. The steam is desuperheated by passing through tubes surrounded by water at a controlled level. Inasmuch as the pressure of the water is such that the saturation temperatures of steam and water are not very different, it is not likely that the desuperheated steam will ever become wet.

Stokers and Furnaces

The inherent nature of the combustion problem necessarily obviates any spectacular accomplishments in the stoker field and limits the gains to what might be termed detailed refinements.

The insistent demand for constantly increasing steam output with high efficiency is characteristic of present day practise. So far, the boiler units have increased in horse-power rating at a greater ratio than in width. This has called for stokers of constantly increasing length with longer time-interval for the burning of the fuel and added complications in its distribution over such a length of grate surface.

Two factors have contributed in large measure, to the successful application of long stokers—means for the exact control of the movement of the fuel throughout the retort and regulation of the air to unit sections of the stoker according to the condition of the fuel bed at each individual section.

Up to the present time, boiler and stoker equipment has generally been selected without much reference to the heat exchanges of the plant as a whole. The development of such heat reclaiming devices as water-walls, preheaters and economizers is gradually bringing about a tendency to consider the heat exchanges of the entire plant in the selection of the fuel burning equipment. There is also evidence indicating that joint selection of steam generating and fuel burning equipment is preferred to separate selection of the former without regard to its influence in the selection of the latter.

The recent developments in stokers for use with preheated air, have resulted in an appreciable reduction in furnace volume and an improvement in performance. There are under construction very large stokers which will be regularly operated with air preheated to about 400 deg. fahr. These stokers are being arranged for operation with air preheated to a maximum of approximately 600 deg. fahr., for the purpose of obtaining information as to their operating characteristics under such conditions. When air is preheated to high temperatures, it is necessary, because of its relatively large specific volume, that it pass through the fire bed at high velocities in order to maintain high rates of combustion per square foot of grate surface. There are some who maintain that there will be a considerable agitation of fuel on the grates with high air velocities and therefore the use of air preheated to a high temperature will result in reduced rates of combustion in stoker fired furnaces when air velocities are held down to rates that are not excessive.

As an indication of the trend toward the great increase in fuel burning capacity per foot of furnace width, stokers with 45 tuyeres that will underfeed coal for a distance of 16 ft. are being installed in furnaces 19 ft. 5-11/16 in. from the inside of front wall to the rear breaker apron of the clinker grinders, in extensions to the Edgar Station. Stokers of the same length will be installed in the Saginaw River Station of the Consumers Power Company in Michigan. Also in the Hudson Avenue Power Station there were installed, during the past year, stokers with 39 tuyeres underfeeding coal for a distance of 15 ft. A stoker for a furnace 19 ft. 1 in. from face of bridge wall to face of front wall has just been ordered by the Stamford (Conn.) Gas & Electric Company.

For the purpose of showing the recent marked improvement in underfeed stoker development, Fig. 4 is given which compares the performance of underfeed stokers only three years old, with that which is claimed by one manufacturer, for a unit on the present basis of design up to 700 per cent of boiler rating.

Probably the most radical change in any phase of central station design is in the furnace. It is significant that water-cooled walls with certain amounts of exposed refractory surface have been installed to an increasing extent during the past year, particularly in stoker installations such as at Richmond, Hudson

Avenue, and Edgar Stations. However, engineers have not yet reached any final conclusion in regard to the proper proportion of refractory surface to install in such furnace walls.

In the proposed addition to the boiler house at Kearny, to be stoker fired as is the original installation, all four walls will be water cooled by tubes with slight refractory material showing between tubes. Powdered fuel furnaces, such as are installed at Calumet, Fordson, Kipps Bay, East River, and Charles R. Huntley plants, apparently lend themselves more readily to complete water cooling than do stoker-fired furnaces.

The introduction of water walls has made possible the increasing of capacity of boilers to a point never even dreamed of three years ago. Before water walls were developed it was impossible to operate boilers continuously at high ratings owing to the limitations of refractory materials used. Now it is apparently only a question of the amount of fuel which can be burned within the furnace walls.

Furnace cooling by water walls has stimulated the use of air preheaters and it can be said these two pieces of equipment go hand in hand. The regenerative cycle

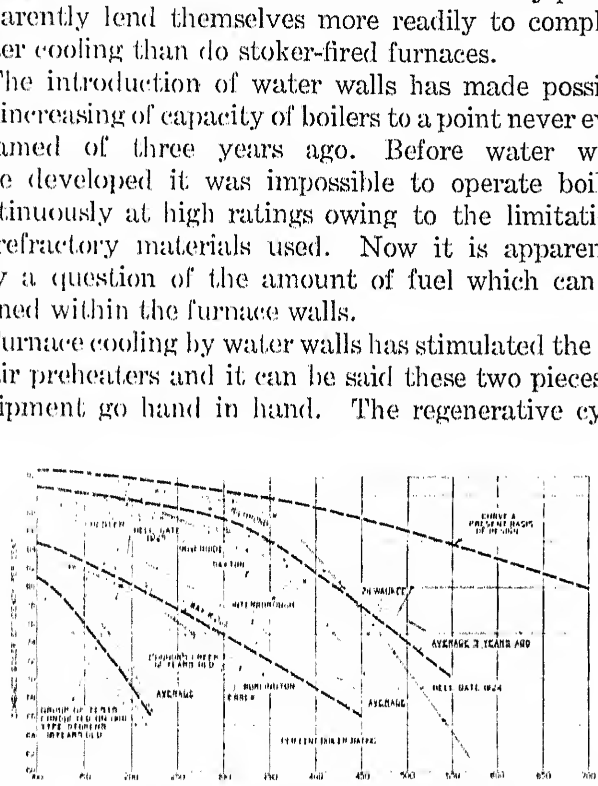

FIG. 4 DEVELOPMENT OF BOILER AND STOKER PERFORMANCES DURING THE PAST 17 YEARS

with its high temperature feed water coming to the boiler room, minimizes the absorption of heat from the flue gases by an economizer unless it be of the steaming type. The ability of the preheater under these conditions to lower the flue gas temperature below the temperature possible to obtain with an economizer alone, has frequently dictated the installation of the preheater rather than an economizer.

With brick walls it was impossible to take full advantage of the benefits of the air preheater, as higher furnace temperatures resulted in excessive maintenance of the refractory walls. With water cooled walls the limits to the degree of preheat are fixed by the character of the fuel when burned on stokers, the material used in the manufacture of the preheater, or the highest velocity of the air through the tuyeres, that will not blow the coal off the grates. In some cases it has been necessary to install an economizer before the air heater in order to hold down the temperature of the gases.

The size of pulverized fuel furnaces for a given amount of heat liberated is definitely on the decline. Turbulence accomplished in one way or another, to secure agitation and rapid mixing of air and carbon, greatly accelerating and improving combustion, has obviated the need for large combustion chambers formerly thought necessary to accomplish the same result. Preheated air and water cooled walls have also played a part in the reduction of furnace volume. All of these factors have either permitted or dictated that less excess air be introduced in the furnace thus allowing a smaller combustion space.

PULVERIZED FUEL

A striking feature in the expansion of pulverized fuel firing is the introduction of this form of combustion into a number of large outstanding steam generating stations during the past year. When it is recalled that the first major installation was made in connection with a 40,000-kw. plant in 1921, the development of burning pulverized fuel becomes impressive when it is considered that six years later it has been adopted for the power station which will have the largest generating unit on record.

In a comparatively short period of rapid growth it is perhaps natural that the best method of utilizing this system of combustion has not yet been defined generally. For example, turbulence is accomplished in several ways, each way requiring radically different furnaces; dryers of different types are installed in some cases and not in others. Further, quite a number of installations of unit pulverizers has been made in the last two years, but there is still a difference of opinion among engineers in regard to the question of unit mills as compared to the storage or central system. At the present time, each individual case must be studied at length, giving full consideration to operating conditions, price and kind of fuel, operating costs, and fixed charges. Results from unit system installations are becoming available and the characteristics of this type of firing show many peculiarities which should be carefully considered, particularly in central station application. These results no doubt will permit of a better comparison relative to lower combined operating costs and fixed charges when considering stokers or the storage system of pulverized fuel.

Considerable progress has been made in the last year in improvements of apparatus directly connected with pulverized fuel, and there seems to have been a radical departure from many previous methods of applying this system of firing to the steam boiler.

Four factors of primary importance are, the preliminary preparation of coal including drying, fineness of pulverization, turbulence in burning and furnace volume, all of which have been and are still being intensely studied. One of the most important single factors in the combustion of pulverized fuel is mixing of the air and coal streams. The intimate mixing of the secondary air with the primary air and coal immediately upon leaving the burners produces a turbulence which

persists throughout the zone of flame activity, thereby completing combustion in a minimum of time and space. In order to keep the dimensions of the furnace within reasonable limits, it is likely that the tangential system of introducing the fuel will be most favored, as greater use of furnace volume can be secured. The importance of the intense turbulence is generally recognized and designers of coal burning equipment have endeavored to obtain this in various ways.

If a forecast can be made of developments, these will include turbulent firing, simplified storage systems, methods of drying of the fuel, and mills of greatly increased capacity. Through these developments still greater advantages will be realized by the use of pulverized fuel in central station practise. The opinion has been expressed that powdered fuel firing will probably be the standard method of the future as it will be impossible to burn sufficient coal per square foot on a stoker to develop the capacities which will be required. However no clear cut supremacy has as yet been demonstrated and the fact must not be lost sight of that stoker development has proceeded at a brisk pace with no indications of a diminution.

The rapid introduction of pulverized fuel into steam generating stations is indicated by the fact that at the present time 40 public utility plants in the United States either partially or fully operate with pulverized coal, the aggregate generator capacity so fired being 2,200,000 kw. This is exclusive of several installations in steam heating plants. In addition to this there are now under construction five new plants and extensions to two old plants, having together a total capacity of 440,000 kw., all of which will be operated with pulverized coal. The significance of these figures can better be appreciated from the following tabulation:

PULVERIZED COAL INSTALLATIONS

	No.	Capacity, kw.
Installations in operation	40	2,200,000
Installations under construction	7	440,000
Total	47	2,640,000
Installations in operation and under construction, entirely operated with pulverized coal	27	1,700,000
Plants with 40,000 kw. capacity or more, operated with pulverized coal	27	2,250,000

Automatic Combustion Control

Considerable progress has been made in the development and application of automatic combustion control equipment to stoker firing, pulverized fuel, and oil burning. Engineers are giving increased attention to this equipment which, judging from the number of installations in operation at the present time, is apparently well advanced from the development stage and should assume a major role in the process of converting the heat in the coal to heat in steam in the most economical manner possible.

Complete automatic combustion control has been in operation for some time in several of the outstanding power stations in the east, and the companies report satisfactory performance of the equipment. Results show that daily operating efficiencies are maintained within 2 per cent of test efficiencies.

The following are some of the outstanding installations of boiler room equipment recently completed, or under construction:

The second boiler in this country to generate steam at a pressure of more than 1000 pounds went into operation late in 1926 at the Lakeside Station. This is a single three drum Stirling boiler built for a working pressure of 1390 pounds and contains 28,532 sq. ft. of heating surface. The drums are forged steel 41 ft. 6 in. long, 40 in. inside diameter, and 5 in. thick. The walls of the furnace are formed by radiant heat superheaters on the sides designed to give an ultimate temperature of 720 deg. fahr., by a radiant heat resuperheater on the rear wall designed to reheat the steam from 447 deg. fahr. at 317 pounds pressure to approximately 720 deg. fahr., and by fin cooling tubes on the front wall. Pulverized coal equipment is used with a plate air heater of 20,160 sq. in., designed to preheat the air to 650 deg. fahr. at maximum load.

Four additional high-pressure boilers are planned, two being under construction, for the Edgar Station. The two units are B. & W. boilers built for a working pressure of 1400 pounds, with a heating surface of 15,090 sq. ft. each, the drums being 4⅝ in. thick, 48 in. inside diameter, and 38 ft. 4 in. long. Each unit is equipped with a primary superheater designed to give an ultimate temperature of 725 deg. fahr., and a reheater unit to give an ultimate temperature of 750 deg. fahr., both at an output of 200,000 lb. of steam per hr. The economizers are the wrought steel return bend type with 5596 sq. ft. of heating surface each, and the tubular air heaters each contain 33,032 sq. ft. The boilers are fired with Taylor underfeed stokers having 16 retorts and 45 tuyeres, the largest of their type ever built. These stokers, using preheated air, are capable of burning 37,700 pounds of coal per hour, and are provided with means for manually regulating the supply of air to various parts of the fire according to the condition of the fuel bed at each part. The furnace will be equipped with Bailey side and rear walls, and a ventilated Bigelow hung front wall.

An ultra high-pressure boiler and turbine installation is planned for the Northeast Power Station of the Kansas City Power and Light Company, but has not yet assumed definite enough form to warrant publication of any details.

European manufacturers are experimenting with ultra high pressure steam generation. It is reported that an installation of 18,000 kw. capacity is near completion and that the boiler in which water is evaporated by superheated steam will supply steam at a pressure of 1500 to 1700 pounds. The boiler setting contains only a superheater and economizer.

The redesigning and rebuilding of No. 2 boiler and furnace unit at the Fordson Plant, illustrates the tendency to secure the maximum capacity from a single unit. This unit is a Ladd boiler of originally 26,470 sq. ft. of heating surface with a furnace designed to burn pulverized coal, blast furnace gas, oil, tar, and coke oven gas, either singly or in combination. At the time of installation this boiler and three more of identical pattern in the Fordson Plant were the largest ever built. By adding 12 per cent of the total water-heating surface in the form of water screens in the bottom of the furnace, equipping the side walls with fin tubes and radiant superheaters, protecting the arches with water tubes besides doubling the number of burners and installing air preheaters the actual steaming capacity was increased 100 per cent. A peak output of 500,000 pounds of steam has been attained, which is said to be a record for a single unit.

There are being installed in the Stanton Power Station of the Pennsylvania Power & Light Company, six standard and two reheater B. & W. cross drum boilers built for a working pressure of 732 lb. and to be operated at approximately 650 lb. pressure. The standard boilers contain 17,962 sq. ft. of heating surface each and are equipped with superheaters designed to give an ultimate temperature of 750 deg. fahr. at an output of 150,000 lb. of steam per hour. The reheater units contain 5978 sq. ft. of heating surface each, and are equipped with primary superheaters to give 740 deg. fahr. at an output of 81,000 lb. of steam per hr., and with reheater elements designed to reheat the low pressure steam to 730-740 deg. fahr. The boilers will be fired by B. & W. chain grate stokers 24 ft. by 22 ft. burning anthracite slush with preheated air.

An experimental powdered coal installation has been in service in the Calumet Station since November 15, 1926. The heating surface of the unit is divided as follows:

Boiler Heating Surface.........	5,938 sq. ft.
Furnace Heating Surface........	2,460 sq. ft.
Steaming Economizer Surface...	8,365 sq. ft.
Total Water Surface............	16,763 sq. ft.
Air Heater Surface.............	41,700 sq. ft.

This boiler has been operated for short intervals at a rate of 300,000 lb. of steam per hr., but this rate could not be maintained for longer periods because of the lack of pump capacity. This rate corresponds to an evaporation per sq. ft. of total water surface of 17.9 lb. or an evaporation of 35.7 lb. per sq. ft. on the basis of combined boiler and furnace heating surface.

The operation of this Calumet boiler equipment has proved to be so satisfactory that orders have been placed for five similar units for the State Line Generating Company, State Line, Ind. The entire arrangement of these units will be similar to the Calumet equipment as to boilers, superheaters, economizers, air heaters, Bailey furnaces, Calumet burners, and Fuller-Lehigh unit mill pulverized coal equipment, with the exception that the boilers will be built for a working pressure of 800 lb. to operate at about 600 lb. pressure. The individual units, however, will be much larger than the Calumet unit, the boiler drums being 52 in. in diameter, 3¼ in. thick and forged instead of riveted.

Satisfying the demand for still larger units, there is being installed in station "C", for the Pacific Gas & Electric Company, two B. & W. cross-drum boilers which are the largest of their type yet built. These boilers have a heating surface of 35,500 sq. ft. each, and are built for a working pressure of 460 lb. They are equipped with tubular air heaters of 51,232 sq. ft. each and superheaters designed to give 725 deg. fahr. ultimate temperature at an output of 350,000 lb. of steam per hr. The furnaces are to be oil fired and equipped with water-cooled walls. For the Long Beach station of the Southern California Edison Co., there are now under construction three cross drum units of the same type having 34,162 sq. ft. each and built for a working pressure of 450 lb. each with steam at 713 deg. fahr. The furnaces are designed to burn oil when the plant is first put into operation and pulverized coal at some future date, the furnace walls and floor being of water cooled construction.

A notable installation to go into service was the six (6) 1590 hp. Springfield boilers in the East River Plant of the New York Edison Company. The boilers are pulverized coal fired and furnish steam at 375 lb. pressure and 700 deg. fahr. Each boiler is capable, on continuous overload, of producing 250,000 lb. of steam per hr. No brickwork or refractory material is used, the furnace being completely enclosed by Murray fin tubes, backed up by plastic coating about 6 in. thick consisting of diatomaceous earth, cement, and a painted hard outside finish.

Another outstanding installation is the addition to the Hudson Avenue station, consisting of four 2292-hp. boilers furnishing steam at approximately 400 lb. per sq. in. and 700 deg. fahr. These units have the rear and side walls cooled by water tubes which are protected at the firing line by cast iron and carborundum blocks respectively. The front wall is lined with carborundum blocks. These boilers are fired by Westinghouse 14 retort, 39 tuyere, 18 ft. long underfeed stokers. The stokers use preheated air and provide an actual grate surface of 460 sq. ft. or 427 sq. ft. of projected area.

At the Kearny station a fifth row of three boilers will be added. They will be Springfield cross-drum units of 23,640 sq. ft. of heating surface, similar to the original units but with water-cooled rear, side, and front walls composed of tubes backed up by refractory tile, a layer of insulating material, and a finished casing of transite board. Cast iron blocks will be bolted to the wall cooling tubes just above the fire line to protect

them and reduce heat absorption. Preheated air will also be employed in combustion. It is expected that with these two features of water cooled walls and preheated air, not possessed by the boilers in the original installation, much higher ratings will be secured. Riley superstokers of about the same huge dimensions as the original units in this station will be installed under these boilers.

The installation of four boilers, burning pulverized coal, at the Charles R. Huntley Station of the Buffialo General Electric Company is unique in several respects. These boilers have 12,515 sq. ft. of heating surface, well-type furnaces tangentially fired, and Bailey water walls on four sides. The wells in three of the furnaces are as wide as the furnace in each case and about two-thirds its length. Tap holes are provided for removing the ash as molten slag. The unit system of pulverizing is employed. These boilers can be operated at outputs of from 60,000 to 250,000 lb. of steam per hr.

Two Combustion Steam Generators furnishing steam at 825 lb. pressure and fired by unit pulverizers using preheated air, are being installed in the Syracuse, N. Y., plant of the Solvay Process Company. Another such unit is being installed in the Calumet Station, a brief description of which is as follows:

Water-heating surface		
Rear bank of tubes	3,637 sq. ft.	
Side Walls	1,710 sq. ft.	
Roof	254 sq. ft.	
Bottom Bank of tubes	1,171 sq. ft.	
Total Water-heating surface	6,772 sq. ft.	
Superheating surface	3,000 sq. ft.	(Approx.)
Economizer	5,250 sq. ft.	
Air heating surface	25,200 sq. ft.	
Steam pressure	360 lb. gage	
Effective Combustion space	5,000 cu. ft.	
Normal Capacity of unit	125,000 lbs. per hr.	
Peak Capacity of unit	150,000 lbs. per hr.	

Cheap water power, for industries using large amounts of steam for process work, has encouraged the development and use of electric steam boilers. At the beginning of 1927, an aggregate of 750,000 kw. of these units was installed in Canada and the U. S. Three such boilers having a capacity of 42,000 kw. each and operating at 6600 volts, were installed in 1926.

Ultra-High Pressure Steam Turbine Generator Installations

Considerable progress has been made during the last few years in the development of turbines, boilers, and other equipment operating at the ultra-high pressures, from the pioneer stage into an important commercial development. At the Edgar Station of the Edison Illuminating Company of Boston, the original high-pressure installation in this country, a 3150-kw. unit has given remarkably satisfactory results for nearly two years. Upon the basis of this experience a 10,000-kw. 1200-lb. unit is now being installed and a second 10,000-kw. unit is contemplated. The Milwaukee Electric Railway and Light Company has also installed a 7000-kw., 1250-lb. unit in its Lakeside power station. It has been reported in the technical press that a third installation is contemplated for the Northeast Power Station of the Kansas City Power and Light Company. This installation will consist of a 1400-lb. boiler with a 10,000-kw. high-pressure turbine exhausting to the main steam header of the station.

The problem of the use of both high pressures and high temperatures is very difficult, particularly in the design of the boilers and superheaters, where the stresses in the tubes are increased by the temperature differences between the outside and inside surfaces. The difficulty of the use of both high temperatures and high pressures is due to the fact that at high temperatures the strength and stability of the materials normally used are seriously reduced. The question of materials for use in high pressure turbine construction is somewhat less troublesome than in boiler work, because of the fact that small high-speed units are used with temperatures fairly uniform at any section, and therefore the stresses can be controlled so as to prevent high unit-stresses in high temperature zones.

The advantage of using ultra-high pressure turbines in connection with normal pressure units is not only the increased fuel economy, but also the fact that the space required is nearly the same for the high and normal pressure installation combined as for the normal pressure alone. The increased capacity is therefore a net gain, which approximately balances the increased cost of the equipment, so that the improved thermal efficiency represents very nearly a corresponding economic gain.

The entirely satisfactory operating results and full realization of expected gains of the ultra-high-pressure installations now in operation in this country shows that they are of unquestionable commercial value and proves by actual test the advisability of improving the efficiency of existing "normal pressure" stations as well as new stations by the convenient addition of high pressure equipment instead of more low pressure apparatus. This is especially the case in stations having a low load factor where the equipment operating on the high pressure cycle can be installed sufficient to supply the base load only.

Edgar Station. The high-pressure plant now in operation at the Edgar Station consists of one high-pressure boiler and a 3150-kw. turbine. Based on its successful operation for nearly two years, an addition is now being constructed which includes two 15,090-sq. ft. cross-drum Babcock & Wilcox boilers, a 10,000-kw., 3600-rev. per min. General Electric high-pressure turbo generator together with the 65,000-kw. normal-pressure turbo generator. The boilers will generate steam at approximately 1400 lb. pressure and 725 deg. fahr. It will be expanded in the 10,000-kw. turbine, which has 16 impulse stages, to 375 lb. per sq. in. and returned to the reheating superheaters which

form part of the new boilers. After being reheated to approximately 750 deg. fahr., the steam will be discharged into the main 350-lb. steam header and together with steam from the normal pressure boilers will supply the two existing 32,000-kw. turbo generators and the new 65,000-kw. turbo generator.

Each high-pressure boiler will be equipped with a 5596-sq. ft. economizer operating at approximately 1500 lb. water pressure and with a 33,032-sq. ft. air preheater, and will be fired by a 16 retort, 45 tuyere underfeed stoker. The side and rear furnace walls will consist of refractory-faced, cast-iron blocks, bolted to boiler tubes which will be connected to the boiler.

The next high pressure extension contemplated will include two additional 15,090-sq. ft. boilers and one 10,000-kw. turbine. At that time, the four high-pressure boilers will serve the two 10,000-kw. turbines and the steam from those two high pressure turbines will be sufficient to operate the 65,000-kw., 350-lb. pressure turbine.

Before entering the economizers, the feed water will be heated to 420 deg. fahr., by means of steam bled from three points of the 65,000-kw. turbine and from the exhaust of the 10,000-kw. turbine at a pressure of 375 lb. It is of interest to note that feed water has never before been heated to this high temperature by bled steam. This high-feed temperature is of particular interest in view of the fact that the feed water will pass through an economizer after leaving the high pressure heater and before entering the boiler.

Three boiler feed pumps of interesting design are being installed. Two will be motor-driven at 1800 rev. per min. and will be used for normal operation and the third will be turbine-driven at 3600 rev. per min. and will be used for emergency only. Each motor-driven pumping unit will consist of four pumps in series, one single and two five-stage volutes, and one six-stage turbine pump. The single stage volute and one five-stage volute will be driven by one motor and will discharge at 500 lb. per sq. in. through the high pressure feed water heaters to the suction of the second five-stage volute pump. The second five-stage volute pump and the six-stage turbine pump will be driven by one motor and will deliver the water to the boiler feed headers at a maximum pressure of 1600 lb. per sq. in. All motors will be adjustable speed and will be automatically regulated. The turbine-driven pump will also be a six-stage turbine pump and will develop the full 1600 lb. per sq. in. in the one casing. This pump is designed for automatic starting when the pressure in the 1600-lb. boiler feed header drops below a safe limit.

The coal consumption per kw-hr. at the Edgar Station is approximately 1.02 lb. when only the present 30,000-kw. normal pressure turbines are operating. When about one-third the output of the station is generated by steam from the high-pressure boilers and turbines, the coal rate is approximately 0.98 lb. per kw. hr., an improvement of 4 per cent. For a complete 1200-lb. installation it is estimated that the gain should be approximately three times this figure or 12 per cent.

Lakeside Station. Prior to the installation of the 1300-lb. boiler and the 1250-lb., 720 deg. fahr. turbine, the capacity of the Lakeside Station was 160,000 kw., made up of two 20,000-kw. and four 30,000-kw. machines. The boiler room capacity was 1,600,000 lb. of steam per hr. with a throttle pressure of 285 lb. per sq. in. and a temperature of 700 deg. fahr.

The new high pressure boiler is a Babcock and Wilcox Stirling type boiler and is the largest of its kind. Its nominal rating is 2853 b. hp. and it is capable of delivering 240,000 lb. of steam per hr. Pulverized coal is burned in a 30,100 cu. ft. Lopulco type furnace. The high-pressure turbine unit is a 7000-kw. General Electric machine and its speed is 3600 rev. per min. It exhausts to the reheater at 310 lb., the temperature of the steam after reheating being approximately 720 deg. fahr.

The high pressure installation has been in service since October 1926. It was in continuous operation from January 29th to March 19th, 1927, a period of 50 days. During this period, the kw-hr. output of the high pressure turbine was about 7.5 per cent of the total station output, while the kw-hr. generated by both the high-pressure (1250-lb.) turbine unit and the normal pressure units from the steam originating in the high pressure boiler only, was about 34.3 per cent of the total station output. The load factor of the load (in this case equal to the capacity factor) on the high-pressure turbine was approximately 90 per cent, the load being less than maximum at times due to the fact that the total station load on Sundays is below the capacity of the high-pressure boiler.

Operating results showed a coal saving on the entire station of about 4 per cent due to the operation of the high-pressure cycle since this cycle was approximately 12 per cent more efficient than the 300-lb. cycle and furnished 34 per cent of the station output.

The high pressure boiler installation has shown several remarkable operating features. Ability to average 16½ per cent CO_2 over long periods without CO losses and with unusually low carbon losses has been obtained in the operation of the high-pressure installation. This CO_2 average represents use of 12 per cent excess air, and as such establishes a record in economy of fuel burning. Automatic and instantaneous stoppage of coal feed and by-passing of 1200-lb. steam to 300-lb. pressure has been utilized in service several times when the high-pressure turbine tripped from service. Not a safety valve opened under these conditions.

Mercury Vapor Installation

After some four years of experience with the mercury vapor installation in its Dutch Point Station, the Hartford Electric Light Company has ordered mercury vapor equipment, including a 10,000-kw. turbine, to be

installed and to go into operation early in 1928 in its South Meadow Plant. This will be a strictly commercial application of the mercury-steam cycle and will be representative of the size and design of equipment to be placed on the market.

The commercial success of this process provides a means of effecting marked economies in power production, made possible by being able to go to higher temperatures of a working substance than when using steam alone. The very moderate pressures required permit using the higher temperatures with our present materials. In effect, the mercury is used to convey heat from the furnace to the steam boiler acting as a mercury condenser; before reaching the condenser some of the heat is developed into electrical energy by the mercury-turbine generator.

It is claimed that the remarkable record of 27 per cent efficiency, attained by the Columbia Plant, operating on a straight steam cycle, could be increased to 36 per cent in a similar plant arranged to operate on the mercury-steam cycle. The savings in fuel consumption for less efficient plants will be even greater. Of course, from a commercial viewpoint, the cost of plant must be studied with relation to capacity factor.

The original single-stage 1800-kw. unit operating at 35 lb. pressure, installed at Dutch Point in 1923, developed about 60 per cent of the available energy in the mercury. This was supplanted by a three-stage machine, developing 70 per cent of the available mercury energy, that went into operation late in 1926. The unit to go into the South Meadow Plant, estimated to develop 75 per cent of the available mercury energy, will be a five-stage 10,000-kw. machine receiving mercury vapor at about 70 lb. pressure and exhausting it at one lb. absolute to two mercury condensers. In these condensers 125,000 lb. of steam per hour will be generated at 250 to 350 lb. pressure and superheated by the mercury-boiler furnace flue gases to an ultimate temperature of 700 deg. fahr. It is expected that about 10,000 kw. will be obtained from the steam generated by the condensed mercury.

The present boiler at Dutch Point, of different design from the original one, generates mercury vapor at 70 lb. pressure and 884 deg. fahr. The new boiler consists of a group of drums, each carrying dead-ended tubes six ft. long, giving the unit the appearance of a huge coarse brush. There will be required for the entire installation 135,000 lb. of mercury, the cost of which will represent a substantial portion of the plant investment. In the process of generating energy the mercury will be circulated in the system eight or nine times an hour. An experimental boiler in the Schenectady G. E. Plant has been operated at 110 lb. pressure, generating vapor at 940 deg. fahr., at a rate more than twice that planned for the South Meadow unit with no difficulties whatsoever. It is expected that this Hartford unit will operate indefinitely without interruptions.

The approximate fuel saving, at an estimated figure of 11,000 B. t. u. per kw-hr. output developed from mercury and steam from the mercury condenser, based on a conservative use factor, is expected to be about $200,000 a year. While the maximum saving is obtained when carrying base load, under light load conditions the savings are material. The operating company reports that in its Dutch Point Station it has been able to obtain as good a coal economy on 5 per cent capacity factor as the entire station is capable of doing on a 60 per cent load factor.

As a means of increasing the capacity and the economy of existing stations or even planning new base load high-economy stations, this system of power generation is competitive with the ultra-high pressure generation and utilization of steam with its attendant steam reheating complications and relatively large auxiliary power consumption.

The supply of mercury is expected to be ample although price disturbances may occur until the industry adjusts itself to the increased demands to be ultimately made upon it.

Hydroelectric Development

While the increase in electrical energy generated during 1926 by steam plants of public utilities was only about 9 per cent over that generated in 1925, the increase for waterpower plants was approximately 17 per cent. Furthermore, the aggregate capacity of waterwheels and generators produced was greater than for the preceding year. However, except for the trend toward larger units, there have not been any radical changes in turbine types or general form or design, but certain details of design and special features have shown development or improvement.

During the past year a large number of power companies for whom hydroelectric units were installed, adopted electric drives for the governors. This form of drive is becoming increasingly popular for hydroelectric installations. The driving motors are of the induction type and operate in close synchronism with the frequency of the generator unit which it is required to regulate. This provides a simple and convenient drive and has been found to give extremely smooth and quiet operation free from operating troubles.

Another interesting development in hydraulic turbine design was the introduction of a water-lubricated guide bearing with a rubber lining. It may be of interest to note that bearings of this type have recently been adopted for use with four turbine installations in which the shaft diameters range from 9 to 24 in. The chief advantage of the rubber lined bearing is the great durability and the long life obtainable.

In the past year a number of hydraulic turbine units have been built, equipped with plate steel casings of the volute type. Engineers are becoming increasingly interested in the possibilities of welding instead of caulking the plate steel joints for these casings, and it

may be of interest to note that the welding of these casing joints will actually be undertaken in connection with one or more of the largest and most recent turbine installations.

Hydroelectric plants automatically operated and controlled established another record during the past year. In one instance, two units of 28,500 hp. each have been installed in a station designed to operate automatically. New methods of applying automatic control to both a reaction and impulse type of unit are being developed. This equipment is of particular advantage in connection with steam-operated plants as supplementary sources of power.

In one of the outstanding major hydraulic developments under construction where the contracts for both the turbines and generators have been split between two companies, it was found economical to have one manufacturer build all of the oil pumping system. Also, in general, the design of all the main turbine parts which are subject to wear and replacement are made interchangeable. The generators are being built with the same degree of cooperation between the manufacturers, to insure interchangeability of some of the important mechanical parts.

There has been a tendency towards the closed circuit for air circulation with surface coolers, similar to the method of cooling commonly employed for steam turbine generators. This arrangement simplifies the construction of air ducts and permits the use of an inert fire extinguishing gas if desired. A number of machines have been constructed for the closed system of circulation.

Some of the Hydroelectric Developments of exceptional interest recently completed or now under construction are given below:

Conowingo Development. The outstanding hydraulic turbine development in 1926 was the seven 54,000-hp. 89-ft. head, 81.8-rev. per min. single-runner vertical-shaft hydraulic turbines for the Susquehanna Power Company's Conowingo Development. Three of the turbines are of I. P. Morris manufacture and four are Allis-Chalmers. The runners are made of cast steel in three sections and represent a very difficult problem in casting. The total weight of the runner will be approximately 200,000 lb. and outside diameter 179 in. The division of the runner into three parts was necessitated by shipping limitations which seem to be one of the principal factors now limiting the size of hydraulic equipment. The sections of the runner are bolted together by flange joints and in addition have steel bands mounted on the crown of the runner and the discharge ring. The spiral casing is made up of riveted steel plate sections and has an inlet diameter of 27 ft. The butterfly valve housing is joined to both the penstock and turbine casing by riveted connections. The feature of particular interest incorporated in the design of the butterfly valves is the installation of a rubber tube fitted into an annular recess in the valve body around the circumference of the gate when the valve is in closed position. This rubber tubing is designed to expand and hold tightly against the outer circumference of the gate when pressure is admitted to the inside of the tube when the gate is closed. This characteristic of the valve will insure unusual tightness against leakage. An innovation was used in the design of the pit ring which extends from the speed ring to the generator base in that this ring was built entirely of structural steel. After repeated tests, the hydraucone draft tube was accepted as the best design of tube offered for the conditions and as a result the hydraucone and the Moody spreading tube were used for the entire development. The draft tubes will be equipped with cast steel stay vanes at the lower ends, designed to carry the weight of the draft tube above, in addition to the weight of the unit and its portion of the station structure, this having been found to give greater economy in construction costs than to strengthen the concrete reinforcements which would otherwise be necessary. The center concrete cones for these tubes will extend all the way up to the turbine runner.

Each water-wheel unit will be direct connected to a 40,000 kv-a. 90 per cent power-factor, 81.8-rev. per min., 13,800-volt, 60-cycle generator, four of which will be of General Electric manufacture and three of which will be Westinghouse machines. These alternators are notable, not only because they are the largest in physical dimensions, of any electrical machines ever built, but also because of the fact that they are to supply power to the first 200-kv. transmission line in the eastern part of the United States. The outside diameter of the stator frame is 38 ft. The largest capacity thrust bearings ever built will be required for these generators, their capacity being the total load of 750 tons. Mounted upon each 40,000-kv-a. generator will be a 715-kv-a. auxiliary generator and above the auxiliary generator will be the 41-kw. exciter set.

By a large degree of cooperation between the manufacturers of turbines and generators, it has been possible to obtain similarity in characteristics and appearance and the interchangeability of some of the important mechanical parts.

The Conowingo units will be required to operate, in most cases, on the peak loads with unusual conditions, and will be shut down during the low load portions of the day in order to store water to the greatest possible extent. For this reason it is important to avoid leakage when the units are shut down and consequently the large pivot valves will be installed in the turbine casing rather than have head gates at the upper ends of the penstock, thus insuring quick closure and reducing the loss of water to a minimum. It is expected that this plant will show a world's record performance from the standpoint of efficiency and reliability of operation.

Automatic Hydroelectric Stations. During 1926, two 28,500-hp., I. P. Morris turbines driving 25,000-kv-a.,

60-cycle, 11,000-volt Westinghouse generators at 300 rev. per min. were placed in operation in the Wallenpaupack Power Station of the Pennsylvania Water & Light Company. These units operate under a head of 300 ft. and the station is designed for carrier-current type of automatic control. These are the largest units on record that will be controlled automatically.

A 17,500-hp. Pelton Water Wheel driving a 13,333-kv-a., 60-cycle, G. E. generator is under construction for the Glines Canyon Power Station of the Northwestern Power & Light Company. This unit which will operate under a head of 190 ft. will be controlled by the operator of the Elwha River Plant, seven miles away by means of selector supervisory control. In addition to the main unit, the 62.5-kv-a. auxiliary water wheel and the motor driven oil pump will also be controlled by the automatic equipment.

The largest plant built up to date for full automatic control is the Louisville hydroelectric installation now under construction which will consist of eight 13,500 hp., Allis-Chalmers turbines. The generators are 12,500-kv-a., 14,000-volt, 100-rev. per min. vertical General Electric machines which will have a self-contained ventilating system because of the high air temperatures during the summer time when they will carry the heaviest loads.

High Head Impulse Wheels. The largest capacity impulse wheels ever constructed are the two 56,000-hp. turbines which are under construction for the Big Creek No. 2-A plant of the Southern California Edison Company. These machines will operate under a head of 2300 ft., one being an Allis-Chalmers machine and the other will be made by the Pelton Water Wheel Company. Both machines will be of the double overhung type, having separate governor control for each nozzle. The main shaft bearings of these units will be 30 in. in diameter and the total weight carried on each bearing will be 230,000 lb. The present speed of the units will be 250 rev. per min. for 50 cycles, but the machines are designed for 60-cycle operation at 300 rev. per min. The jet diameter for each overhung impulse wheel will be 8½ in. Each bucket will weigh 900 lb. and in case of the runaway of the unit, the combined forces on the bucket bolts will be approximately 300 tons per bucket.

The Westinghouse generators for these units will have a capacity of 45,000 kv-a. at 11,000 volts, 250 rev.per min. but will have a capacity of 50,000 kv-a. at 12,500 volts when operating at a speed of 300 rev. per min.

A 40,000 hp. Allis-Chalmers double overhung impulse wheel has been placed in operation at the Kings River Plant of the San Joaquin Light & Power Corporation for operation under a head of 2243 ft. The generator will be a General Electric 33,000-kv-a., 13,200-volt, 360-rev. per min. machine. Two exciters are provided, each of which is of sufficient capacity to excite the main generator. Each exciter is driven by a single-jet, single-overhung impulse wheel.

Two Pelton Water Wheels of 40,000 hp. capacity each have been installed at Santos, Brazil for operation under an effective head of 2450 ft. The General Electric alternators are of the horizontal type with a capacity of 33,000 kv-a. at 11,000 volts and 360 rev. per min.

The turbines to operate under the highest head up to the present time will be the units for the Bucks Creek Plant of the Feather River Power Company. These will be of the double overhung impulse type Pelton Wheels with a capacity of 30,000 hp. The head will be 2548 ft. and the turbines will drive 25,000-kv-a., 11,000-volt, 450-rev. per min. General Electric generators.

Propeller Type Turbines. There are being installed in the Great Falls Plant of the Manitoba Power Company, one 28,000-hp., Moody and one 31,500-hp. Bell type turbines driving General Electric generators. These units are the largest propeller type units now being installed and will operate under a head of 56 ft. at 138 rev. per min.

Power Station Auxiliaries

The prevailing practise seems to be motor driven auxiliaries, with the added protection of having certain auxiliaries steam driven. The chief reasons for this are the extensive adoption of the regenerative cycle for feed water heating and the rapid development of motors suitable for auxiliary drive. The electric drive is very efficient and reliable and it is probable that in most cases a station using electrically driven auxiliaries will show on the average, a better thermal efficiency and a lower cost per unit of output including fixed charges, than if steam driven auxiliaries were used.

Steam drive, however, is still most favored for boiler feed pumps. It is interesting to note that a large station recently constructed in the East has adopted steam drive for all of its essential auxiliaries, but this is largely a local condition peculiar to its system. The refinements of design details, and improvements developed for large turbines have been extended to smaller capacities so that manufacturers are prepared to furnish turbines for auxiliary service having very much improved water rates.

There are still many opinions in regard to the best source of electric power for auxiliaries. On account of the higher efficiency of the main units, there has been a tendency to put all the station load on these machines. There are not so many house turbine generators being installed as in the past. The house generator in tandem with and being direct connected to the main generator shaft, appears to be gaining in favor and is extensively used.

Power Production Economies

A record for thermal efficiency was attained at the Columbia Station of the Columbia Power Company in Ohio. For a period of one month this station was operated on a heat consumption of approximately 12,462 B. t. u. per kw-hr. net output, which is the

lowest figure obtained by any steam plant to date. The following figures, for two consecutive months, are of particular interest:

	December 1926	January 1927
Kw-hr. net output	44,998,400	42,547,900
Load factor	65.7%	60.7%
B. t. u. per kw-hr. net output	12,495	12,462
B. t. u. per lb. coal as fired	13,838	14,002
Coal factor, lb. per kw-hr. net Output	.903	.890
Station water rate	7.76	7.85
Standard Boilers;		
Average efficiency	87.06%	87.54%
Average Rating	216 %	233 %
Reheat Boilers:		
Average efficiency	90.7%	90.92%
Average Rating	408 %	422 %
Auxiliary power consumption	5.27%	5.41%

The results in many other stations put into operation during the last year have also been very reassuring and in some cases have exceeded the expectations of their designers. High pressures, high temperatures, water walls, regenerative cycle, reheat cycle, air preheaters, improved combustion due to better stokers or pulverized fuel, reduction in exit gas losses by economizers and preheaters, use of electrical drives for auxiliaries, and improvements in turbine and condenser design have all contributed to improve the thermal efficiency of power plants so that the reduction of operating costs have more than kept pace with the increased price of fuel and increased operating labor rates.

The marked improvement in utilization of fuel by public utility power plants is revealed by figures given in the Geological Survey Report, which shows that in 1926 the average large generating plant turned out a kw-hr. on 1.94 lb. of coal as compared with 2.07 in 1925. These figures include coal, oil, and gas fired plants and represent the equivalent coal consumption. It is interesting to note that since the World War, using 1919 as a basis, the equivalent coal consumption per kw-hr. has been reduced 40 per cent.

ACKNOWLEDGMENT

In attempting to present a résumé of the outstanding technical achievements brought about during the past year in a complex industry like that of power generation, every effort was made to obtain from many sources as complete and reliable information as possible of the existing conditions in the field. The committee is indebted to those engineers and manufacturers who so splendidly assisted in this work and wishes to express its appreciation of their cooperation.

W. S. GORSUCH, *Chairman.*

Bibliography

Many articles relating to power generation have appeared in the technical press during the past year, but for this list, only the more interesting and readily available have been selected.

Complete remodelling of steam power plant, involving new boiler house and reconstruction of turbine room for modern conditions.

Electrical Review, "The Popular Electricity Undertaking," Vol. 100, No. 2579, April 29, 1927, pp. 667-670.

New station using "Lopulco" pulverizing equipment.

Electrical Review, "Glasgow Corporation's Electricity Supply," Vol. 98, No. 2584, June 18, 1926, pp. 899-902.

Development of Dalmarnock Generating Station; station was designed for ultimate capacity of 200,000 kw.

Electrical Review, "Electricity Supply at Liverpool," Vol. 99, No. 2541, August 6, 1926, pp. 211-214.

New Lister Drive No. 3 Station when completed will be capable of housing 5 sets of 25,000 kw.

Electrical World, "21,400 B. T. U. Per Kilowatt Hour Sold," Vol. 89, No. 2, January 8, 1927, pp. 93-96.

Study with tables as to economy of conversion of energy from coal pile to customers meter.

Electrical World, "Work on Long Beach No. 3 to Start," Vol. 89, No. 2, January 8, 1927, p. 115.

Additional details on equipment and design.

Electrical World, "Eliminates Idle Superstructure," Vol. 89, No. 7, February 12, 1927, p. 340.

Outdoor gantry crane used instead.

Electrical World, "Steam Plant Improvements Costing $5,000,000 Completed at Providence, R. I.," Vol. 89, No. 16, April 16, 1927, pp. 806-807.

New pulverized coal plant and additional 35,000 kw. turbo-generator.

Electrical World, "Hartford Makes Prime-Mover History," Vol. 89, No. 19, May 7, 1927, p. 949.

South Meadow Station to have 20,000 kw. mercury-vapor generating installation.

Electrical World, "Features of Avon Station," Vol. 88, No. 6, August 7, 1926, pp. 260-272.

Reliability, simplicity, and safety predominate in electrical and mechanical design.

Electrical World, "Experiences with Modern Stations," Vol. 87, No. 19, May 8, 1926, pp. 983-993.

Operating performance of some modern plants and their experience with the regenerative cycle.

Engineering and Boiler House Review, "The Use of Very High Steam Pressures and Temperatures," Vol. 40, No. 8, February, 1927, pp. 385-386.

Results from Landebrugge, Belgium; 710 lbs, pressure and 840 deg. fahr.

General Electric Review, "The East River Generating Station of the New York Edison," Vol. 30, No. 5, May 1927, pp. 238-260.

Complete description.

Hester, E. A. and Bonnett, L. B., "Isolating Faults in Hudson Avenue Plant," *Electrical World*, Vol. 87, No. 17, April 24, 1926, pp. 853-854.

Scheme and operation of protective equipment, sequence of switch operations.

Holmes, W. C., "The Operation of the Hudson Avenue Generating Station of the Brooklyn Edison Company," *Mechanical Engineering*, Vol. 49, No. 4, April 1927, pp. 321-326.

Hopping, E. L., "Coordinating Departmental Functions in Station Construction," *Electric Light and Power*, Vol. 5, No. 5, May 1927, pp. 30-31.

Details of how the Philadelphia Electric Company's Station Engineering Division harmonizes the work of design, construction, and operation of its plants.

Hubbard, C. L., "Piping for Power Plants," *Southern Power Journal*, Vol. 44, No. 1, January 1926, pp. 20-28.

Design and remodeling.

Johnston, W. S., "Heat Balance at the Sterlington Power Station," *Power Plant Engineering*, Vol. 30, No. 13, July 1, 1926, pp. 735-739.

Features of the new station of Louisiana Power Co. near Monroe, La.

Kapp, R. O., "Generating Station Costs," *Electrical Review*, Vol. 100, No. 2566, January 28, 1927, pp. 124-126.

Graphic analysis of costs by logarithmic and hyperbolic—ruled charts, with examples.

Kerins, J. S., "Building Foundation of a 1,000,000 H. P. Generating Station," *Engineering World*, Vol. 29, No. 3, September 1926, pp. 143-145.

Construction details of foundations for 14th Street, East River Station of N. Y. Edison Co., details of excavation.

Kershaw, J. B. C., "The Crawford Avenue Station, Chicago," *World Power*, Vol. 6, No. 35, November 1926, pp. 253-258.

General features of station described.

Krasha, W., "The Goldenberg Central Station," *Elektrotechnische Zeit.*, Vol. 47, No. 384, January 21 and 28, 1926, pp. 65-70 and 104-108.

Details of 400,000 kw. station near Cologne at mouth of soft coal mine and in close proximity to Rhine River.

Lacombe, C. F., "Cost Analysis for Electric Utilities," *Electrical World*, Vol. 88, No. 9, August 28, 1926, pp. 427-431. *Electrical World*, Vol. 88, No. 12, September 18, 1926, pp. 575-579. *Electrical World*, Vol. 14, October 2, 1926, pp. 701-705.

Economic survey which diagnoses health of company; gives more exact data of costs required by increasing expansion and economic changes; description of method used.

Lieb, John W., "New East River Station of the New York Edison Company," *Combustion*, Vol. 16, No. 4, April 1927, pp. 207-210.

Points in design showing provisions for future installations.

Mechanical Engineering, "Progress in Steam Power Plant Engineering," Vol. 48, No. 12, December 1926, pp. 1419-1421.

A. S. M. E. Power Division report of progress in theory and practise.

Mechanical Engineering, "A Sixty-Atmosphere Steam Plant," Vol. 48, No. 8, August 1926, pp. 854-855.

Abstract of article in *The Engineer*, Vol. 142, No. 3684, August 20, 1926.

Mellanby, A. L. and Kerr, W., "The Use and Economy of High-Pressure Steam Plants," *Engineering*, Vol. 123, Nos. 3185 and 3186, January 28 and February 4, 1927, pp. 117-120 and 149-151; *The Engineer*, Vol. 143, No. 3708, February 4, 1927, pp. 126-128; *The Engineer*, Vol. 143, No. 3709, February 11, 1927, pp. 166-168.

The steam cycle and its probable limits. Curves of Thermal Efficiency against initial temperature, re-heating stage, feed heating, flue gas temperatures.

Moultrop, I. E. and Norris, E. W., "High-Pressure Steam at Edgar Station," Synopsis in *Mechanical Engineering*, Vol. 49, No. 5a, Mid-May 1927, p. 587.

Design of new 1400 lbs. pressure plant. Paper presented at Spring Meeting of A. S. M. E. May 23-27, 1927.

Muir, J. F., "The Somerset Power Station," *Stone & Webster Journal*, Vol. 38, No. 4, April 1926, pp. 461-491.

Details of the new station located on the Taunton River.

Neblett, H. W., "Trend in Steel Plant Power," *Power*, Vol. 65, No. 18, May 3, 1927, pp. 656-660.

One hundred and eighteen boilers replaced by seven in modern plant.

Neblett, H. W., "Minnequa Steel Works Installs New Power Plant," *Power Plant Engineering*, Vol. 31, No. 9, May 1, 1927, pp. 495-501.

Main fuel is blast-furnace gas with pulverized coal as auxiliary.

Newbury, F. D., "Load Division between Alternators," *The Electric Journal*, Vol. 24, No. 5, May 1927, pp. 241-243.

Analysis of load division between alternators.

Ohlmuller, F., "Recent Additions to the Charlottenburg Central Station," *Elektrotechnische Zeit.*, Vol. 47, No. 17, April 29, 1926, pp. 494-500.

New high pressure unit exhausting into original medium pressure turbine is a feature of new stations.

Peneker, A., "Progress in Lignite Power Plant Construction in Germany," *Electrical World*, Vol. 87, No. 26, June 26, 1926, pp. 1392-1393.

Methods of handling this fuel at Zschornewitz Station.

Pfaehler, R., "100,000 Horse Power Steam Auxiliary Station," *Power Plant Engineering*, Vol. 31, No. 10, May 15, 1927, pp. 552-558.

Features of Buck Steam Station.

Pillans, J. S., "The Economical Loading of Power Plants, *Electrical Review*, Vol. 98, No. 2521, March 19, 1926, pp. 451-452.

Use of Willans Line.

Pigott, R. J. S., "The Kearny Station of the Public Service Electric Power Company," *Power*, Vol. 64, No. 9, August 31, 1926, pp. 306-312.

Plant relies for efficiency on superior operation of simple equipment rather than the addition of special heat recovery devices.

Pollard, "Features of Kearny, N. J.," *Electrical World*, Vol. 88, No. 9, August 28, 1926, pp. 412-423.

Outstanding features of the new Public Service Station.

Power, "Sixty-Four Per Cent Less Coal per Pound of Product," Vol. 65, No. 19, May 10, 1927, pp. 692-696.

Hercules Powder Co. saves $175,000 annually due to use of modern power plant methods.

Power, "Regulation of Load Between Power Plant Units," Vol. 65, No. 19, May 10, 1927, p. 696.

Discussion of different methods used in various kinds of generating stations.

Power, "The Ford Canadian Power Plant," Vol. 64, No. 23, December 7, 1926, pp. 850-855.

Heating and power plant using pulverized coal.

Power, "Year's Progress in the Central Station Field," Vol. 65, No. 1, January 4, 1927, pp. 2-8 (Annual Review No.).

Review of the accomplishments of the Large Power Stations in obtaining better operating characteristics, with increased efficiency during the past year.

Power, "The Cleveland Electric Illuminating Company's Plant at Twentieth Street," Vol. 65, No. 4, January 25, 1927, p. 128.

Pulverized fuel a feature at the new steam heating plant.

Power, "Reliability and Safety Outstanding Features in New Harbor Point Steam Plant," Vol. 65, No. 5, February 1, 1927, pp. 154-158.

Complete description of 185,000 kv-a. station of Utica Gas & Electric Co. List of mechanical equipment also given.

Power, "The New 14th Street East River Station," Vol. 65, No. 11, March 15, 1927, pp. 390-397.

Description of the 14th Street Station of the New York Edison Co.

Power, "Generating Power with Mercury Vapor," Vol. 65, No. 15, April 12, 1927, pp. 566-567.

Abstract and discussion of a paper presented by B. P. Coulson of General Electric Co. at an A. S. M. E. meeting held April 4, 1927.

Power, "High Spots in the Design of Cleveland's New Avon Plant," Vol. 64, No. 13, September 28, 1926, pp. 466-470.

New station has two 35,000-kw. units installed at present.

Power, "New Station at Columbus Embodies Many Refinements," Vol. 64, No. 20, November 16, 1926, pp. 724-728.

New Picway Station has all latest improvements.

Power, "The 1200 lb. Unit at Edgar Station after Six Months' Operation," Vol. 63, No. 24, June 15, 1926, pp. 935-936.

Results of the experiment of Edison Electric Illuminating Co. of Boston with the extremely high pressure unit.

Power, "Addition to Barking Station, Part of London's Electrical Consolidation," Vol. 64, No. 23, December 7, 1926, pp. 859-860.

Features of new boiler house now under construction.

Power, Sterlington Power Station Erected in Louisiana Gas Fields," Vol. 63, No. 23, June 8, 1926, pp. 878-881.

Cheap fuel responsible for simplicity in design and low installation cost.

Power, Building up an Organization to Operate the New Plant," Vol. 64, No. 9, August 31, 1926, pp. 324-325.

Continuity of service and efficiency are most important.

Power, "Virginian Railway Adopts Pulverized Coal for Widely Fluctuating Load," Vol. 64, No. 10, September 7, 1926, pp. 359-362.

New power station is designed for high efficiency in handling railway load.

Power, "Kip's Bay Plant of the New York Steam Corporation," Vol. 65, No. 22, May 31, 1927, pp. 808-812.

Details of the Kip's Bay Plant, designed for extremely high efficiency in the limited space available.

Power, "The Mercury Vapor Power Plant at Hartford," Vol. 65, No. 22, May 31, 1927, pp. 818-819.

Details of the 10,000 kw. mercury vapor system now being installed in the plant of the Hartford Electric Light Co.

Power Plant Engineering, "Modern Power Plant Trends," Vol. 31, No. 1, January 1, 1927, pp. 2-7.

Effort to achieve greatest heat economy and heat adaptation to condition is evident.

Power Plant Engineering, "Higher Superheat Demands Many Changes," Vol. 31, No. 1, January 1, 1927, pp. 38-39.

Power Plant Engineering, "Inland Steel Company Completes New Power Plant," Vol. 31, No. 4, February 15, 1927, pp. 256-257.

Boilers fired by blast furnace kilns and auxiliary oil burners.

Power Plant Engineering, "New Hudson Ave. Unit to Save 50,000 Tons of Coal Yearly," Vol. 31, No. 5, March 1, 1927, p. 330.

Description of the largest single generating unit in service at the present time.

Power Plant Engineering, "East River Station," Vol. 31, No. 6, March 15, 1927, pp. 338-346.

Details of new station of New York Edison initial installation 120,000 kw.

Power Plant Engineering, "New Bayside Station Aids Wisconsin Hydro Plants," Vol. 31, No. 11, June 1, 1927, pp. 596-601.

Description of plant which is of latest design.

Power Plant Engineering, "Tendencies in Power Plant Design," Vol. 30, No. 24, December 15, 1926, pp. 1334-1339.

Power Plant Engineering, "New Features at Rummelsburg Super Station," Vol. 30, No. 24, December 15, 1926, p. 1323 (See description in *Electrician*, Vol. 96, No. 2502, April 30, 1926).

Influence of economic factors on design discussed.

Power Plant Engineering, "Hunlock Creek, Penn. Power Station," Vol. 30, No. 19, October 1, 1926, pp. 1040-1045.

Details of 190,000-kw. plant.

Power Plant Engineering, "Richmond Goes on the Line with 100,000 Kilowatts," Vol. 30, No. 10, May 15, 1926, pp. 564-573.

Details of the new station of the Philadelphia Electric Co.

Power Plant Engineering, "Tecumseh Serves Topeka District," Vol. 30, No. 20, October 15, 1926, pp. 1088-1091.

New plant of Kansas Power & Light Co. described.

Power Engineer, "A Traction Power Plant Extension," Vol. 22, No. 252, March 1927, pp. 88-93, 109.

A very complete description of the 18,750 kw. addition to the Power Station of the Metropolitan Railway, Neasden.

Price, C. W., "New York's New Central Station," *Engineering World*, Vol. 30, No. 4, April 1927, pp. 217-220.

Interesting description of the new East River Station of the New York Edison Co. at 14th St.

Rauber, E., "Use of High Steam Pressures and Temperatures in Central Stations," *Power*, Vol. 64, No. 17, October 26, 1926, pp. 935-936.

Problem of steam pressures; practical developments in high pressure steam generation. Abstract translated from paper presented at a convention in Rome.

Rehmer, M., "Super Power House at Rummelsburg," *Elektrotechnische Zeit.*, Vol. 47, No. 42, October 21, 1926, pp. 1249-1257.

Steam station for City of Berlin on Spree River has initial installation of 3 units of 100,000 kv-a. each.

Ritchie, R. G., "Power Station Efficiency," *Combustion*, Vol. 14, No. 4, April 1926, pp. 237-240.

Review of situation with view to arriving at some definite conclusion.

Roberts, J. D., "Grand Tower Power Station," *Electric Light and Power*, Vol. 5, No. 1, January 1927, pp. 23-26, 80-84.

Description of the new 50,000-kw. station of the Central Illinois P. S. Co.

Shoudy, W. A., "Investigation of Power Costs," *Manufacturing Industries*, Vol. 12, No. 3, September 1926, p. 203.

Methods for studying utilization and generation of power to show where costs may be reduced.

Southern Power Journal, "St. John's River Power Station," Vol. 45, No. 2, February 1927, pp. 36-41.

Ultimate capacity of plant 100,000-kw., steam pressure 400 lb. gage.

Southern Power Journal, "New Buck Station of the Southern Power Co.," Vol. 45, No. 3, March 1927, pp. 36-41.

Ultimate capacity 100,000 horse power. Pulverized coal used as fuel.

Southern Power Journal, "Fourth Street Station Memphis Light & Power Co.," Vol. 44, No. 11, November 1926, pp. 36-43.

Main features of apparatus in new extension to power plant.

Stauffer, R. D., "Features of Parr Shoals Steam Power Plant," *Power Plant Engineering*, Vol. 31, No. 3, February 1, 1927, pp. 172-180.

South Carolina station designed for ultimate capacity of 80,000 kw., burns pulverized coal.

Struck, Henry W., "Neches Station Increases Texas Power Facilities," *Power Plant Engineering*, Vol. 31, No. 7, April 1, 1927, pp. 390-395.

New plant illustrates recent design tendencies.

Sykes, W., "Latest Practise Found in New Power and Blowing Plant of Inland Steel Company," *Power*, Vol. 65, No. 6, February 8, 1927, pp. 194-195.

Boilers burn blast-furnace gas and oil; power generated for less than 20,000 B. t. u. in gas.

Taylor, S. A., "Location of Central Power Plants and Coal Selection," *Power*, Vol. 65, No. 8, February 22, 1927, p. 285.

The Engineer, "A Sixty-Atmosphere Steam Plant," Vol. 142, No. 3684, August 20, 1926, pp. 204-205.

The Engineer, "The Langerbrugge Power Station," Vol. 141, No. 3673, June 4, 1926, pp. 570-573-582.

Details of the new Belgian Station at Ghent.

The Engineer, "Extensions to the Treforest Power Station," Vol. 143, No. 37, May 6, 1927, pp. 500-502.

Details of extensions to the Treforest Station.

The Engineer, "A New Power Station at Poplar," Vol. 143, No. 3720, April 29, 1927, pp. 456-467.

Engineering, Vol. 123, No. 3198, April 29, 1927, pp. 513-516.

Details of the new station at Poplar.

The Engineer, "The Narrows Power Plant of the Virginian Railway Company," Vol. 142, No. 3689 and 3690, September 24 and October 1, 1926, pp. 340-342 and 356-357.

Power plant on New River at Narrows, Va., contains four 10,000 kw. turbines and five 1521 hp. cross drum boilers fired with pulverized fuel.

The Engineer, "A New Power Station for Birmingham," Vol. 143, No. 3701, January 7, 1927, page 4.

Brief description of new Birmingham Plant.

The Engineer, "Bristol Power Scheme," Vol. 143, No. 3706, January 21, 1927, p. 63.

New Power Station at Portishead to have ultimate capacity of 280,000 kw.

The Engineer, "The Use and Economy of High Pressure Steam Plants," Vol. 143, No. 3707, January 28, 1927, pp. 94-96.

Discussion of a paper presented before the Institution of Mechanical Engineers. High pressures and temperatures featured.

The Engineer, "Congella Power Station, Durban," Vol. 143, No. 3707, January 28, 1927, p. 106.

Congella Station is first pulverized coal fired station in S. Africa.

The Engineer, "New Circulating Water System at Woolwich Power Station," Vol. 143, No. 3709, February 11, 1927, pp. 150-152.

Description of the new inlet and outlet channels and conduit for Woolwich Station's condensers.

The Electrician, "Poplar Electricity Undertaking," Vol. 98, No. 2552, April 29, 1927, pp. 460-462.

The Electrician, "Extensions at Yarmouth," Vol. 98, No. 2542, February 18, 1927, p. 171.

The Electrician, "Electricity Supply at Bradford," Vol. 98, No. 2537, Jan. 14, 1927, p. 35.

Efficiency of 1000 lb., 800 deg. fahr. Station.

Wood, M. R., "Steam Purifiers Effect Saving in Texas Plant," *Power Plant Engineering*, Vol. 31, No. 6, March 15, 1927, pp. 359-360.

Steam rate of turbine shows noticeable increase due to solids in the steam.

World Power, "Power Station Efficiency in Great Britain," Vol. 5, No. 26, February 1926, pp. 93-96.

Details of Greenwich Station supplying whole of power for London Tramways.

BOILER PLANT DESIGN AND OPERATION

Allen, R. H., "Induced Draft," *Combustion*, Vol. 16, No. 5, May 1927, pp. 278.

Discussion of certain points in Mr. J. G. Mingle's article on same subject in February 1927 issue.

Bailey, A. D., "Boilers and Superheaters Show Improvements," *Power Plant Engineering*, Vol. 31, No. 1, Jan. 1, 1927, pp. 33-34.

Higher pressures and temperatures, larger boilers, higher

ratings, reheat boilers, water walls, and improved appurtenances combine to make progress in this field notable.

Bailey, E. G., "Tendencies in Steam Boiler Furnaces," *Power Plant Engineering*, Vol. 30, No. 24, Dec. 15, 1926, pp. 1311-1312.

Combustion rates of 40,000 to 50,000 B. t. u. per cu. ft. of furnace volume are predicted for progressive installations.

Bailey, E. G., "What is the Limit in Reducing Excess Air," *Power*, Vol. 64, No. 2, July 13, 1926, pp. 65-66.

Summary of current practise.

Berry, C. H., "Size, Load and Ratings of Boilers," *Power*, Vol. 64, No. 9, Aug. 31, 1926, pp. 314-315.

Discusses necessity for distinguishing accurately the three basic quantities.

Blanning, H. K., "Advantages of Automatic Boiler Control," *Power Plant Engineering*, Vol. 30, No. 8, April 15, 1926, pp. 470-472.

Abstract of paper read before Prime Movers Committee N. E. L. A.

Blaum, R., Bremen, "Thermal Methods of Feedwater Preparation," in *Zeits. des Verein Deut. Ingrs.*, Vol 71, No. 9, Feb. 26, 1927, pp. 285, 290, also extract in *Mechanical Engineering*, Vol. 45, No. 5, May 1927, pp. 465-467.

Feedwater preparation by distillation and some installations in Germany.

Chaleur et Industrie, "Forced Draft Without Motive Power," Vol. 6, No. 69, Jan. 1926, pp. 51-53.

Details of Chanard-Etaile aspirating stack.

Contant, J. Gould, "Effect of Direct Heating Surface on Efficiency," *Combustion*, Vol. 16, No. 2, February 1927, pp. 99-100.

Effect of water cooled walls on exit gas temperature and boiler efficiency.

Contant, J. G., "Does Additional Direct Heating Surface Pay?", *Combustion*, Vol. 15, No. 2, Aug. 1926, pp. 106-107.

Demonstrates economical features of additional direct heating surface.

Christie, A. G., "Effect of Radiant Heat on Water Cooled Furnace Walls," *Power*, Vol. 65, No. 22, May 31, 1927, pp. 841-844.

Discussion of probable rates of heat absorption, velocities attained, and effects produced in the water walls.

Dockstader, E. A., "Electrical Determination of Temperatures in Chimney Shells," *Electrical World*, Vol. 88, No. 8, Aug. 21, 1926, pp. 363-365.

Importance of temperature stresses in reinforced concrete chimneys is emphasized, preliminary heat drop data.

Engineering, "Recorder for Dissolved Oxygen in Feedwater," Vol. 122, No. 3174, Nov. 12, 1926, p. 610.

Details of the Cambridge dissolved oxygen recorder.

Engineering, "Riveted and Welded Joints in Boiler Construction," Vol. 122, No. 3170, Oct. 15, 1926, pp. 489-490.

Engineering, "The Prevention of the Formation of Boiler Scale," Vol. 122, No. 3168, Oct. 1, 1926, pp. 415-416.

Details of the linseed oil process and other modifications.

Engineering and Boiler House Review, "New Turbine Furnace Development," Vol. 40, No. 7, January 1927, p. 362.

Description with method of eliminating black smoke.

Engineering and Boiler House Review, "Recent Practice in Land Boiler Design," Vol. 40, No. 8, February 1927, pp. 439-442.

Review of present-day practise in the construction of different types of boilers.

Engineering and Boiler House Review, "Large Boiler Units at the Prince's Generating Station, Birmingham," Vol. 40, No. 8, February 1927, pp. 501-506.

Some details of four 150,000 lb. boilers, fired with powdered fuel, in course of erection at Michells, Birmingham.

Engineering and Boiler House Review, "The Radiant Heat Superheater," Vol. 39, No. 11, May 1926, pp. 519-520.

To replace side walls.

Engineering and Boiler House Review, "Modern Superheaters," Vol. 39, No. 7, January 1926, pp. 329-332.

Engineering and Boiler House Review, "The Manufacture of Bricks from Boiler House Ash and Clinker," Vol. 39, No. 7, January 1926, pp. 319-320.

Describes principle of calcium silicate process, and leading features of installations.

Fish, E. R., "Developments in Steam Boiler Practice," *Power Plant Engineering*, Vol.30, No.24, December 15, 1926, pp.1308-1310.

Methods of using high-pressure steam still in course of development.

Forssblad, N., "Calculation of the Temperature of a Boiler Furnace," *Combustion*, Vol. 15, No. 1, July 1926, pp. 33-35.

Table for simplifying furnace temperature calculations.

Foulk, C. W., "Present Knowledge of Foaming and Priming of Boiler Feed Water, with Suggestions for Research," *Mechanical Engineering*, Vol. 48, No. 11a, Mid-November, 1926, pp. 1364-1367.

Progress report of Sub-Committee No. 3 of Joint Research Committee on boiler feed water studies.

Funk, Nevin E., "The Effect of Water-Cooled Walls on Preheater Performance," *Mechanical Engineering*, Vol. 49, No. 1, January 1927, pp. 25-28.

Data on design of water-cooled walls and air-preheater.

Gleichmann, G. H., "Experience with the Benson Steam Generator," *Power*, Vol. 65, No. 22, May 31, 1927, pp. 838-840.

Description of the Siemens-Schuckert Company's experimental installation of the 3200-lb. Benson System.

Goehnauer, H. W., "Proper Use of Motors in Boiler Room Improves Efficiency and Reduces Investments," *Power*, Vol. 65, No. 4, January 25, 1927, pp. 118-121.

Goerg, B., Dr., "The Transfer of Heat from Combustion Gases to Surrounding Walls," *Combustion*, Vol. 16, No. 4, April, 1927, pp. 214-218.

Studies in radiation and convection under various conditions of wall design.

Greene, T. W., "Stresses in a Large Welded Tank Subjected to Repeated High Pressure," *Mechanical Engineering*, Vol. 49, No. 1, January, 1927, pp. 124-133.

Complete report of test including theoretical discussions and stress-strain curves.

Greer, W. N. and Parker, H. C., "The Potentiometric Determination of Hydrogen-ion Concentrations as Applied to Boiler Waters," *Mechanical Engineering*, Vol. 48, No. 11, November, 1926, pp. 1129-1132.

Grunert, A. E., "Overfire Supplementary Air Introduction," *Power Plant Engineering*, Vol. 31, No. 4, February 15, 1927, pp. 245-247.

Operation and advantages fully discussed.

Guy, H. L., "The Economic Value of Increased Steam Pressure," *The Engineer*, Vol. 142, Nos. 3696 and 3697, November 12 and 19, 1926, pp. 534-537 and 561-563.

Hardie, P. H., "High Heat-Transfer Rates for Surface Type Desuperheaters," *Power*, Vol. 65, No. 7, February 15, 1927, pp. 253-255.

Results obtained from tests conducted at Hudson Avenue Station.

Henry, H. K., "Some Advantages of Mechanical Draft," *Southern Power Journal*, Vol. 45, No. 5, May 1927, p. 44.

Principally a comparison with induced draft.

Housley, J. Elmer, "Care and Inspection of Electric Steam-Flow Meters," *Power*, Vol. 65, No. 8, February 22, 1927, pp. 288-290.

Joos, C. E., "Purifying Steam with a Separator," *Power*, Vol. 65, No. 19, May 10, 1927, p. 710.

Special receiver-separator described.

Joos, C. E., "Finding and Curing Corrosion," *Power*, Vol. 65, No. 21, May 24, 1927, pp. 768-772.

Josse, E., "Preheating Pump," *Zeit. des Vereines Deut. Ingrs.*, Vol. 70, No. 25, June 19, 1926, pp. 853-854.

Pump developed by Berlin firm in which boiler feed water is heated by direct contact with bleeder steam within pump.

Keenan, W. F., Jr., "Modern Superheater Problems," *Power Plant Engineering*, Vol. 30, No. 24, December 15, 1926, pp. 1321-1323.

Kinzel, A. B., "The Design of Dished and Flanged Pressure Vessel Heads," *Mechanical Engineering*, Vol. 49, No. 6, June 1927, pp. 625-644.

Abstract and discussion of a paper presented at a joint meeting of the Metropolitan Section A. S. M. E. and New York Section of American Welding Society.

Knowles, C. R., "Pretreatment of Boiler Feed-Water," *Mechanical Engineering*, Vol. 48, No. 11a, Mid-November, 1926, pp. 1361-1363.

Progress report of Sub-Committee No. 2 of Joint Research Committee on Boiler Feed-Water Studies on water softening by chemicals (external treatment).

Kriegsheim, H., "Intercrystalline Cracks in Riveted Seams," *Power*, Vol. 64, No. 7, August 17, 1926, p. 261.

Author maintains that intercrystalline cracks in boiler seams are fully explained by action of prolonged high total stresses.

Krug, F., "Enlarged Oil Furnace Increases Efficiency," *Power Plant Engineering*, Vol. 31, No. 4, February 15, 1927, pp. 242-244.

Boiler Furnace remodeled to increase capacity and decrease maintenance expenses.

Leitch, H. W., "Boiler and Stoker Performance at Hell Gate," *Mechanical Engineering*, Vol. 48, No. 10, October, 1926, pp. 1011-1016.

Shows effect of yearly extensions to boiler house on overall efficiency and maintenance. Detailed test of latest installation given.

McMillan, L. B., "Heat Transfer Through Insulation," *Power*, Vol. 65, No. 5, February 1, 1927, pp. 180-181.

Digest of a paper presented at the Heat Transfer Session arranged by the National Research Council at the annual meeting of the A. S. M. E. (December 1926) in joint session with the A. S. R. E.

McVicker, G. G., "Experiments with Furnace Slag Prevention," *Power*, Vol. 65, No. 20, May 17, 1927, pp. 743-744.

Mechanical Engineering, "Heat Transmissionin Water-tube Boilers," Vol. 49, No. 2, February, 1927, p. 152 (abstract).

From a paper by Dr. T. Barratt before the Institute of Fuel Economy Engineers.

Mellanby, A. L. and Kerr, Wm., "Materials Limit Boiler Operating Conditions," *Power Plant Engineering*, Vol. 31, No. 11, June 1, 1927, pp. 639-641.

Nickel-chromium alloys allow safety margin at high temperatures and pressures.

Mellanby, A. L., and Kerr, Wm., "The Use and Economy of High Pressure Steam Plants," *Power*, Vol. 65, No. 13, March 29, 1927, pp. 494-495.

Abstract of a paper read before the British Institution of Mechanical Engineers.

Mingle, J. G., "Modern Methods of Producing Draft in Steam Plants 3," *Combustion*, Vol. 16, No. 2, February, 1927, pp. 100-115.

Description with drawings of induced draft systems; advantages and disadvantages.

Mingle, J. G., "Economical Design of Natural Draft Chimneys," *Power Plant Engineering*, Vol. 31, No. 7, April 1, 1927, pp. 399-402.

Mingle, J. G., "Modern Methods of Draft Production in Steam Plants," *Combustion*, Vol. 15, No. 5, November, 1926, pp. 295-299.

Aspirated and Induced Drafts.

Mingle, J. G., "The Importance of Proper Chimney Design," *Combustion*, Vol. 14, No. 3, March 1926, pp. 166-168.

Factors influencing design; determination of chimney size.

Mosshart, D. J., "Another Stoker Fired Boiler Shows High Efficiency," *Power*, Vol. 63, No. 24, June 15, 1926, p. 925.

High Bridge Station at St. Paul, Minn., gives from 78 to 81 per cent efficiency.

National Electric Light Ass'n., "Stacks and Flues," Report No. 267-13 of Prime Movers Committee.

National Electric Light Ass'n., "Boilers, Superheaters and Economizers," Report No. 267-33 of Prime Movers Committee.

National Electric Light Ass'n., "Boiler and Turbine Room Instruments," Report No. 267-12 of Prime Movers Committee.

Oppenheimer, P. H., "Rolling Tubes in Boiler Plates," *Power*, Vol. 65, No. 8, February 22, 1927, pp. 300-303.

The effect of rolling on the strength of both tube and sheet.

Parker, Benjamin J., "What About the Water Level?", *Power*, Vol. 65, No. 17, April 26, 1927, p. 631-632.

Parr, S. W. and Straub, F. G., "Caustic Embrittlement," *Power*, Vol. 63, No. 26, June 29, 1926, pp. 994-998.

Summary of results of studies carried on at engineering experiment stations of University of Illinois.

Phelps, C. C., "The Overworked Chimney," *Power*, Vol. 63, No. 21, May 25, 1926, p. 813.

Points out that increasing CO_2 materially increases chimney's capacity.

Pigott, R. J. S., "Fundamentals of Safety Valve Design," *Power*, Vol. 65, No. 16, April 19, 1927, pp. 580-583.

Potter, A. A. and Zucrow, M. J., "Smoothing Out of the Load with a Steam Accumulator," *Power*, Vol. 64, No. 15, October 12, 1926, pp. 554-556.

Increase efficiency and allow use of inferior fuels.

Powell, S. T., "Boiler Feed Water Purification," *Power*, Vol. 64, No. 1, July 6, 1926, pp. 12-15; Vol. 64, No. 2, July 13, 1926, pp. 49-52; No. 3, July 20, 1926, pp. 93-95; No. 4, July 27, 1926, pp. 129-132; No. 5, August 3, 1926, pp. 165-168; No. 6, August 10, 1926, pp. 208-210; No. 7, August 17, 1926, pp. 236-238; No. 8, August 24, 1926, pp. 279-281; No. 9, August 31, 1926, pp. 330-333; No. 10, September 7, 1926, pp. 371-374; No. 11, September 14, 1926, pp. 406-410; No. 12, September 21, 1926, pp. 441-444; No. 13, September 28, 1926, pp. 471-474; No. 14, October 5, 1926, pp. 520-523; No. 15, October 12, 1926, pp. 552-554; No. 16, October 19, 1926, pp. 595-598.

A comprehensive series of articles on boiler feed water purification covering all phases of the subject.

Power, "The Steam Loop and How it Operates," Vol. 65, No. 18, May 3, 1927, pp. 661-662.

Power, "Tests Indicates Need of Radical Changes in Dished Head Design for Boiler Steam Drums," Vol. 65, No. 2, January 11, 1927, pp. 72-74.

Results of recent tests show present designs to be irrational and weak.

Power, "Developments in Boilers and Boiler Auxiliaries," Vol.65, No.1, January 4, 1927, pp.9-13 (Annual Review Number).

Power, "Swiss Boiler Generates 1500 lb. Steam Pressure in Two Stages," Vol. 65, No. 5, February 1, 1927, pp. 160-162.

Description of experimental plant at Winterthur.

Power, "Boiler Feed-Water Abstracts," Vol. 65, No. 7, February 15, 1927, pp. 264-265.

Bibliography of "Joint Research Committee on Boiler Feed Water Studies." First two reports only.

Power, "How to Prevent Carryover," Vol. 65, No. 11, March 15, 1927, pp. 420-421.

Simple and reliable tests for the control of boiler blow down.

Power, "Calumet Boiler Generates 300,000 lb. of Steam per Hour," Vol. 65, No. 14, April 5, 1927, pp. 519-520.

A description of the new pulverized fuel boiler at Calumet Station.

Power, "Boiler Feed-Water Abstracts," Vol. 65, No. 15, April 12, 1927, p. 568.

Bibliography of "Joint Research Committee on Boiler Feed Water." Third report of Sub-committee No. 9.

Power, "Crawford Ave. Tests Prove the Value of Constant Pressure Differential in Feed-Water Regulation," Vol. 64, No. 10, September 7, 1926, pp. 357, 358.

Tests show advantage of having one variable to contend with.

Power, "How the Bailey Meter Control Operates," Vol. 64, No. 6, August 10, 1926, pp. 198-202.

System utilizes electrical motive power.

Power, "A New Boiler Steel and Intercrystalline Cracks," Vol. 64, No. 17, October 26, 1926, p. 623.

Experiments with new boiler steel and cause of intercrystalline cracks.

Power, "Automatic Control of Boilers Plants," Vol. 65, No. 22, May 31, 1927, pp. 814-817.

A brief description is given of a number of these systems.

Power Plant Engineering, "Feed Water Treatment in Power Plants," Vol. 31, No. 1, January 1, 1927, pp. 25-28.

Higher pressures and ratings have made feed-water heating a vital problem.

Power Plant Engineering, "Forced, Induced and Natural Draft Practise," Vol. 31, No. 1, January 1, 1927, pp. 20-22.

More effective application of present equipment sought.

Power Plant Engineering, "Steam Generating Equipment," Vol. 31, No. 2, January 15, 1927, pp. 130-137.

Developments in boiler construction; recent superheater developments.

Power Plant Engineering, "Boiler Pressures Continue to Increase," Vol. 31, No. 1, January 1, 1927, pp. 35-37.

Higher pressures and ratings bring out new designs and problems; reheat and water-screen boilers used in new stations.

Power Plant Engineering, "Practise in Feed Water Heating," Vol. 31, No. 1, January 1, 1927, pp. 28-29.

Use of regenerative cycle in most modern stations.

Power Plant Engineering, "Furnace Wall Design Keeps Pace with Demands," Vol. 31, No. 2, January 15, 1927, pp. 113-116.

Statements by various manufacturers.

Power Plant Engineering, "Practise in Construction and Use of Air Heaters," Vol. 31, No. 2, January 15, 1927, pp. 117-118.

Statements by manufacturers.

Power Plant Engineering, "Feed Water Preparation," Vol. 31, No. 2, January 15, 1927, pp. 119-121.

Statements of problems of design and developments by manufacturers.

Power Plant Engineering, "Development in Boiler Construction," Vol. 31, No. 2, January 15, 1927, pp. 130-135.

Statements by manufacturers.

Power Plant Engineering, "Recent Superheater Developments," Vol. 31, No. 2, January 15, 1927, pp. 135-137.

Statements by leading manufacturers.

Power Plant Engineering, "Boiler Operates Successfully at 1500 lbs.," Vol. 31, No. 5, March 1, 1927, pp. 300-301.

Possibilities of higher efficiencies and greater economies in boiler plant operation are proved possible in the German development.

Power Plant Engineering, "Modern Methods Influence Boiler Tube Size," Vol. 31, No. 7, April 1, 1927, p. 402.

New Heine boiler with front section of 3-in. tubes and rear of 2-in. tubes.

Power Plant Engineering, "Electrical Features of a Modern Draft System," Vol. 31, No. 8, April 15, 1927, pp. 460-463.

A description of the unusually flexible draft control system at Somerset Station.

Power Plant Engineering, "Some Hydraulic Methods of Ash Disposal," Vol. 31, No. 8, April 15, 1927, pp. 451-454.

Types of open and enclosed sluices using continuous flow or intermittent high-velocity jet.

Power Plant Engineering, "Tonowanda Paper Company Burns Pulverized Coal," Vol. 31, No. 4, February 15, 1927, pp. 232-236.

Turbine-driven unit-pulverizers serve boilers.

Power Plant Engineering, "Economizers Developed to Meet High Pressures," Vol. 31, No. 1, January 1, 1927, pp. 29-32.

Steel tubes with protected surfaces is outstanding feature of economizer development.

Power Plant Engineering, "Operating Boiler Tests Show Important Relations," Vol. 30, No. 17, September 1, 1926, pp. 944-946.

Variation of draft loss, superheat, efficiency, and losses with rate of forcing and percentage of CO_2.

Rice, Cyrus M., "Some Observations on Priming and Foaming," *Power*, Vol. 65, No. 15, April 12, 1927, pp. 544-546.

Effect of rating on impurities in steam.

Ruths, J., "Use of the Ruths Steam Accumulator in Parallel Operation of Hydro-Electric and Steam Plants," World Power Conference, 1926. Advance paper No. 34.

Sforzini, Lewis J., "The Design and Construction of Pressure Vessels," Part I, *Power*, Vol. 65, No. 17, April 26, 1927, pp. 623-625; Part II, *Power*, Vol. 65, No. 18, May 3, 1927, pp. 670-674.

Fabrication of seamless and welded vessels.

Sherman, Ralph A., "Temperatures in Powdered-Coal Furnaces Having Extended Radiant-Heat-Absorbing Surfaces," *Mechanical Engineering*, Vol. 49, No. 4, April, 1927, pp. 335-338.

Progress Report of A. S. M. E. Special Committee on Boiler-Furnace Refractories.

Southern Power Journal, "Some Advantages of Artificial Draft," Vol. 45, No. 1, January 1927, pp. 55-61.

High combustion rates require higher draft pressures.

Southern Power Journal, "Economizers, Where and Why Used," Vol. 45, No. 1, January 1927, pp. 63-67.

Size of economizers required, operating conditions, fixed charges, and saving of fuel considered.

Sprague, B. C., "Overcoming Boiler-Water Troubles with Tri-Sodium Phosphate," *Power*, Vol. 65, No. 9, March 1, 1927, pp. 321-322.

Stromeyer, C. E., "Cause of Dangerous Boiler Deterioration," *Power*, Vol. 65, No. 17, April 26, 1927, pp. 648-649.

An abstract of the 1926 report of the Manchester Steam User's Association of London, England, as presented to the association's executive committee.

Tenney, E. H., "Recent Development in Feed-Water Treatment," *Power Plant Engineering*, Vol. 31, No. 1, January 1, 1927, pp. 23-24.

Practise in chemical methods of treatment, evaporation, deaeration, and stage heating.

Thayer, H. C., "Designing Boiler Furnace Arches," *Power Plant Engineering*, Vol. 30, No. 8, April 15, 1926, pp. 473-474.

The Engineer, "The Manufacture of High-Pressure Boiler Drums," Vol. 143, No. 3712, March 4, 1927, pp. 246-248.

Description of method in which the seams are welded.

The Engineer, "The Sulzer 1500-lb. Boiler," Vol. 142, No. 3703, December 31, 1927, pp. 706-709.

Description of boiler plant in Switzerland employing a working pressure of 110 atmos. (1565-lb. gage per sq. in.) with total steam temperature of 707 deg. fahr.

The Engineer, "Proposed Method for the Automatic Superheating of Steam," Vol. 141, No. 3671, May 21, 1926, p. 516.

On principle opposite of refrigeration cycle, without running machinery.

The Engineer, "A Boiler Blow Down Accident," Vol. 142, No. 3682, August 6, 1926, p. 142.

Abstract of report concerning explosion of blow down tank.

The Engineer, "An Electrically Operated Flow Meter," Vol. 142, No. 3695, Nov. 5, 1926, pp. 504-505.

Description of meter for indicating, recording, or integrating rate of flow of steam, water, etc.

Wade, C. F., "Heat Transmission in Water Tube Boilers," *Combustion*, Vol. 14, No. 3, March 1926, pp. 163-164.

Wade, C. F., "CO_2 Records and Their Interpretation," *Electrical Review*, Vol. 98, No. 2533, June 11, 1926, pp. 863-865.

Ware, C. M., "Operating Boilers at the Minimum Cost," *Combustion*, Vol. 16, No. 3, March, 1927, pp. 153-154.

Study to determine most economical period of operation of boiler.

Wharton, C. J., "The Economic Production of Steam by Electricity," *Combustion*, Vol. 16, No. 5, May, 1927, pp. 271-273.

Advantages of electric boilers for process steam.

White, A. E. and Clark, C. L., "Properties of Boiler Tubing at Elevated Temperatures Determined by Expansion Tests," paper presented at A. S. M. E. meeting December 6-9, 1926.

Investigation to determine safe working loads for low carbon steel seamless tubing at elevated temperatures.

Wigginton, R., "Economy in Steam Raising," *Institute of Mining Engineers, Trans.*, Vol. 70, January, 1926, pp. 274-729-284.

Problem of cheap steam raising resolves itself into use of cheapest suitable fuel and burning of this to best advantage.

Yoder, J. D., "Recent Influences on Boiler Water Treatment," *Power Plant Engineering*, Vol. 30, No. 24, December 15, 1926, pp. 1316-1318.

Higher ratings and higher pressures recent innovations in power plant design closest related to boiler-feed water treatment.

Zeits. des Verein. Deut. Ingrs., "Double-Pressure Boiler Plant," Vol. 71, No. 4, January 22, 1927, pp. 139-140.

Eliminates costly high-pressure heating surface in zone of low-temperature gas.

STEAM TURBINES, GENERATORS, AND AUXILIARY EQUIPMENT

Andrews, R. H., "Heat Transfer Through Wet Condenser Tubes," *Power*, Vol. 64, No. 26, December 28, 1926, pp. 981-982.

Bancel, P., "Operating Performance of Some Modern Surface Condensers," *Mechanical Engineering*, Vol. 49, No. 3, March 1927, pp. 219-226, and (discussion) pp. 233-236.

High efficiency resulting from good design causes change to single-pass type.

Byles, F. A., "Automatic Load Regulators for Electric Generators," *Power*, Vol. 65, No. 8, February 22 1927, pp. 281, 283.

Operation and adjustment of automatic load regulators.

Chatel, E. J., "Steam Condenser Practise and Performance," *Mechanical Engineering*, Vol. 49, No. 3, March 1927, pp. 227-233.

General idea of steam condenser practise and performance in four plants of Detroit Edison Co.

Christie, A. J., "Bigger and Better Turbines Ahead," *Power Plant Engineering*, Vol. 31, No. 1, January 1, 1927, pp. 40-42.

Developments show trend toward higher pressures and temperatures, reheat and extraction.

Colborn, Chas. E., "Testing a Surface Condenser in Action," *Power*, Vol. 64, No. 12, September 21, 1926, pp. 431-433.

Dana, W. Jay, "Surface Condenser Heat Transfer," *Power*, Vol. 65, No. 16, April 19, 1927, pp. 584-586.

The principal factors involved and some solutions.

Lauffer, W. G., "Where to Bleed Turbine," *Power*, Vol. 64, No. 10, Sept. 7, 1926, pp. 363-365.

Curves and calculations.

Leitch, H. W., "Condenser Practise Trends Well Defined." *Power Plant Engineering*, Vol. 31, No. 1, Jan. 1, 1927, pp. 47-48.

Improved design and use of auxiliaries give better performance.

Lochner, R., "The Hunting of Synchronous Machinery." *Institution of Electrical Engineers Journal*, Vol. 65, No. 360, Dec. 1926, pp. 81-89.

Deals with problem of hunting from a mathematical standpoint.

Lowenberg, M. J., "Generator Practise in Central Stations," *Power Plant Engineering*, Vol. 30, No. 24, Dec. 15, 1926, pp. 1324-1326.

Considerations involved in arrangements of generators and auxiliaries in modern plants.

McAdams, W. H., Sherwood, T. K., and Turner, R. L., "Heat Transmission from Condensing Steam to Water in Surface Condensers and Feedwater Heaters," A. S. M. E. paper for meeting. Dec. 6-9, 1926, 28 pp.

New experimental data for single tube water heaters supplied with exhaust steam.

McJannet, D. W., "Power Transformer Operation," *Electrical Review*, Vol. 100, No. 2577, April 15, 1927, pp. 589-592.

Mechanical Engineering, "Westinghouse 104,000 K. W. Capacity Turbine and Combination Turbine," Vol. 49, No. 2, February 1927, pp. 174-175.

Chief features of these machines.

National Electric Light Ass'n., "Condensing Equipment" Report No. 267-12 of Prime Movers Committee.

National Electric Light Ass'n., Report No. 256-29 of the Electrical Apparatus Committee.

Nicholas, A. J., "Auxiliary Supercooling in Surface Condensers," *Power*, Vol. 63, No. 21, May 25, 1926, pp. 804-805.

Condensate vs. steam air temperatures; effect of supercooling on volumetric efficiency of vacuum pump.

Parsons, Sir. Charles A., "Erosion of the Tubes of Surface Condensers," *The Engineer*, Vol. 143, No. 3717, April 8, 1927, pp. 390-391; *Engineering*, Vol. 128, No. 3195, April 8, 1927, pp. 433-435.

An investigation of the causes of condenser tube erosion.

Parsons, C. A. and Walker, R. J. and Cook, S. S., "Progress in Economy of Turbine Machinery on Land and Sea," *The Engineer*, Vol. 143, No. 3706, Jan. 21, 1927, pp. 69-71.

Abstract of paper presented before North-East Coast Inst. of Engineers and Shipbuilders.

Plumer, W. D. and Dodge, J. W., "Control Equipment for Electrically Driven Central Station Auxiliaries," *General Electric Review*, Vol. 29, No. 9, Sept. 1926, pp. 617-623.

Auxiliary control requirements for Central Stations.

Pohl, R., "The End-Connection Leakage Field of Turbo-Generators and Their Losses," A. E. G. *Mitteilungen*, Sept. 1926.

Powell, J. A. and Vetlesen, H. J., "Surface Condensers in Steam Power Plants," *Mechanical Engineering*, Vol. 49, No. 5, May 1927, pp. 417-421.

A study for most economic installation.

Power, "Largest Tandem Compound Turbine under Construction," Vol. 65, No. 19, May 10, 1927, p. 697.

Views with dimensions and weights of Southern California Edison's new machines.

Power, "Additional Details of 80,000 K. W. Turbine Unit at Hudson Avenue Station," Vol. 65, No. 2, January 11, 1927, pp. 52-54.

Power, "Progress in Steam Turbine Designs," Vol. 65, No. 1, January 4, 1927, pp. 18-22 (Annual Review No.).

Trend of recent developments in larger units and higher steam pressures discussed.

Power, "What Europe is Doing in Steam Turbine Design," Vol. 65, No. 1, January 18, 1927, pp. 89-91.

Novel four element 85,000 K. W. 500 lb. per sq. in. absolute pressure turbine for Berlin described.

Power, "The 160,000 K. W. Turbine Generator for Hell Gate," Vol. 65, No. 6, February 8, 1927, pp. 226-227.

Brief description of the large Hell Gate unit.

Power, "Forestalling Trouble by an Annual Inspection of Steam Turbines," Vol. 65, No. 11, March 15, 1927, pp. 401-403.

Discussion of the various points to be covered in making the annual inspection.

Power, "Another 'Largest' Turbine," Vol. 65, No. 22, May 31, 1927, pp. 832-833.

Details of the 100,000-kw. Westinghouse compound unit for the Crawford Avenue Station in Chicago.

Power, "60,000 K. W. Turbine at Buffalo," Vol. 65, No. 17, April 26, 1927, p. 630.

Brief description of the new unit at the Charles R. Huntley Station.

Power, "80,000 K. W. Turbine Unit," Vol. 64, No. 22, Nov. 30, 1926, pp. 815-818.

Design features of 2-cylinder unit at Hudson Ave. Station of Brooklyn Edison Co.

Power, "50,000 K. W. Steam Turbine for Waukegan," Vol. 64, No. 25, Dec. 21, 1926, pp. 942-943.

Single generator; 2 cylinder, tandem-compound reaction turbine with double flow in the low pressure cylinder.

Power Plant Engineering, "Progress in Condenser Design," Vol. 31, No. 2, Jan. 15, 1927, pp. 143-146.

Statements by various manufacturers.

Power Plant Engineering, "Condenser Improvements Benefit Entire Station," Vol. 31, No. 1, Jan. 1, 1927, pp. 49-53.

Single pass, divided water box, improved steam distribution are main improvements.

Power Plant Engineering, "Analysis of Present-Day Turbine Installations," Vol. 31, No. 1, Jan. 1, 1927, pp. 42-45.

Comment on pressures and temperatures employed, use of reheat and "bleeding."

Power Plant Engineering, "Developments in Steam Turbine Construction," Vol. 31, No. 2, Jan. 15, 1927, pp. 138-143.

Presents statements by different manufacturers.

Power Plant Engineering, "Development in Steam Turbine Construction," Vol. 31, No. 1, January 1, 1927, pp. 45-46.

Discussion of types; changes in blading, staging, and bleeding; effect of changed steam conditions.

Power Plant Engineering, "Efficient Auxiliaries Help Condensers," Vol. 31, No. 1, Jan. 1, 1927, pp. 53-54.

Variable speed motors, vertical pumps and improved vacuum pumps influence condenser design and selection.

Power Plant Engineering, "Electric Generator Practice," Vol. 31, No. 1, January 1, 1927, pp. 55-57.

Methods used by main power station.

Power Plant Engineering, "Progress in Generator Cooling," Vol. 31, No. 1, January 1, 1927, pp. 60-61.

Closed system used at present may lead to use of an inert gas.

Power Plant Engineering, "Air Cooling for Generators," Vol. 31, No. 2, Jan. 15, 1927, pp. 147-149.

Statements by leading manufacturers.

Power Plant Engineering, "G. E. to Build Large High-Pressure Turbine," Vol. 31, No. 4, Feb. 15, 1927, p. 280.

New 10,000-kw. 1200 lb. pressure turbo-generator being built for Edgar Plant.

Power Plant Engineering, "Some Operating Troubles with Turbo-Generators," Vol. 31, No. 8, April 15, 1927, pp. 458-459.

Starting curves and shutting down curves for turbines.

Power Plant Engineering, "Experience Alters Condensing Practice," Vol. 30, No. 12, June 15, 1926, pp. 685-686.

Changes in design and operating practise reported from many plants during past year.

Power Plant Engineering, "Systems for Cooling Electric Generators," Vol. 30, No. 16, August 15, 1926, pp. 905-907.

Among various systems developed and suggested, proposed use of hydrogen as cooling medium is most novel.

Power Plant Engineering, "Principles of Steam Turbine Governors," Vol. 30, No. 18, Sept. 15, 1926, pp. 991-996.

Construction details and method of operation of various makes of governors in present day use.

Quayle, L. A., "Test of 15,000 K. W. Turbine at Cleveland Municipal Plant," *Power*, Vol. 64, No. 16, Oct. 16, 1926., pp. 583-586.

Ricketts, E. B., "Some Results of Condenser Operation," *Mechanical Engineering*, Vol. 48, No. 11a, Mid-Nov. 1926, pp. 1312-1314.

Results of year's operation of four condensers differing radically in design, but operated under same water conditions, and under same supervision.

Robinson, E. L., "Notes on the Comparison of Steam Turbine Efficiencies," *General Electric Review*, Vol. 29, No. 7, July 1926, pp. 503-510.

Ross, M. D., "How Steam-Turbine Generator Windings are Insulated," *Power*, Vol. 65, No. 4, January 25, 1927, pp. 124-126.

Describes the manufacturing and installing of large generator coils.

Power Engineer, "Coal Drying and Preheating," Vol. 21, No. 247, Oct. 1926, pp. 379-380.

Discusses economy derived by preheating coal before firing.

Power Engineer, "Fuel Economy," Vol. 22, No. 251, Feb. 1927, pp. 63-65.

The comparative thermal accountancy of air preheating.

Power Engineer, "Underfeed Stokers," Vol. 21, No. 245, Aug. 1926, pp. 285-287.

General survey of their characteristics and modern development.

Power Plant Engineering, "Modern Furnace Walls Last Longer," Vol. 30, No. 14, July 15, 1926, pp. 787-789.

Shows how air and water cooled walls have revolutionized boiler furnace construction.

Power Plant Engineering, "Oil and Gas Burners are Interchangeable," Vol. 30, No. 22, Nov. 15, 1926, pp. 1200-1202.

Kansas Gas & Electric Co's. plant at Wichita has interchangeable burners.

Power Plant Engineering, "Coal Carbonization on a Large Scale at Milwaukee," Vol. 30, No. 12, June 15, 1926, pp. 688-690.

Power Plant Engineering, "Modern Fuel Handling in Power Plants, Vol. 30, No. 10, May 15, 1926, pp. 589-594.

Power Plant Engineering, "Utilizing Iowa's Coal Resources," Vol. 31, No. 10, May 15, 1927, pp. 558-559.

Power Plant Engineering, "Progress in the Burning of Pulverized Coal," Vol. 31, Jan. 1, 1927, pp. 9-16.

Discussion of types of furnaces used; preparation and burning of coal.

Power Plant Engineering, "Pulverized Coal Equipment Shows Steady Progress," Vol. 31, No. 2, Jan. 15, 1927, pp. 106-118.

Data on pulverized coal equipment; progress in design of stokers, furnace walls, and air heaters.

Power Plant Engineering, "Stoker Improvements Meet High Ratings," Vol. 31, No. 1, Jan. 1, 1927, pp. 17-20.

Furnace design limits stoker capacity.

Power Plant Engineering, "Progress in Stoker Design," Vol. 31, No. 2, January 15, 1927, pp. 109-113.

Statements by manufacturers.

Ritchie, E. G., "Radiation from Pulverized Coal," *Combustion*, Vol. 14, No. 3, March 1926, pp. 170-175.

Its significance in relation to pulverized coal furnace design.

Rhodin, J. G. A., "Can the Heat of Combustion of Coal be Turned Directly into Electrical Energy?" *The Engineer*, Vol. 142, No. 3680, July 23, 1926, pp. 80-81.

Points out intrinsic difficulties of finding new way to generate power.

Roberts, John "The Carbonization of Coal—5," *Combustion*, Vol. 16, No. 1, January 1927, pp. 36-41.

Conservation of coal made possible by utilization of high oxygen coals in high and low carbonization.

Rollow, J. G., "Burners for Combination Gas Oil Furnaces," *Power Plant Engineering*, Vol. 30, No. 14, July 15, 1926, pp. 789-790.

Continuous operation must be insured and quick changeover possible without loss of load.

Rosin, P. and Rammler, E., "Fineness and Structure of Pulverized Coal," *Power*, Vol. 65, No. 11, March 15, 1927, pp. 419-420.

Rothwell, F. A., "Good Design Increases Life of Furnaces," *Power Plant Engineering*, Vol. 30, No. 13, July 1, 1926, pp. 740-743.

Changes which were made in setting of oil-fired boiler and benefits resulting.

Runge, W., "Low Temperature Distillation," *Power*, Vol. 65, No. 19, May 10, 1927, pp. 720-721.

Description of three processes—Cost of production and values of products—Calorific values.

Runge, Walter, "The McEwen-Runge System for the Low Temperature Distillation of Coal," *Combustion*, Vol. 16, No. 1, January 1927, pp. 29-50.

New method using pulverized coal.

Sayers, W. W., "Modern Methods in Coal and Ash Handling," *Power*, Vol. 64, No. 4, July 27, 1926, pp. 133-136; No. 5, Aug. 3, 1926, pp. 169-171; No. 6, Aug. 10, 1926, pp. 204-206; No. 7, Aug. 17, 1926, pp. 240-241; No. 8, Aug. 24, 1926, pp. 284-286.

Worker, Joseph G., "Underfed Stokers Show Steady Improvement," *Power Plant Engineering*, Vol. 31, No. 11, June 1, 1927, pp. 615-617.

Results obtained using coals from all the different fields in this country.

Wyman, M. B., "Making Electrical Drives Safe in Pulverized Coal Plants," *Power*, Vol. 64, No. 14, Oct. 5, 1926, pp. 504-507.

Zimmerman, C. C., "Improvement in Combustion by the Use of Steam Jets," *Power*, Vol. 65, No. 5, February 1, 1927, p. 159.

Results of experiments at Lake Shore Station.

HYDROELECTRIC STATION DESIGN, OPERATION, AND COSTS

Andrews, R. H., "Turbine and Plant Efficiencies," *Power*, Vol. 64, No. 15, October 12, 1926, p. 560.

Presents efficiency curves obtained with Kaplan and propeller type turbines in low head plant at Lilla Edet in Sweden.

Arbelot, M. G., "Economic Relation between Hydro-Electric and Steam Power Generation," World Power Conference, 1926, advance paper No. 41.

Conditions under which they can operate together advantageously.

Baird, A. F., "Electrical Developments of Province of New Brunswick," *World Power*, Vol. 7, No. 39, March 1927, pp. 113-121.

Hydro-electric developments and possibilities under private control.

Bauer, L. H., "Russian Plans for Dnieper River Hydroelectric Development," *Electrical World*, Vol. 88, No. 5, July 31, 1926, p. 220.

German conception of Ukraine project; additional information.

Blackburn, R. N., "Industrial Development in Saskatchewan," *Engineering Journal*, Vol. 9, No. 5, May 1926, p. 263-265.

Water power development and utilization of Saskatchewan coal.

Burd, E. M., "Consumers Power Co. Adds Hodenpyl to System," *Power Plant Engineering*, Vol. 30, No. 14, July 15, 1926, pp. 803-806.

Description of new 25,000 hp. hydroelectric plant on Manistee River, Mich.

Canadian Engineer, "Report on St. Lawrence Power Project," Vol. 51, No. 22, November 30, 1926, pp. 667-670.

Canadian section of joint Engineering Board recommends two stage development, while American section advocates single stage.

Carpenter, J. S., "Water Velocities in Hydraulic Turbine Plants," *Power Plant Engineering*, Vol. 30, No. 22, November 15, 1926, pp. 1210-1211.

In designing new plants and rebuilding old ones water velocities affect pipe lines, sizes, scroll cases, draft tubes, and speed regulation.

Christie, C. V., "Hydro-Electric Development in Quebec," *World Power*, Vol. 5, No. 29, May 1926, pp. 234-237.

Physical characteristics of province; water power resources, hydroelectric plants.

Dreyer, W., "Volcanic Formations Govern Design in Pit River No. 3 Hydro Development," *Engineering News Record*, Vol. 96, No. 4, January 28, 1926, pp. 144-149.

Ehrensperger, "Economic Relation between Hydro-electric and Steam Power Generation," World Power Conference, 1926, advance paper No. 80.

As in Switzerland.

Electrical Review, "Electric Progress in New Zealand," Vol. 98, No. 2527, April 30, 1926, pp. 692-695.

Particulars of Mangahao hydro-electric scheme, generating station provides for 5 main turbines of Pelton Type.

Electrical Review, "A New Swiss Electricity Project," Vol. 99, No. 2561, December 24, 1926, pp. 1027-1028.

Scheme for utilizing water power of Oberhasli.

Electrical Review, "A Swiss Hydro-Electric Installation," Vol. 98, No. 2528, May 7, 1926, pp. 734-735.

Details of Lake Tremorgio plant.

Electrical World, "Hydro-Electric Developments in Georgia," Vol. 87, No. 15, April 10, 1926, pp. 750-756.

Completion of projects on Tallulah and Tugalo Rivers will result in average annual output of 540,000,000 kw-hrs.

Electrical World, "Hydro-Electric Construction Practice on the Pacific Coast," Vol. 88, No. 15, October 9, 1926, pp. 743-747.

Balch Plant is typical of high head plants; job equipment and construction methods.

Electrical World, "One of the Highest Water Chutes in the World," Vol. 88, No. 19, November 1926, pp. 968-969.

Swiss power plant at Fully in Canton of Valais holds world's record among piped water chutes; its fall is 5460 ft.

Electrical World, "South Develops another Hydro Resource," Vol. 89, No. 4, January 22, 1927, pp. 195-197.

Description of the Bartlett's Ferry Plant of the Columbia Electric & Power Co.

Electrical World, "Another Big Hydro Plant for South," Vol. 89, No. 10, March 5, 1927, p. 516; Vol. 89, No. 14, April 2, 1927, p. 722.

200,000 hp. project on Saluda River, 10 miles from Columbia, S. C. Map in latter issue.

Electrical World, "Developed Water Power in the United States," Vol. 89, No. 15, April 9, 1927, p. 786.

Tables giving report of Geological Survey on January 1, 1927.

Electrical World, "First Unit of Insull's New Hampshire Hydro Development," Vol. 89, No. 19, May 7, 1927, p. 961.

Photos showing construction of penstock and scroll case.

Electrical World, "Conowingo Power in 1928," Vol. 89, No. 16, April 16, 1927, p. 822.

First unit of hydroelectric plant will be ready in June 1928, then one a month until end of year.

Engineering, "Hydroelectric Development in New Zealand," Vol. 122, No. 3180, December 24, 1926, pp. 793-794.

Details of hydroelectric development scheme for New Zealand.

Engineering, "The Construction of the Isle Maligne Power Plant, Quebec," Vol. 122, No. 3179, December 17, 1926, pp. 747-750.

Present plant consists of eight 45,000 hp. units.

Engineering, "The Lawaczeck Turbines at Lilla Edet," Vol. 123, No. 3196, April 15, 1927, pp. 449-451.

A 10,000-kw. propeller type hydraulic turbine for low head operation.

Engineering News Record, "Draft Tube Lined with Cast Iron

at Big Creek No. 8 Plant," Vol. 97, No. 5, July 29, 1926, pp. 182-183.

Engineering News Record, "Balch High Head Power Project Well Under Way," Vol. 97, No. 21, November 18, 1926, pp. 836-839.

Plant on Kings River, Cal., to use 2381 ft. head.

Engineering News Record, "Construction Plant and Plant at the Falls of the Ohio," Vol. 98, No. 19, May 12, 1927, pp. 762-769.

Engineering World, "Power Development on Feather River," Vol. 30, No. 3, March 1927, p. 150.

Eustrom, A. F., "Hydraulic and Steam Power in Sweden," World Power Conference, 1926, Advance paper No. 33.

Steam power used to supplement hydraulic power, and as a by-product. Description of state- and city-owned power generation systems.

Foster, W. C., "Western Hydro-electric History," *Journal of Electricity*, Vol. 57, No. 12, December 15, 1926, pp. 447-449.

Details of Station B, Portland Electric Co., located on Willumette River at Oregon City.

George G. C., "Automatic Hydro-electric Plant Designed for Peak Load Service," *Power*, Vol. 64, No. 4, July 27, 1926, pp. 116-119.

Installation in Soft Maple plant of Northern New York Utilities, Inc., designed for three 10,500-hp. turbines.

Haggas, Geo. E., "Developing Hydro Plant Addition to Conserve Stream Flow," *Electrical World*, Vol. 89, No. 14, April 2, 1927, pp. 705-710.

Space limitations introduce interesting problem.

Hale, F. E. and Stone, R. R., "Martin Dam Aids Control of Alabama System," *Power Plant Engineering*, Vol. 31, No. 5, March 1, 1927, pp. 284-291.

New hyrdo-station forms storage project to aid steam and run-of-river plants during low water.

Harza, L. F., "Distinctive Features of Hydro-Electric Construction," *Electrical World*, Vol. 88, No. 13, September 25, 1926, pp. 657-661.

Phases of hydro-electric construction; factors which determine schedule; grading methods; progress records.

Hornaday, W. D., "Guadalajara Hydro-Electric Development," *Electrical World*, Vol. 88, No. 10, September 4, 1926, pp. 469-470.

American owned system in second largest Mexican city has 1900 ft. head and possible rating of 30,000 hp.

Jourdan, J. W. and Rhine, C. P., "Balch Hydro Development," *Electrical World*, Vol. 89, No. 18, April 30, 1927, pp. 906-911.

500,000 hp. will be ultimate capacity of 2243 ft. head development.

Jourdan, J. W., "Kings River Plant Added to Central California Power System," *Journal of Electricity* (Elec. West.), Vol. 58, No. 5, May 1927, pp. 253-260.

Description of the 33,000 kv-a. 2243 ft. head Balch plant of the San Joaquin Light & Power Corporation.

Journal of Electricity (Elec. West.), "Review of Western Hydro and Steam Construction Projects," Vol. 58, No. 2, February 1927, pp. 67-74.

Table of projects, developments, and changes.

Journal of Electricity (Elec. West.), "The Cushman Hydro-electric Development," Vol. 58, No. 3, March 1927, pp. 129-136.

Description of the dam and adjuncts, and the two 25,000-hp. turbines at 230 ft. head.

Krieger, F., "Economic Relations between Hydraulic and Steam Generation of Electric Power," World Power Conference, Sect. Basel Meeting 1926, Advance paper, No. 58, p. 23.

Leavitt, L. S., "Hydro-electric Progress in Canada during 1926," *Electric Light and Power*, Vol. 5, No. 3, March, 1927, pp. 27-28.

Lee, W. S., "Rack Structure and Head Gates of Cedar Creek Hydro-electric Station," *Mechanical Engineering*, Vol. 49, No. 5a, Mid-May, 1927, pp. 521-523.

Details of design.

Livingston, R. L., "Charts Simplify Hydraulic Computations," *Power*, Vol. 64, No. 26, December 28, 1926, pp. 986-989.

Presents chart giving relation between speed, head, horse power, and specific speed; its practical application.

Meares, J. W., "Power Developments in Northern India and Burma," *World Power*, Vol. 7, No. 40, April 1927, pp. 172-180.

Hydro-electric developments and possibilities in an agricultural country.

Mechanical Engineering, "Progress in Hydraulics," Vol. 48, No. 12, December 1926, pp. 1417-1419.

Progress report contributed by Hydraulic Division A. S. M. E. dealing with water control, penstocks, turbines, automatic plants, impulse wheels, governors and oil sets, and valves.

Meyer, A. and Noack, W. G., "Economic Relation between Hydro-electric and Steam Power Generation," World Power Conference, 1926, advance paper No. 79.

Steam Power can compete with Hydro-electric Power even where coal is very expensive. Combined Steam Power, Heating, and Hydro-electric plants advantageous.

Mitchell, W. E. and Gallalee, J. L., "Economic Relation between Hydro-electric and Steam Power Generation, as in the United States," World Power Conference, 1926, Advance paper No. 76.

National Electric Light Ass'n., "Methods of Increasing Head on Turbines by means of Excess Flow."

Report No. 267-10 of Hydraulic Power Committee.

National Electric Light Ass'n., Report No. 256-52 of the Water Development Committee.

National Electric Light Ass'n., Report No. 256-26 of the Hydraulic Power Committee.

Nelzen, J. H., "Supervisory Control of Hydro-electric Power Stations," *Electric Light and Power*, Vol. 5, No. 4, March 1927, pp. 26-28.

Nizzola, A., "Economic Relation between Hydro-electric and Steam Power Generation," World Power Conference 1926, Advance Paper No. C-e.

General survey of reports from many European countries.

Pfan, A., "Engineering versus Banker Efficiency in Hydro Developments," *Electrical World*, Vol. 88, Nos. 20-21, November 13-20, 1926, pp. 1005-1007 and 1063-1065.

Points out that interconnected plants absorb load fluctuations better and afford more permanent service. Engineering and banker efficiency differ.

Power, "Increased Activity in Water-Power Developments," Vol. 65, No. 1, January 4, 1927, pp. 25-28 (Annual Review No.).

Review of recent activities in the hydroelectric field.

Power, "Large Hydro Project Pumps Water for Power Development," Vol. 65, No. 4, January 25, 1927, p. 132.

Large Swiss plant utilizes excess power available during summer to fill storage reservoir to provide for operation of plant during winter.

Power, "The Conowingo Hydro-electric Development," Vol. 65, No. 8, February 22, 1927, p. 284.

Brief description of the 600,000 hp. hydro-electric project on Susquehanna River. Completion in 1928 now expected.

Power, "Are Hydro-electric Installations without Governors Justified?", Vol. 65, No. 10, March 8, 1927, pp. 378-379.

Power, "Automatic Hydro-electric Plant Built into Dam," Vol. 65, No. 22, May 31, 1927, p. 813.

Brief description of the new plant of the Chimney Rock Mountains, Inc.

Power Plant Engineering, "Balch Hydro Plant to Operate at 2740 ft. Head," Vol. 30, No. 7, April 1, 1926, pp. 433-434.

First unit of 500,000 hp. hydroelectric project of San Joaquin Light and Power Corp., now under construction.

Power Plant Engineering, "Ice Troubles in Hydraulic Power Plants," Vol. 30, No. 24, December 15, 1926, pp. 1341-1342.

Power Plant Engineering, "Hydro Plant Operating Routine and Tests," Vol. 30, No. 15, August 1, 1926, pp. 860-862.

Power Plant Engineering, "Using Excess Flow to Increase Head on Turbine," Vol. 31, No. 5, March 1, 1927, pp. 314-316.

Several devices have proved both economical and convenient at large hydro-plants.

Reed, Oren, "Notes on European Practice in Penstock Design," *Engineering News-Record*, Vol. 98, No. 18, May 5, 1927, pp. 718-721.

Reid, C. R., "Routine Inspection Procedure for Power Station Equipment," *Power*, Vol. 64, No. 13, September 28, 1926, pp. 482-486.

Methods of inspection and record keeping are described for large hydroelectric stations.

Rich, T., "Hydro-electric Power on the Lower Isere," *Electric Review*, Vol. 98, Nos. 2531-2532, May 28—June 4, 1926, pp. 795-798 and 827-828.

Station is equipped with seven turbines of vertical Francis Type, first transmission in France at 120,000 volts.

Rivett, E. S., "Operating the Hydro-Electric Plant," *Power House*, Vol. 19, No. 15, August 5, 1926, pp. 29-30.

Discusses trend towards standardization, from operation point of view.

Scheller, C. P., and Carr, W. B., "Automatic Non-Governing Hydro Plant," *Elec. World*, Vol. 87, No. 24, June 12, 1926, pp. 1285-1288.

Annual report of British Electrical and Allied Manufacturers Ass'n. (Beama.)

Discussion

Philip Torchio: Electrical engineers should have particular interest in following the development of the size of the generators. The report states that there is a 208,000-kw. unit under construction. It should have said that it consists of three machines cross-compound. If I remember rightly, the largest single unit in operation in the New York Edison 60,000-kw. The Edison-United Companies have a large cross-compound 160,000-kw. unit on order and placed an order June 21 for a 165,000-kw. unit. The generators of the unit order last year are, one, 85,000-kw. and the other 75,000-kw. and, for the unit ordered yesterday, the generators will be 80,000-kw. each.

In pointing this out, I am not saying that the manufacturers are not ready to make larger generators, because, as a matter of fact, for another installation for which we are now securing bids, we already have offers of more than 100,000 kw. in one unit, and probably single units larger than 125,000-kw. will be obtained.

Another point that I wanted to bring out in this general review is that while we are making great progress in saving coal, it is nevertheless our duty not to let the public misunderstand how we accomplish it. The truth is that we are saving coal by spending more in investment in plants. It does not necessarily follow, once we consider the total cost, that we are making such radical improvements which might lead the public to assume that the cost of power is also rapidly being reduced. The cost of power is being reduced, but at a gradual, moderate rate. We are making great advances in saving coal, but we are putting more capital in our plant investment to secure those higher economies. An extreme illustration of this is the Dutch Point station with the mercury boilers and similar installations throughout the country.

F. A. Scheffler: My discussion of this report is more particularly an addition to the table of the pulverized-coal installations in the country.

The installations in operation last year consisted of an installed capacity of 2,200,000 kw. and those under construction, 440,000, making a total of 2,640,000-kw. capacity installed.

Assuming that these stations, of which there are about thirty-eight, average an annual load factor of 50 per cent, the output would be 9,414,810,000 kw-hr., and also assuming that the average coal consumption is $1\frac{1}{2}$ lb. of coal per kw-hr., the total fuel used would be 7,061,100 short tons per year.

During the year 1927, the total coal consumption in public utility plants in the United States was 41,245,000 short tons.

The ratio of the total coal used in pulverized form to the total coal consumption, is therefore approximately 17 per cent.

In addition to the above, there are under construction new plants and additions to others as follows:

Station	Company	Kw. capacity installed
State Line.........	State Line Generating Co.	208,000
Toronto...........	Ohio River Edison Co. (2-30,000 kw.)	60,000
Glenhead..........	Long Island Lighting Co.	25,000
Trenton Channel...	Detroit Edison Co.	50,000
Aurora, Ill.........	Western United Gas & Elec. Co.	10,000
Pekin, Ill..........	Super-Power	50,000
Montaup..........	Montaup Electric Co.	40,000
		443,000

With the exception of four or five on the above list of generating plants, all of the stations were new ones built during the last seven years.

There are five or six other utility plants using pulverized coal, which are not listed above, because they are not primarily power plants for generating current, but are used more for steam heating purposes. Some of these are as follows:

Puget Sound Traction, Light & Power Co., Seattle, Wash.—capacity about 8500 boiler hp.

Allegheny Heating Co., Pittsburgh, Pa.,—capacity 10,000 boiler hp.

Lockport Light, Heat & Power Co., Lockport, N. Y.—capacity 2500 boiler hp.

New York Steam Co., 36th St. & East River, New York—capacity 30,000 boiler hp.

Rochester Gas & Electric Corp., Lawn St. Station, Rochester, N. Y.—capacity 250,000 lb. steam per hr.

W. S. Gorsuch: It is important, as Mr. Torchio has pointed out, to state the type when referring to a certain size generator unit. This has been done in every case in the report, not in the brief outline of progress in the art of power generation, but in the description that follows, in which outline drawings are also given for exceptional designs. It will be noted that the plan of this report is first to give a general statement of the trend of the art in each class of power-station equipment and then under the heading "Outstanding Installations" a full description is given of the equipment referred to in the preceding general statement.

Reference has been made to the remarkable economies brought about in fuel burning stations and the additional investment cost to achieve these results. In this connection I believe because of the increasing number of interconnections a comprehensive study should be undertaken at this time to show the relative cost of power of hydroelectric and steam plants, and also the relative merits of the two systems.

Transmission and Distribution

Annual Report of Committee on Power Transmission and Distribution*

To the Board of Directors:

Foreword

In presenting the annual report of the Committee on Power Transmission and Distribution it has seemed best to largely confine its scope to a discussion of the progress that has been made in those branches of the art with which the Committee has been actively concerned during the year. Several of the members have collaborated in the preparation of the report and it represents the consensus of opinion of the Committee as a whole.

It is felt that the coordination of effort which has been secured through the medium of the Committee has resulted in a very substantial stimulus to the advancement of the state of knowledge regarding those problems which have been particularly studied and if this report in presenting a résumé of the progress made also succeeds in indicating profitable fields for further study and research its purpose will have been accomplished.

Lightning on Transmission Lines

With the growing tendency toward interconnection of large power systems and the increasing dependence on high-tension transmission lines for the service of large communities, the question of continuity of service for such lines has become very important.

Inasmuch as lightning has been responsible for most of the interruptions to service over transmission lines a subcommittee was appointed whose duties were to investigate lightning and its relation to transmission lines.

The work assigned to the sub-committee was of considerable magnitude and importance. The various lightning difficulties that had been encountered on transmission lines in the past two years were discussed, as well as the various data that had been gathered in connection with these difficulties.

The following are the subjects taken into consideration in the discussion of the general problem.

Klydonograph Tests. Inasmuch as the transients due to lightning are of extremely short duration it was very difficult to determine their characteristics until the advent of the klydonograph. By means of the klydonograph it has been possible to obtain information regarding the operation of transmission lines of voltages ranging from 6.6 kv. to 220 kv. The nature of the tests and the inherent variation of the physical conditions under which lightning occurs necessitated a great amount of data to determine the facts definitely. However, the data secured is sufficiently extensive to indicate the following important conclusions.

1. The most important voltage surges on overhead transmission lines are those produced by lightning.
2. On 120- to 140-kv. lines surges of 1200 to 1400 kv. and on 220-kv. lines surges of 1800 to 2000 kv. can be established.
3. Majority of lightning surges were positive.
4. Highest surges were negative, which would indicate that they were direct strokes and that the clouds causing these surges were negative.
5. While very high positive surges were recorded, they were few in number and only slightly over 1000 kv.
6. The number of surges per storm at a given point is not great.
7. When a surge above the flashover of the insulation is induced, the insulator flashover relieves the energy and limits further rise of voltage.
8. The steeper the rate of application, the higher is the voltage reached before flashover, and when no flashover occurs, the insulators must withstand the surge for its entire duration.
9. High-voltage surges do not travel far. Such surges are damped below the corona voltage in a relatively few miles, while low-voltage surges travel many miles.
10. Lightning strokes are unidirectional or at most highly damped oscillations.

Lightning Strokes. What is the amount of current that can be encountered in a lightning stroke?

It is fairly definitely known that in the case of a direct stroke, currents of the order of 10,000 to 100,000 amperes can be encountered, whereas in the case of an induced lightning stroke this current is probably of the order of 3000 amperes.

A point also to be taken into consideration is that when a lightning stroke does take place the number of insulator units that are likely to be spilled will depend

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

to a large extent on the resistance of the principal unit paths, the resistance consisting of the tower and the ground resistances. To amplify: if the resistance of the lightning path at a particular string is of a high enough value, the effect of the current going through it will be to raise the potential of the conductor at that point above the flashover value of the string in question and a wave above the spillover value of the string will travel on to the next string to be spilled over and so on until it reaches the point where the flashover of a string is in excess of its crest in which case it will travel on until it is dissipated in some other manner and so disappears.

This, of course, shows clearly that the ground resistance plays a considerable part in the determination of how the lightning flashover will act over the line. With a low value of ground resistance, it will take fewer strings to dissipate a particular impulse or stroke. On the other hand, with a low value of ground resistance, the amount of power current to be handled at any particular string will be greater and therefore the possible arc damage will also be greater.

There is another point to be taken into consideration in determining the value of ground resistance, and that is the question of short circuit current required for the successful operation of relays. It is essential that the relays controlling transmission lines operate very quickly under lightning disturbances in order to minimize the damage of the power arc to the insulator string and the conductor.

Some data were available as to what value of ground resistance was encountered in practise. Some companies had made measurements of ground resistance on towers and found that the average resistance was between 15 and 25 ohms, while some towers, however, showed a resistance as low as 2 ohms, others as high as 100 ohms, and the highest encountered was in the neighborhood of 300 ohms.

The question as to what is, therefore, a correct mean value of a ground resistance is one that is of considerable importance and it would be highly desirable to obtain some data both from a theoretical and experimental standpoint to establish that value definitely.

Lightning Discharges. The question of lightning discharges under power and the power arcs which follow brings with it another question and that is whether it is definitely known that in all cases a power arc follows the lightning discharge.

One or two cases were cited in which reports had been received from observers who claimed that they had seen a lightning discharge on a string of insulators with no accompanying power follow-up arc, but the Committee agreed that the amount of data available on this was meagre and in all probability what was available was highly unreliable. It is conceivable that a lightning discharge could take place and yet if the amount of lightning current were small enough, sufficient ionization of the atmosphere would not take place to render a power arc possible. However, just what is the amount of current necessary to do this is not known and it is a problem for further investigation.

It has been estimated that the duration of dangerous lightning impulses encountered on transmission lines is of the order of a fraction of a micro-second to ten micro-seconds.

Ground Wire. The value of the ground wire as a protection against lightning has been a much mooted question. In the past where the maximum operating voltages were in the neighborhood of 66 kv., the consensus of operating opinion has been that interruptions to service by lightning were as frequent on the transmission lines equipped with ground wire as those that were not equipped with ground wire. In addition a great deal of mechanical trouble was encountered with the ground wire which was often accompanied by interruptions to service.

Very little attention in the past has been paid to the erection of the ground wire both from a mechanical and electrical standpoint and it is believed that the chief objection to the ground wire on transmission lines has been as a result of this lack of attention. It is believed that the ground wire conductor should have a layer of non-magnetic conducting material. Some operating companies have used aluminum steel reinforced or copper clad conductors for ground wires and other companies are using copper and high-strength copper alloy conductors.

As to the value of ground wire for reducing the induced lightning voltage data obtained on a 132-kv. line operated without ground wire were studied, and charts prepared in which the various flashovers that occurred were plotted on a profile on which tower locations had been indicated by two different sets of coordinates. In one set, the coordinate consisted of distance from the station and average height above ground of the bottom conductor of the span on side of tower away from the station and in the other case, the coordinate consisted of distance from the station and elevations of the bottom conductors on the towers.

On this chart all the flashovers which occurred were spotted opposite each tower. A careful examination of the chart showed very markedly that the flashovers were concentrated on the high spots and were generally absent from the low spots on the line. It also indicated very clearly that the great majority of the trouble was on the top conductor.

There were three stations located on that line and while the line was literally peppered with lightning at other points, these stations were apparently free from trouble. The chart showed that the line was particularly low for a distance of two or three miles from the stations and this explains at least partially the absence of trouble at the stations.

The number of flashovers during the 1925 season was approximately 88. In the early spring of 1926 a ground wire was installed on this line and the corre-

sponding number of flashovers during the lightning season of 1926 was only about 8 or 10. This with other evidence that is available clearly shows the value of the ground wire.

Effect of Tower Design. The question of the effect of the tower itself on the electro-static field surrounding a conductor and what effect this has on the flashover value of the insulator units, was considered.

It was the opinion of the Committee that any effect which the tower may have on the field is of relatively little importance in determining whether a flashover will or will not occur. The fact that some semi-flexible towers are known to have less lightning trouble than some of the other towers of the square type is undoubtedly due to the fact that in the first place they are very much lower lines, the spans being comparatively short and, second, they invariably are equipped with ground wires since the structures themselves are generally not self-supporting and the ground wire which is put in for mechanical reasons serves, of course, the additional function of giving them lightning protection at the same time.

It was considered advisable that all the points on which the committee was in agreement should be set down to serve in the nature of principles for guidance in the design of high-tension transmission lines.

It is the opinion of the Committee that these principles have sufficient theoretical background for their conclusions and generally also a considerable amount of actual experience to further back up the theory.

The following are the principles referred to:

1. Under any given set of conditions, the lightning voltage which can be picked up by a line is a function of the height of the line, being directly proportional to the height and is further a function of the ground wire arrangement but is independent of the power voltage.

2. The lightning voltage under any set of conditions on a line is limited by the insulator flashover for the particular wave in question. It should be pointed out, however, that this is only true where the ground resistance and the tower resistance are comparatively small. If this resistance is high, the total voltage may then be appreciably higher than that corresponding to the flashover of the insulator string.

3. In any line design, it is desirable first to hold down the lightning voltage. This can be done by

(a) Keeping the line as low as is economically feasible, and

(b) By the proper use of ground wires, again within economical limits. Failing to do this, the next best thing is to prevent the power arc following the lightning flashover. Unfortunately we are not at present in a position to state how this can be done.

4. The higher you go in transmission voltage, the more beneficial, as a rule, is the ground wire. This may be seen by the following simple example:

Assume two lines built with the same type of structure, the same conductor, with one built for operation at 66,000 volts, say the other for operation at 132,000 volts. Assume that the 66,000-volt line utilizes 5 ordinary suspension units and that the 132,000 volt line utilizes 10 suspension units. The lightning flashover of the first is in the neighborhood of 600,000 volts and of the second in the neighborhood of 1,200,000 volts. Assume that the average lightning voltage that you can get on the 66,000-volt line is 2,000,000 volts. Then if the ground wire has the effect of reducing that by 50 per cent, the lightning voltage with the ground wire will still be 1,000,000 volts which is 400,000 volts in excess of the flashover value of the 5 unit string. Therefore, under these conditions, a flashover will take place.

In the case of the 132-kv. line, the height, the conductor, and everything else being the same it follows that the voltage with or without the ground wire would be the same as before and therefore with the string having a lightning flashover of 1,200,000 volts no flashover will occur.

A similar example could be employed to show that a 220-kv. line where with 14 standard suspension units the lightning flashover of the insulators may be expected to reach values of the order of 1,800,000 volts would hold and not flash.

5. The design of substations should be co-ordinated with that of transmission lines as there is a great tendency to over insulate the line and thereby tend to transfer the trouble to substation equipment.

A great deal of attention is being paid at the present time in specifications for electrical apparatus to the impulse strength of apparatus.

The manufacturers are working on the problem of impulse strength of apparatus. There is considerable evidence to show that there is a fairly definite ratio between the impulse strength and the 60-cycle strength of the apparatus. If this is demonstrated to be true, it will be possible to design a complete system, including the transmission line and connected apparatus, with a relation of insulation values that will give the greatest efficiency and continuity of service consistent with minimum cost.

Future Work. For the lightning season of 1927, several power companies are arranging for future klydonograph tests which will give us more information on the value of the ground wire and on the amount of attenuation of traveling waves. We also hope to obtain data to determine the following points:

1. Wave fronts of lightning surges
2. Duration, of energy of lightning surges
3. Maximum voltages induced on continuous transmission lines
4. Maximum field gradients.

Arrangements are also being made to determine attenuation, potentials at stations, and at short distances therefrom, potentials on adjacent sections of line with and without ground wires, potential on both

sides of choke coils, and discharge currents of lightning arresters.

Lightning Protection of Distribution Circuits

For a number of years studies in lightning protection for 4000-volt, four-wire, three-phase circuits have been made in Chicago, and the results have been reported to the Institute.* During this period, several new types of arresters have been placed on the market, and the most promising of these arresters have been installed in Chicago.

In attempting to analyze the records obtained during the past few years on the various types of lightning arresters and determine their relative efficiency in protecting transformers from damage by lightning, some very discordant results were observed. The results obtained from the service records were not in accord with the theories, nor with the results of laboratory tests.

To make a more comprehensive study of the situation, the engineers of manufacturers whose lightning arresters were under investigation in Chicago accepted the invitation to join in a conference for determining the cause of these discrepancies. The investigations resulting from this conference will probably require at least a year before definite results can be secured. The indications are that, by giving more attention to the details of line construction and perhaps making some alterations, it will be possible to make a considerable further improvement in lightning protection on distribution circuits.

Many of the factors which affect lightning arrester performances are not constant and alike for all installations, and it appears from the data that a large share of the transformer failures, are due to limitations in protection which are imposed by conditions outside the arrester, of which good examples are, high ground resistance, currents from several circuits through ground connections of moderate resistance and entrance through the secondary. Before a conclusion is made that the arrester has failed to function properly, the variables must be thoroughly considered. A list of these variables is as follows:

1. Ground resistances
2. Transformer history
3. Primary exposure
4. Secondary exposure
5. Shielding
6. History of immediate territory
7. Lightning entrance.

These variables are quite well known to engineers who have studied lightning arrester performances. In attempting to determine their individual importance on each failure, they are studied somewhat as follows:

1. *Ground Resistance.* Ground resistances are measured on the nearest three arrester installations in each direction from the failure. This assists in determining the ability of the arresters to relieve the line. Resistance above 20 ohms should be considered inadequate, and lower values are in doubt, that is, the value of resistance to be considered as dangerous must be in relation to the amount of current which the ground connection may be expected to carry and the maximum strength of the insulation which is being protected.

2. *Transformer History.* The transformer history includes the make, size, age, connected load, previous failures, previous fuse failures, and the type of installation, whether it be power or light. Of these factors, the first two affect failures, inasmuch as some transformers may be more susceptible to damage than others. Windings of the older transformers are quite apt to be of a lower insulating value, transformers operating with an overload and previous fuse failures may also weaken this insulation. Transformers which have previously failed are repaired and re-installed on the lines. The rewinding of the transformer coils may result in the transformer being more susceptible to damage by lightning. Lightning transformer installations are grounded, and also one power transformer, of a power bank installation, is grounded. This factor—whether the transformer be grounded or not grounded—also may affect the failures.

3. *Primary Exposure.* The height, length, number of primary wires, number of arresters, and the underground cable connecting to the overhead conductors are features which are studied in connection with the primary conductors. The height of mains connected to the transformer failure are of importance, the charge induced increases as the distance from the earth, or the point of zero potential, increases. The length of these wires is important, since the increased exposure increases the charge on the line. The number of arresters discharging, and the length of the line relieved by each arrester, should be considered. Long lengths of underground cables connected to overhead conductors at distances of 100 feet or so from the failure aid in reducing the induced potential, and are a variable factor.

4. *Secondary Exposure.* The length and height of secondary phase wire and the length of secondary neutral exposure is of importance. The secondary neutral is grounded on some systems and ungrounded on others. The grounded secondary neutral furnishes shielding of considerable value.

5. *Shielding.* Structure shielding is quite low unless the structure is of steel adjacent to and higher than the line. Frame and brick structures, unless extending two or more stories above the line and adjacent to it, furnish little shielding. Trees extending above the line and adjacent to it, and telephone cables on the same pole as the primary conductors, furnish good shielding and must be considered.

6. *History of Immediate Territory.* Transformers burned out and fuses blown due to lightning in the

*Studies in Lightning Protection on 4000-volt Circuits. Trans. A. I. E. E., Vol. XXXIX, p. 1895; Vol. XXXV, p. 655.

adjacent areas of approximately one square mile should be considered to determine the severity of lightning within that area. Certain areas may be more susceptible to lightning disturbances than others; this susceptibility may be due to geographical conditions, or the character of the structures within the area.

7. *Lightning Entrance.* A study of the transformers burned out should be made and an attempt to determine the lightning entrance, whether it be over the phase or neutral primary, or over the secondary wires. Evidences of arcing on the case, bushings, and pole should be noted and the extent and nature of the burns on the windings of the transformer. Any damage to customer's equipment should be studied as evidence of lightning entrance over the secondary side of the transformer.

These are the factors which should be studied in connection with each case of failure, whether it be transformers, underground cables, or secondary equipment. After this study, one of the factors may be found to be almost entirely responsible for the failure, and with sufficient data covering a period of years, an attempt can be made to eliminate these factors as much as possible and better the protection.

The Commonwealth Edison Company now installs 2300-volt arresters on primary phase, and 300-volt arresters on the primary neutral; and as a result of their studies of the seven factors listed, the advisability of arrester installation on the secondary side of the transformer is being considered as a means of further reducing interruptions of service due to lightning burnouts.

Voltage Standardization

Several excellent papers dealing with transmission and distribution voltage standardization have been presented to the Institute during the past year and undoubtedly have contributed much toward clarifying the status of this problem. The ultimate solution, however, is still somewhat obscure. With the present tendency toward interconnection of systems the standardization of voltages becomes of increasing importance and it seems urgent to push the studies in this field.

Stability and Load Limitations of Power Systems

During the past year, the most significant development has been the engineering studies of several of the power companies which have led them to adopt special means to improve operating conditions and minimize the probability of outage. The stability studies have led to the adoption of synchronous machines of low reactance and high short-circuit ratio provided with quick-response excitation. The first installation of this kind will be in California followed quickly by similar installations in Pennsylvania and Alabama. The inclusion of these features in specifications for these installations shows the importance that the engineers of large utilities are attaching to the subject of stability.

An important advancement in the transmission art is the development by Frank G. Baum of "A Transmission System." Broadly, the principle of this system consists in supplying to the line at each point the reactive kv-a. required for transmitting the power over the line at that point, irrespective of whether power is taken in or given out there and incorporating in the devices used for this purpose the necessary characteristics to enable them to supply the reactive power required for stability under all conditions of operation, Practically, this means the installation of synchronous condensers of proper characteristics at intermediate points of long distance transmission line, in order to increase the amount of power that may be transmitted over that line as compared with the same line without the condensers.

Sustained attention is being given to the design and construction of machines having characteristics appropriate for long-distance power transmission. It is recognized that the desirable characteristics in synchronous machines from the standpoint of stability are low leakage reactance and high short-circuit ratio. The better performance thus obtained may be utilized to increase the amount of power transmitted rather than the margin of stability. Generators of low reactance were decided upon by the Southern California Edison Company for its Big Creek 2-A power plant and for the motor end of the frequency changer set at Farmersville located at an intermediate point on their Big Creek transmission system. Maintenance of stability is essential not only for long-distance transmission lines but also for comparatively short systems of large capacity and high standard of service. For example, in the case of the Conowingo development of the Philadelphia Electric Company, it was found that the use of generators having special characteristics would increase the reliability of the system.

Quick-response excitation which has been introduced commercially during the past year, maintains a high average value of voltage in synchronous machines at time of changes in circuit or load conditions thus improving the stability of operation. In some cases it will be desirable to use quick-response excitation in addition to special characteristics in the synchronous machines. The speed of response of the excitation system is obtained by the use of multiple-connected field windings in the exciters and separate excitation. Motor-driven exciters have been employed instead of direct-connected exciters for low-speed generators, because quicker response can be obtained with exciters of higher rotational speed and smaller air gaps which are possible with motor-driven units. To obtain the advantages of the quick response excitation system it must be controlled by a suitable voltage regulator capable of acting promptly and keeping its contacts closed until the system voltage has approached normal value. In order to secure correct operation of the voltage regulator under all conditions of operation, two

potential transformers with a positive phase sequence network are employed instead of the single potential transformers normally used. Quick-response excitation systems have been ordered for each of the plants described above, and in addition for the Lock 18 and Tallassee plants of the Alabama Power Company.

In last year's report mention was made of the theory of artificial stability which had been previously advanced and which had been substantiated by actual calculations and to some extent by experimental tests. Further experimental data not only confirms the laboratory data previously obtained but establishes the fact that artificial stability can be obtained on commercial power systems. While it is not expected that systems would normally be operated in the range of artificial stability it is undoubtedly desirable to take advantage of this increased limit as a margin. It should of course be appreciated that the real advantages of quick response excitation systems lie in the increased power limits under transient conditions.

Going further in the development of voltage sustaining devices, successful experiments with a small inherently compensated synchronous condenser have been carried out. The compensating current responds not only to a change in the magnitude of the load current but also to a change of the load power factor. It is necessary to keep in mind that this response to change of angle is quite important during transient conditions.

An important development during the past year has been the increased interest in the recording of systems data useful from the stability standpoint. The most suitable instruments for this purpose are of the oscillographic type arranged to operate automatically on the occurrence of system trouble. For instance, on the occurrence of a fault to ground, a ground relay places the automatic recording apparatus in operation and after the record had been obtained, auxiliary relays automatically disconnect the apparatus and prepare it for a subsequent operation. Particular mention should be made of the instantaneous watt elements, a sample of which was displayed to the Committee during the year. Such a watt element is particularly useful in stability studies.

These instruments should be very valuable to enable operating engineers to obtain data on the performance of their systems during transients. This data will be useful also in planning future extensions, ties, and interconnections.

Another point, mentioned in last year's report as being incomplete, is the matter of fault resistance. The effective value of the fault resistance at the time of a flashover cannot in general be measured directly. A new indirect method has been used successfully which consists in making a chart of calculated values of ground currents for various fault locations and for arbitrary values of fault resistance. Lines of constant resistance on this chart are used as parameters of reference and the actual fault current, as measured by the above mentioned oscillographic recording device, is plotted on this chart; its position with reference to the constant-resistance lines gives the actual fault resistance. In this way fault resistance, when comparable to the reactance of the system, can be obtained with a fair degree of accuracy, and since only the order of magnitude of fault resistance is important, this accuracy is adequate.

During the past year progress has been made in increasing our technical knowledge on the subject of transmission stability. One paper on this subject was presented by Mr. O. E. Shirley and another by Mr. H. V. Putman. Mention should also be made of the paper by Messrs. Doherty and Nickle on the *Theory of Synchronous Machine*, which gave consideration to the stability characteristics of machines. Noteworthy progress in the general understanding of the stability problem has been facilitated to a considerable degree by the use of the mechanical analogy due to Mr. S. B. Griscom, and presented before the Transmission Committee and several Section meetings.

Underground Cables

A pronounced drift toward the use of single-conductor cables and three-conductor metal-sheathed unbelted cables is making itself felt. More data are being secured as to the relative merits of these two types of cables as well as the ordinary belted three-conductor cable. Aside from any difference in dielectric strength the belted three-conductor cable is at a disadvantage due to the fact that faults frequently are from phase to phase instead of being confined to ground as is usually the case with the single-conductor or metal-sheathed three-conductor cables.

Where the duct size permits, three single-conductor cables may be installed in one duct thereby avoiding the necessity of having an individual duct for each cable which in many cases would make the subway cost prohibitive. This practise is being followed to a large extent on the system of the New York Edison-United Companies with very satisfactory results.

Progress is continually being made in the development of super-voltage cables. The 66-kv. Cleveland cable has been in service for about three years and the Philadelphia cable which was rated at 75 kv. but operated at 66 kv. has been in service for about one year. While some failures have occurred the operation in general has been satisfactory.

The Commonwealth Edison Company has in service two 75-kv. lines each consisting of three single conductor 750,000-cir. mil cables with 24/32-in. insulation and is installing additional circuits of this size and insulation which will go into service this Fall.

One of the encouraging features has been the highly successful operation of the oil-filled joints.

While short time tests indicate that the 24/32-in. insulation is liberal and that the cables might have a somewhat higher voltage rating, the deterioration rate of insulation stressed on this basis is not yet accurately determined.

Trial installations are being made on 66-kv. cables of joints which incorporate a means of insulating the intervening section of sheath. By suitably connecting the insulated sections the sheath currents may be minimized and the carrying capacity of the cables thereby increased.

The past year has seen considerable development in the use of oil reservoirs of various types on high-tension cable splices. The oil supplied by these reservoirs no doubt reduces or possibly eliminates voids, especially near the joints. This is of considerable importance as it has been found that the cable itself absorbs large quantities of oil for weeks or even months after installation. The indications are that the oil absorption by the line bears a direct relation to the temperature range through which the line is worked, the greater the temperature range the greater the oil absorption. Considerable attention should be given to the volume capacity of the oil reservoirs as the temperature changes also produce appreciable variations in the volume of the insulation for which it is desirable to compensate.

A clear distinction should be made between this type of cable and the 132-kv. cable now being installed in New York and Chicago. The latter has a hollow core filled with an oil which is fluid at all operating temperatures and this central space is connected at suitable intervals with large oil reservoirs capable of compensating for volumetric changes in both oil and cable whether due to temperature changes or other causes. No experience has yet been had with these 132-kv. installations but it is expected that their operating record during the next few years plus the further experience with the lines operating at 66 kv. will indicate whether or not the usual type of cable can be made to operate satisfactorily at over 75 kv. and also show whether the hollow core, oil filled type and its several accessories are good for 132 kv. or possibly more.
